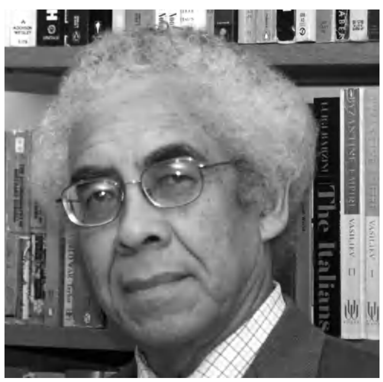
About the General Editor

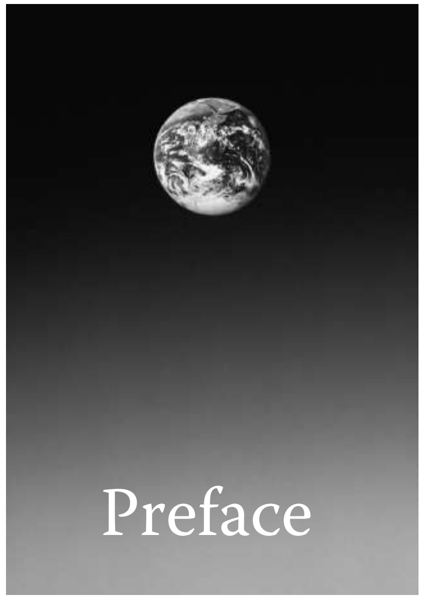
S. George Philander, Ph.D.
Knox Taylor Professor of Geosciences, Princeton University
Research Director, ACCESS



S. George Philander, Knox Taylor Professor of Geosciences at Princeton University, and Research Director of ACCESS (African Centre for Climate and Earth System Science) in Cape Town, South Africa, has a Bachelor of Science degree from the University of Cape Town, and a Ph.D. (Applied Mathematics) from Harvard University.

He is a member of the National Academy of Sciences, and a fellow of the American Academy of Arts and Sciences, the American Geophysical Union, and the American Meteorological Society. Philander's research interests include the oceanic circulation, interactions between the ocean and atmosphere that result in phenomena such as El Niño and La Niña, paleoclimates (including the recurrent Ice Ages of the past three million years), and future global climate changes. His two books for laypersons, *Is the Temperature Rising? The Uncertain Science of Global Warming*, and *Our Affair With El Niño: How We Transformed an Enchanting Peruvian Current Into a Global Climate Hazard* reflect his keen interest in improving communications between scientists and laymen.

The goal of the African climate center, which Philander is currently directing, is to give Africa its own voice on environmental issues such as global warming.



Preface

PLANET EARTH HAS become the concern of everyone. The activities of conservation biologists are now of interest to economists and political scientists who wish to find out whether certain environmental problems are best solved by regulations or market forces. Businesspeople, government officials, and politicians have become involved in science.

To be useful to such a diversity of people, the nearly 750 entries in this 3-volume encyclopedia cover a vast range of topics affecting global warming and climate change. The entries amount to more than a catalog of terms; they are all part of one story about global warming and how it is likely to affect our world.

Scientific objectivity have been the watchwords for the editors of this encyclopedia, yet different perspectives that various authors have on some of these issues are part of a conversation that citizens or students concerned about the environment ignore at their own risk. Even the title of the work, *Encyclopedia of Global Warming and Climate Change*, was carefully considered to include paleoclimatology in the discussion of weather, climate, and the current debate about global warming.

The authors of the entries include geographers, political scientists, chemists, anthropologists, medical practitioners, development experts, and sociologists. They are experts in their fields of specialty; many are researchers with extensive fieldwork experience; most of the entries on emerging techniques and technologies were written by innovators. As the volumes intend, it has become increasingly essential to bring the multiplying global warming issues, concepts, theories, examples, problems, and policies together in one place, with the goal of clearly explaining an emerging way of thinking about people and their planet.

Among the selection of articles, specific country entries are included, rather than climatic or environmental regions, to give the reader the opportunity to get information on the status of global warming—its causes and effects—by country, from Afghanistan to Zimbabwe. Also included are articles within specific categories, including: atmospheric sciences; climate; climate change effects; climate and society; climate feedbacks; climate models; institutions studying climate change; oceanography; paleoclimates; programs and conventions; and people studying climate change.

Pedagogical elements of this encyclopedia include the 4-color Introduction by General Editor Dr. S. George Philander, in which the reader can get a "bird's-eye view" of the sciences behind global warming. Also included in the work are a chronology of climate change, resource guide, glossary, and appendix of charts and table graphically presenting relevant data. Altogether, we hope the encyclopedia provides some groundwork for further discussion and spur possible action to curb global warming.

An Introduction

S. George Philander
Princeton University

IN ITS 2007 report, the Intergovernmental Panel on Climate Change (IPCC), a large, international panel of scientists, all experts on the Earth's climate, concluded that human activities, specifically those that cause an increase in the atmospheric concentration of carbon dioxide, have started affecting the Earth's climate. The panel further predicted that far more significant climate changes are imminent. This report, and Al Gore's documentary *An Inconvenient Truth* are persuading a rapidly increasing number of people that human activities can lead to possibly disastrous global climate changes.

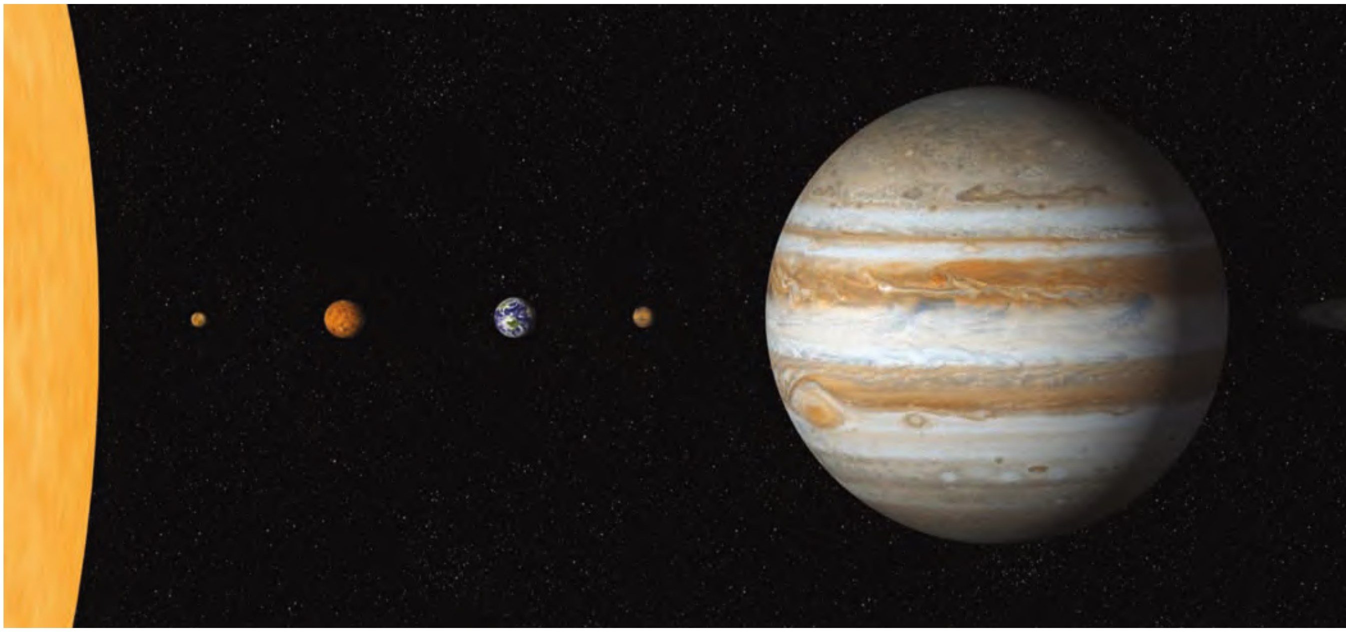
Those nonscientists are passionate about being wise and responsible stewards of the Earth, but at present they are handicapped because they take the words of the scientists on faith, and accept the reality of the threat of global warming without grasping the scientific reasons. This is most unfortunate, because our response to the threat of global warming is far more likely to be effective if it were motivated, not merely by the alarms scientists sound, but also by knowledge of how this very complex planet maintains the conditions that suit us so well. We need an awareness of how extremely fortunate we are to be the Earth's inhabitants at this moment in its long and eventful history, and an understanding of how our current activities are putting us at risk. The purpose of this encyclopedia is to help the reader learn about the intricate processes that make ours the only planet known to be habitable. This encyclopedia covers, in addition to the science of global warming, its social and political aspects that are of central importance to the ethical dilemmas that global warming poses: (1) How do we find a balance between regulations and freedom? (2) How do we find a balance between our responsibilities to future generations, and our obligations to the poor suffering today?

The first dilemma, which generates strong emotions, has caused an unfortunate polarization of a complex, multifaceted issue. The extremists who find regulations abhorrent assert that there is no evidence of global warming. (They are sometimes referred to as deniers or skeptics.) Their opponents, the believers, claim that global warming is underway, and is already causing environmental disasters. For believers, the second dilemma assumes global warming is already contributing to the suffering of the poor and therefore is an urgent priority for everyone. They refuse to accept that, for the many people who are so poor that they have nothing to lose, global warming is not an urgent issue. Dilemmas 1 and 2 call for compromises and hence for an objective assessment of the scientific results. The IPCC reports, which provide such an assessment, are explicit about uncertainties in the available results and hence favor neither the deniers nor the believers. The magnitudes of the uncertainties vary, depending on the time and region under consideration, and depending on whether we focus on temperature, the height of the ocean surface, rainfall or some other parameter.

Earth's temperatures fluctuate in a relatively narrow range; the Earth, unlike its neighbors Venus and Mars, is neither too warm nor too cold.

The following is a very brief synopsis—a bird's eye view—of the discussion of these topics in the numerous entries of this encyclopedia. This information hopefully

TINY FROM AFAR: In our solar system, Earth, third planet from the sun at left, is dwarfed by giants Jupiter and Saturn. The order of the planets starts with Mercury, which is closest to the Sun, then Venus, Earth, Mars, Jupiter, Saturn, Uranus, Neptune, and controversial Pluto.

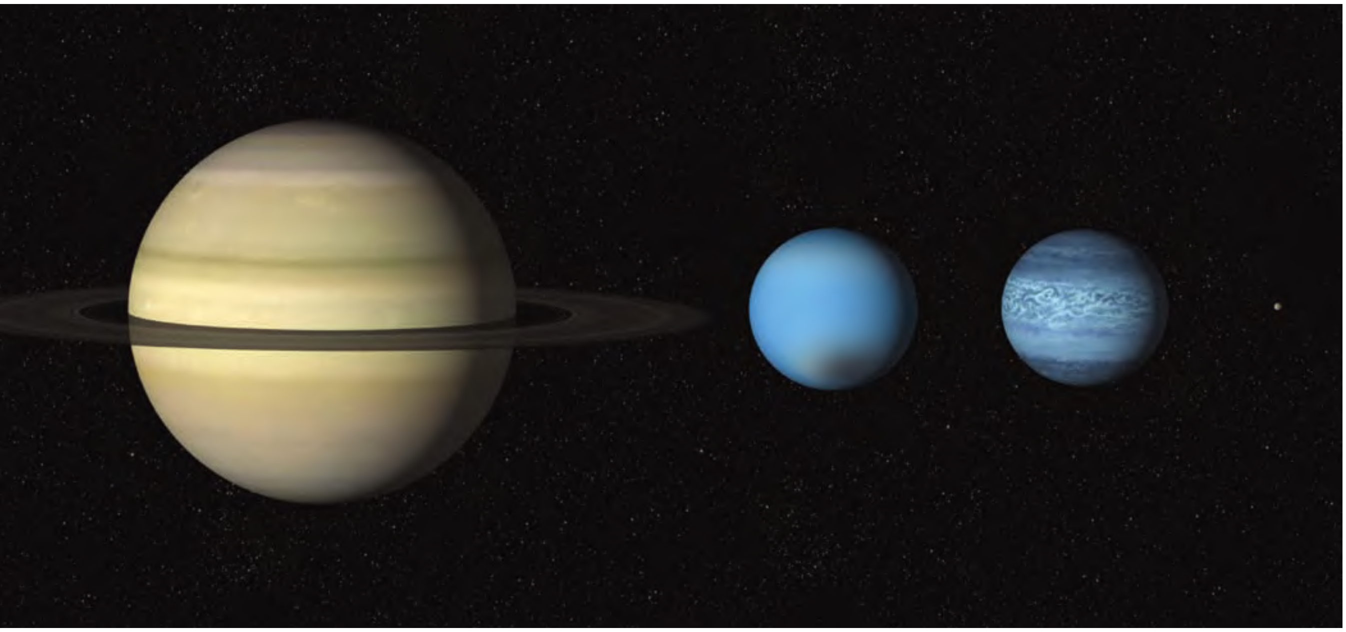


provides a basis for the development of an effective response to the threat of global warming.

Let us assume that we are aliens from another galaxy, in search of a habitable planet. On entering this particular solar system, our attention is at first drawn to the large, spectacular planets Jupiter and Saturn which are adorned with splendid rings and many moons. Earth, tiny by comparison, is a faint, blue dot from afar. Closer inspection shows that two of the Earth's main features are chaotically swirling white clouds, and vast oceans that cover nearly 70 percent of the surface. Both are vitally important to the Earth's most impressive feature of all: a great diversity of life forms that require water in liquid form. The abundance of liquid water means that, on the Earth, temperatures fluctuate in a relatively narrow range; the Earth, unlike its neighbors Venus and Mars, is neither too warm nor too cold.

The Earth's main source of energy is the sun, but this planet would be far too cold for most of its inhabitants were it not for its atmosphere, the thin veil of transparent gases that covers the globe. (If the Earth were an apple, its atmosphere would have the thickness of the peel.) This veil, by means of an intricate interplay between photons of light and molecules of air, serves as a shield that provides protection from dangerous ultraviolet rays in sunlight. The atmosphere serves as a parasol that reflects sunlight, thus keeping the planet cool; and as a blanket that traps heat from the Earth's surface, thus keeping us warm. The blanket is the greenhouse effect, which depends not on the two gases nitrogen and oxygen that are most abundant, but on trace gases that account for only a tiny part of the atmosphere, .035 percent in the case of carbon dioxide.

The most important greenhouse gas is water vapor, which is capable of engaging in escalating tit-for-tats (or positive feedbacks in engineering terms.) If atmospheric



SATELLITE VIEW: A photograph from space of a setting sun shows how thin the atmosphere is. If the Earth were an apple, its atmosphere would have the thickness of the peel.

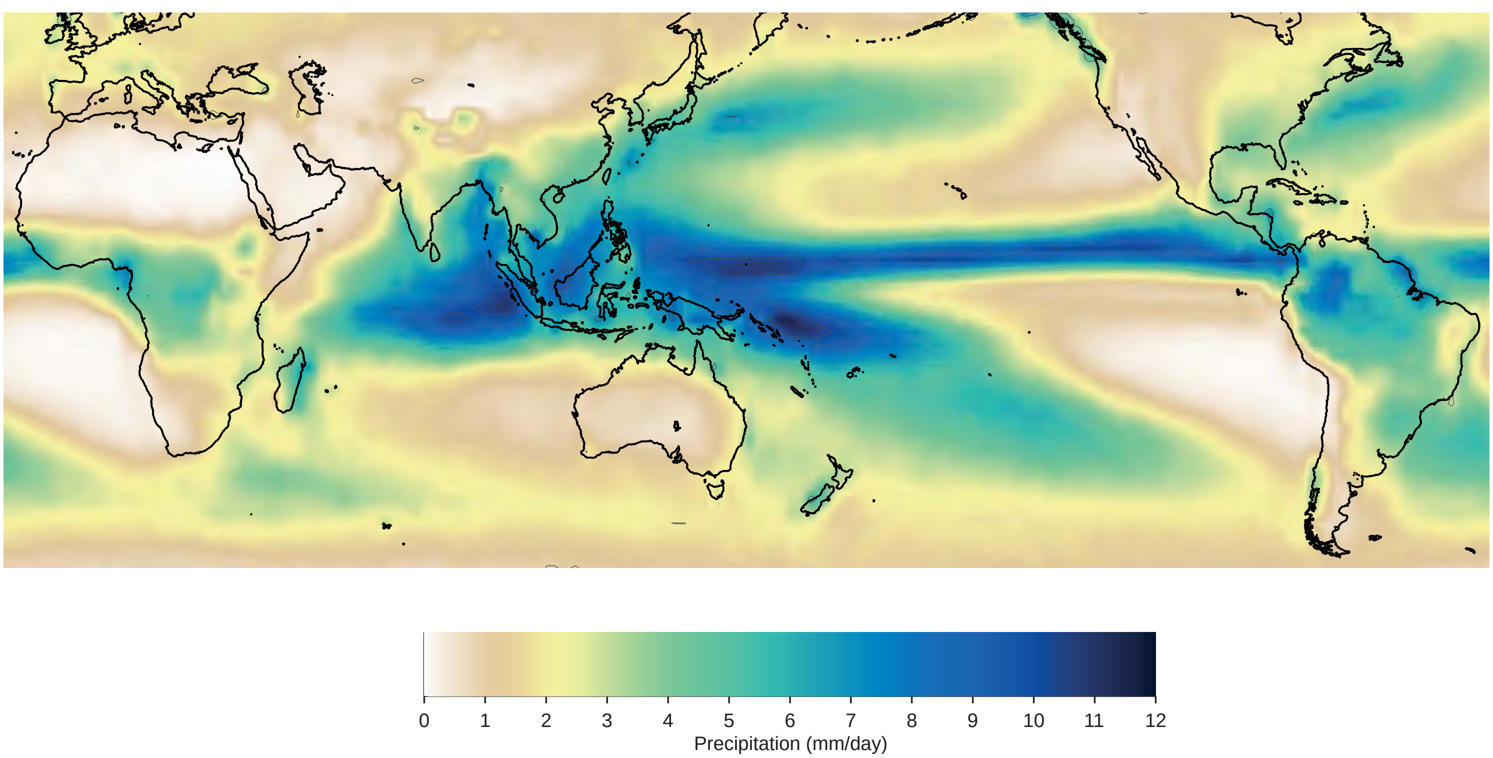
temperatures were to increase by a modest amount, then evaporation from the oceans will increase, thus increasing the concentration of water vapor in the atmosphere. The result is an enhanced greenhouse effect that increases temperatures further, causing more evaporation, even higher temperatures, and so on. The consequence could be a runaway greenhouse effect—this is thought to be the reason why Venus has no water today. The Earth was spared this fate because it is further from the sun than Venus, and is sufficiently cool for the air to become saturated with water vapor, in which case clouds form. Clouds present the following question: Is their net effect cooling, because of the sunlight they reflect, or warming because of their greenhouse effect? The answer depends on the type of cloud. Occasional glances at the sky reveal that there are many, many types. Uncertainties about future global warming stem mainly from uncertainties concerning the types of clouds that are likely in a warmer world. Simulating these fantastical, ephemeral objects is the biggest challenge for scientists trying to reproduce climate in computer models.

The westerly jet streams are so intense that some bands of latitude are known as the Roaring Forties and the Screaming Fifties.

If the atmosphere were static, we would be confined to a band of mid-latitudes, because the tropics would be too hot, the polar regions too cold. Fortunately, the atmosphere has winds that redistribute heat and also moisture, cooling off the lower latitudes, while warming up higher latitudes. The circulation that effects this redistribution includes surface winds that are easterly (westward) in the tropics, where they converge onto the regions of maximum surface temperature at the equator. There the air rises into tall cumulus towers that provide plentiful rain. Aloft, the air flows poleward, cools, and sinks over the subtropical deserts. Some of the air continues further poleward to join the westerly jet streams that are so intense that some bands of latitude are known as the Roaring Forties and the Screaming Fifties. This atmospheric circulation, despite its chaotic aspects that we refer to as weather, creates distinctive climatic zones—jungles and deserts, prairies and savannahs—that permit enormous biodiversity.

In the tropics, the atmospheric circulation, and hence the pattern of climatic zones, are strongly dependent on patterns of sea surface temperature that influence how much moisture the winds take (evaporate) from the ocean, and then deposit in rain-bearing clouds. The most surprising feature in the sea surface temperature patterns is the presence of very cold surface waters right at the equator in the eastern Pacific Ocean. (When he visited the Galapagos Islands, Charles Darwin commented on the curiously cold water at the equator where sunlight is most intense.) To explain this we need to explore the oceans, the thin film of water that covers much of the globe.

The average depth of the ocean, 3.1 miles or 5 kilometers, is negligible in comparison with the radius of the Earth, which is more than 3,700 miles or 6,000 kilometers. Both the atmosphere and ocean are very thin films of fluid, one air, the other water. Measurements made on expeditions from Antarctica to Alaska show that the ocean



PRECIPITATION MAP: There is a strong relationship between amount of precipitation and ocean temperature. Charles Darwin remarked on the surprisingly cold waters off the Galapagos Islands.

EARTH LIGHTS FROM SPACE: This map by NASA shows a composite image of lights on Earth, but both the landforms and lights appear brighter than would be visible to an unaided observer in space. Researchers were able to produce this map of lights showing urban surface activity.

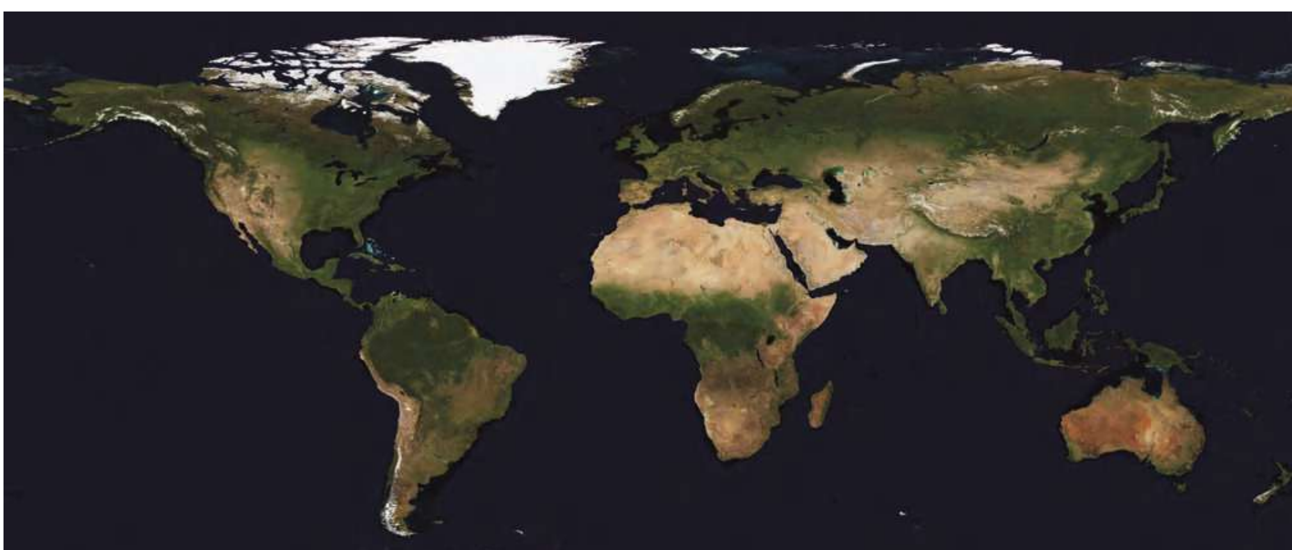
BRIGHT LIGHTS, BIG CITY: What becomes remarkably clear in this image is the energy usage in the United States, western Europe, and Japan, as compared to Africa and the rest of the world. The major national and regional contributors to greenhouse gas emissions are evident.

is composed of a very shallow layer of warm water that floats on a much colder, deep layer. So shallow is the warm layer that, at the equator near the dateline where the surface waters are warmest, the average temperature of a vertical column of water is barely above freezing. An important consequence is that the winds blowing in the right direction can easily expose cold water to the surface by driving oceanic currents in the right direction. The westward trade winds do this along the equator. They drive the warm surface water westward, causing cold water to appear near the Galapagos Islands. Winds parallel to the western coasts of Africa and the Americas, north and south, similarly drive currents that bring cold water to the surface.

Some of the oceanic currents are very slow and deep, others are swift and shallow and include the Gulf Stream and Kuroshio—narrow, rivers of warm water that flow poleward. These currents redistribute heat and chemicals, thus determining patterns of sea surface temperature and oceanic climatic zones that are evident in satellite photographs of the distribution of chlorophyll at the surface of the Earth. Chlorophyll is produced by phytoplankton, literally plants that wander. Those plants, and other life forms that depend on them, are most abundant near the ocean surface, because they need light that penetrates only tens of feet or meters below the ocean surface. When that living matter dies, it sinks and decomposes so that the cold, deep ocean is rich in nutrients.

It follows that ideal conditions for biological productivity—an abundance of light and nutrients—exists where the deep water rises to the surface. These are known as the oceanic upwelling zones, where surface waters are cold, such as off the western coasts of the Americas and Africa. The absence of a layer of warm surface waters around Antarctica makes the Southern Ocean another highly productive zone. Note that the subtropical ocean basins are in effect oceanic deserts with very few plants, because there is practically no exchange between the warm surface waters and the cold water at depth.

The plants on land and at sea, by means of photosynthesis, capture carbon dioxide from the atmosphere during their growing season, and return it when they die and

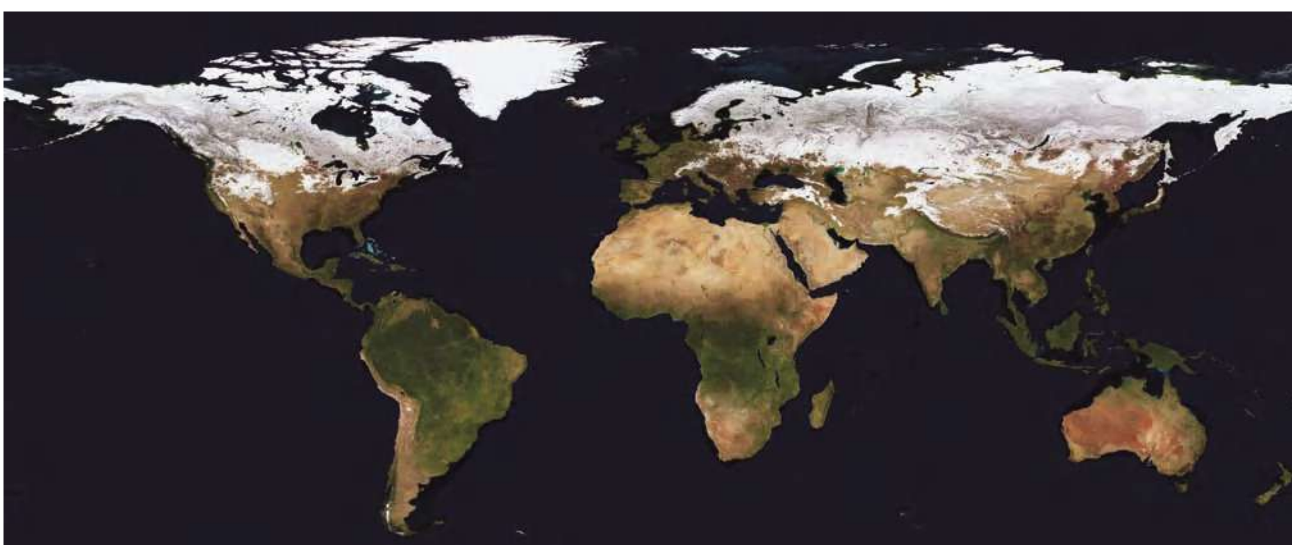


JULY AND JANUARY: True color composite satellite maps of the Earth's surface in July (above) and January 2004 (at right) from NASA illustrate the significance of seasonal snowfall.

decay. This continual flow of carbon between the ocean, atmosphere, and biosphere (the assemblage of all life on Earth) causes variations in the atmospheric concentration of carbon dioxide. Many people think of the composition of the atmosphere as fixed, in the way that water in a glass is composed of two parts hydrogen and one part oxygen. In reality the atmospheric composition changes continually because each constituent participates in a biogeochemical cycle. (The best known is the hydrological cycle, which is associated with continual changes in the atmospheric concentration of water vapor.) At present, we are interfering with the carbon cycle by burning fossil fuels, and thus emitting carbon into the atmosphere. The oceans and the plants absorb a large fraction, but much remains in the atmosphere so that the concentration there is rising rapidly.

A thousand years ago, the northern Atlantic was so warm that Greenland had a large enough population for the pope to send a bishop.

The ocean, atmosphere, and biosphere form a complex interacting system capable of generating fluctuations on its own. This is known as natural variability, in contrast to variability forced by daily and seasonal changes in sunlight, or by human-induced changes in the composition of the atmosphere. Daily changes in the weather, the best-known examples of natural variability, are as natural as the swings of a pendulum and would be present even if there were no variations in sunlight. Another natural fluctuation, with a much longer timescale of years rather than days, is the oscillation between El Niño and La Niña in the Pacific Ocean. From a strictly oceanic perspective, these phenomena are associated with changes in sea surface temperatures, in the currents, and so on, that are attributable to changes in the winds. Along the equator, those winds are intense during La Niña, weak during El Niño. Why do the winds change? From a meteorological perspective, the large

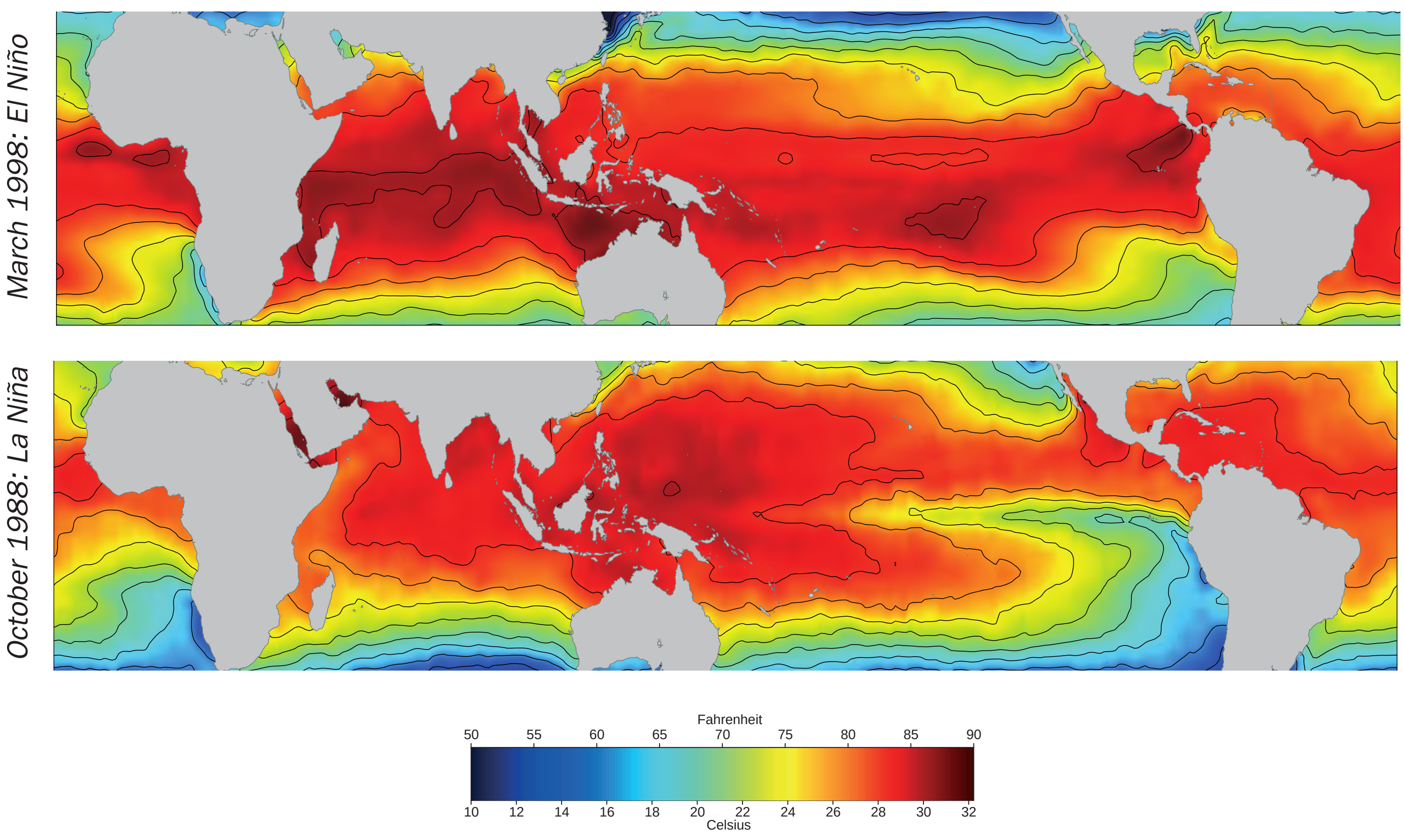


ALBEDO EFFECT: Snow-covered regions effectively cool the Earth by reflecting sunlight back into space, and hence changes in the range of snow cover can serve to amplify climate changes.

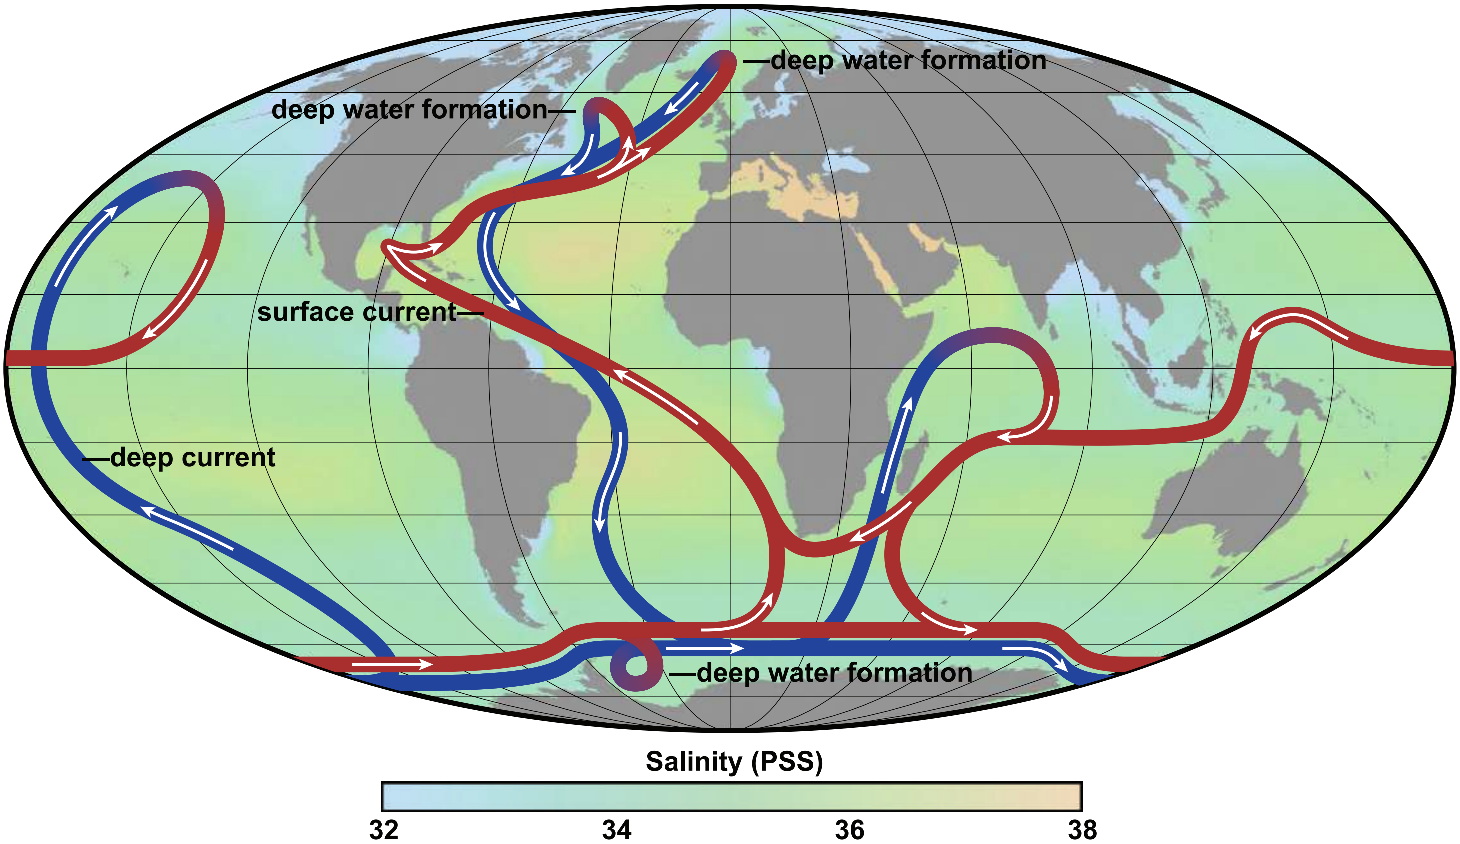
temperature contrast between the western and eastern equatorial Pacific during La Niña drives intense winds that weaken when the contrast weakens. This circular phenomenon—atmospheric changes are both the cause and consequence of oceanic changes—implies that El Niño and La Niña are consequences of interactions between the ocean and atmosphere.

We know a great deal about daily changes in weather because we have ample opportunities to study those changes. Over the past few decades, we learned a fair amount about El Niño, because that phenomenon occurred several times during that period. The past centuries and millennia were also characterized by naturally occurring fluctuations, but information about those climate fluctuations is scant, because of the lack of instrumental records. A thousand years ago, the northern Atlantic was so warm that Greenland had a large population, sufficiently large for the Pope to send a bishop.

That warm period was followed by the frigid Little Ice Age. Those changes were presumably aspects of natural variability, but as yet they are unexplained. Because we know very little about natural variability, it is not possible to determine whether a few unusually warm years, or a few intense hurricanes such as Katrina, or the unusually strong El Niño of 1997, indicate the onset of global warming. Scientists had to search carefully for distinctive patterns, for the "footprints" of global warming, before they could conclude in the 2007 IPCC report that humans activities are affecting the global climate.



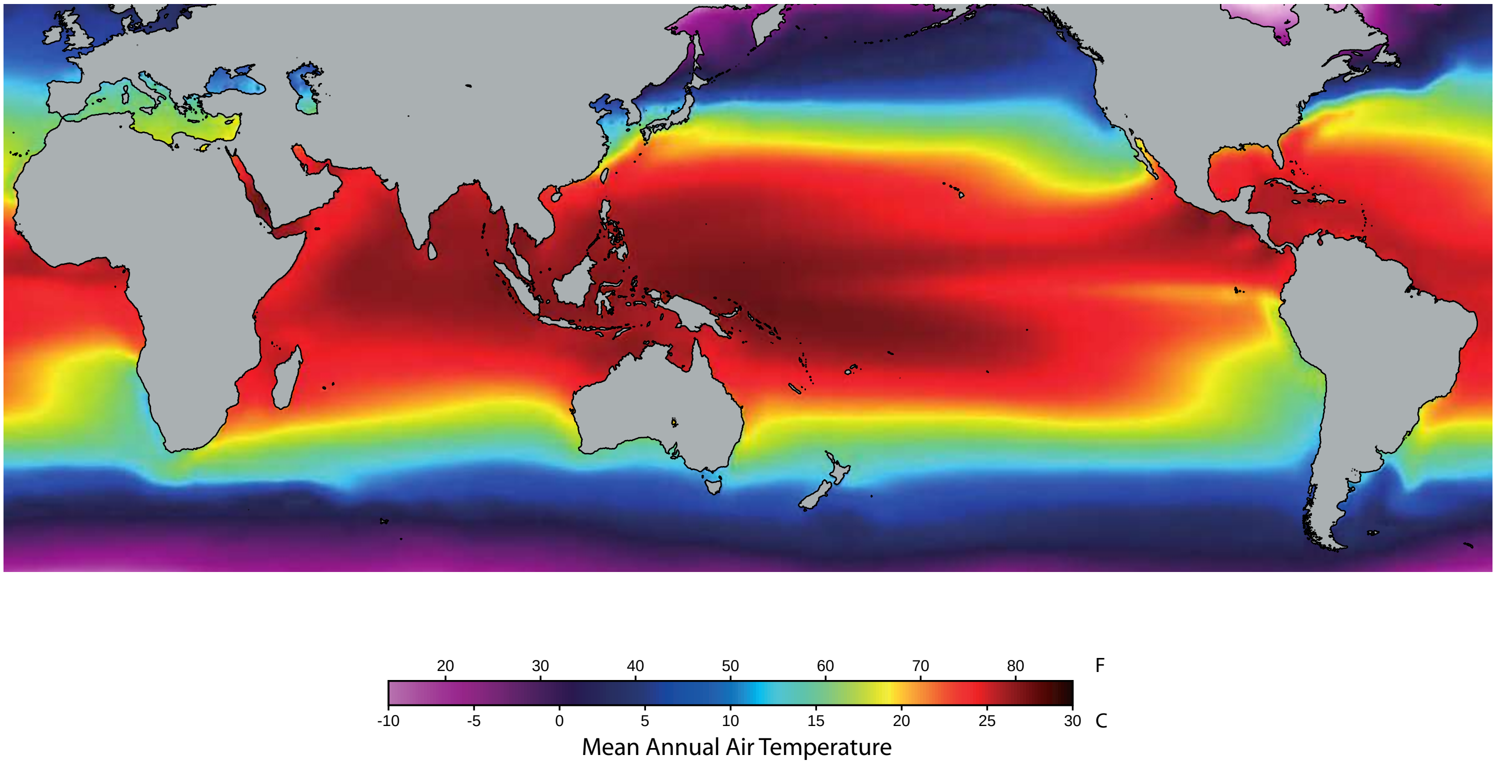
NATURAL FLUCTUATION: With a timescale of years rather than days, the oscillation between El Niño and La Niña in the Pacific Ocean governs weather patterns and storm activity.



OCEAN CURRENTS: The warm surface currents (red) intertwine with the deep cold currents (blue), creating climate patterns across the Earth. (Robert Simons/NASA)

The composition of the atmosphere, which strongly influences climate, depends on biogeochemical cycles involving not only the ocean, atmosphere and biosphere, but also the solid Earth. *Terra firma* is anything but firm; its surface is composed of several slowly moving, nearly rigid plates, on some of which the continents float. This is the surface manifestation of motion deep in the interior of the Earth, where temperatures are very high because of the decay of radioactive material. Earthquakes are common along the plate boundaries, which feature tall mountains where the plates collide, or deep trenches where one plate dives (subducts) beneath another. In regions of subduction, volcanoes are common; that is why the Pacific rim is known as a "ring of fire." When they erupt, volcanoes emit carbon dioxide into the atmosphere. That gas interacts with water vapor to form an acid that erodes rocks, causing the removal of carbon dioxide from the atmosphere. Hence, the building of mountains—the creation of extensive rock surfaces—promotes the removal of carbon dioxide from

> *Some 65 million years ago, the Earth was so warm that there was no ice on the planet. Palm trees and crocodiles flourished in polar regions.*



TEMPERATURE MAP: The areas in dark red with the highest temperatures correlate to the Precipitation Map—regions with the highest precipitation are also the warmest.

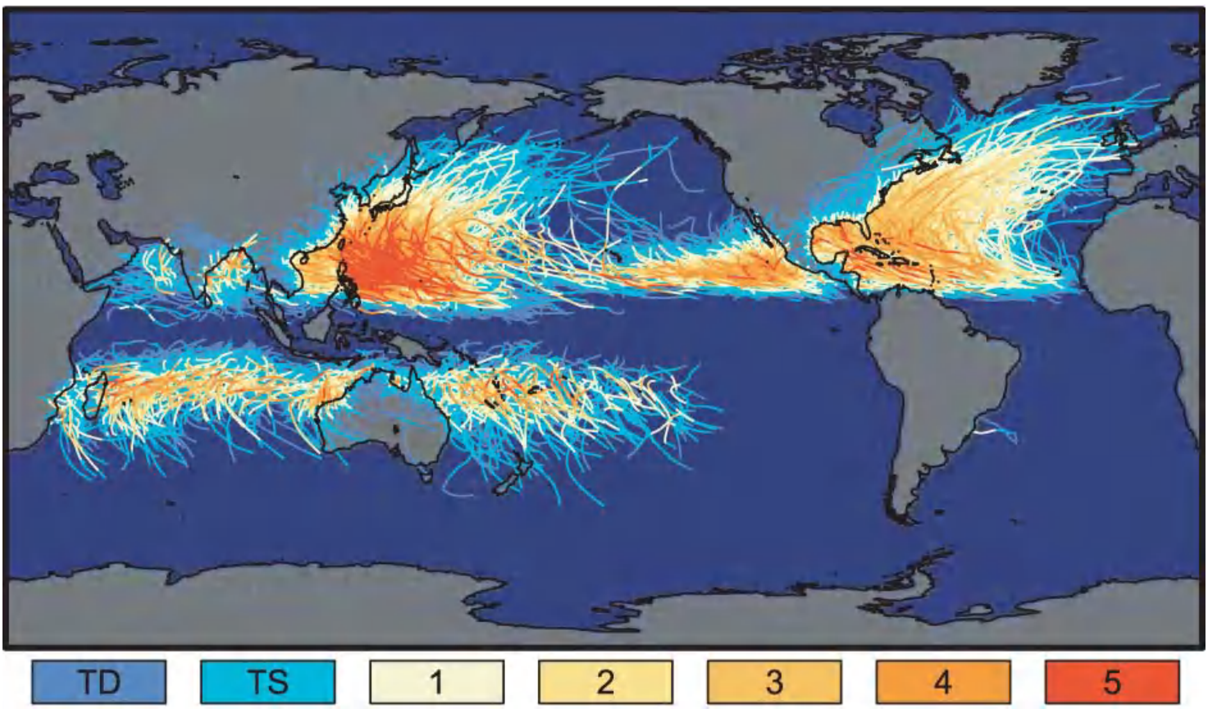
the atmosphere. Continental drift therefore affects the atmospheric composition by bringing into play processes that increase, and others that decrease, the concentration of carbon dioxide. Volcanic eruptions contribute to the increase, the building mountains to the decrease. Continental drift affects climate in a more direct manner by changing the distribution of continents. At one time all the continents were together and formed a supercontinent, Pangea, with a northern part known as Laurasia, and a southern Gondwanaland that included the Antarctic continent. With the breakup that started around 250 million years ago, Africa and South America separated to form the Atlantic Ocean. India traveled northward until it collided with Asia, and started creating the Himalayas.

For those interested in global warming, what happened after the demise of the dinosaurs some 65 million years ago is of special interest. At that time, the Earth was far warmer than it is today, so warm that there was no ice on the planet. Palm trees and crocodiles flourished in polar regions, in part because the atmospheric concentration of carbon dioxide was much higher than it is today. Subsequently, the continued drifting of the continents, accompanied by decreases in the atmospheric concentration of carbon dioxide, contributed to the global cooling. (This period is known as the Cenozoic, the age of new animals, specifically mammals.) What caused the Ice Ages? Why did they start 3 million years ago? The answers involve slight changes in sunlight. Sunlight varies daily and seasonally because the Earth rotates on its tilted axis once a day, while orbiting the sun once a year. Additional variations over

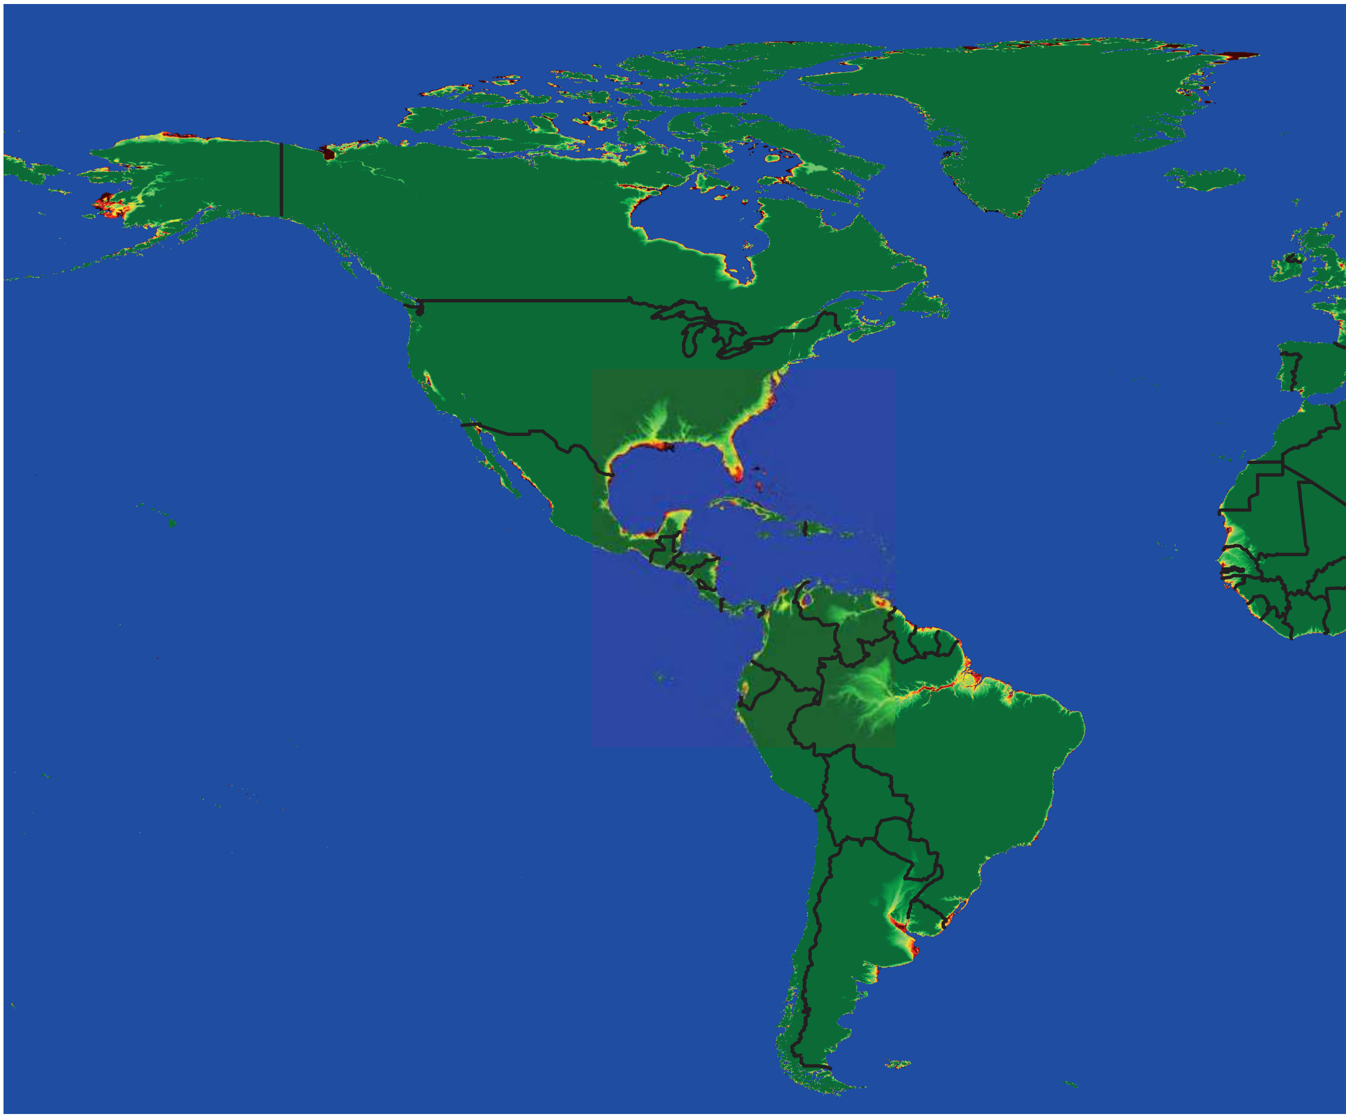
Glaciers, because they are white, reflect sunlight. This reflection deprives the Earth of heat, lowers temperatures, and promotes the growth of glaciers.

much longer periods of thousands of years are associated with slight oscillations of the tilt of the axis, which also precesses, while the orbit changes gradually, from a circle into an ellipse, and back to a circle. The moon and several planets cause these Milankovitch cycles, which have been present throughout the Earth's history. The climate fluctuations induced by these sunlight cycles were modest up to 3 million years ago, but then started amplifying. That amplification required positive feedbacks that translated the slight variations in sunlight into Ice Ages. The feedbacks were brought into play by the drifting of the continents. A complex and poorly understood interplay between the slow, erratic drifting of continents, and the regular variations in sunlight, caused the Ice Ages to be absent during some periods, and prominent during others, such as the present.

The global cooling associated with the drifting of the continents that started 60 million years ago inevitably led to the appearance of glaciers, first on Antarctica, then on northern continents around 3 million years ago. Glaciers, because they are white, reflect sunlight. This deprives the Earth of heat, lowers temperatures, and



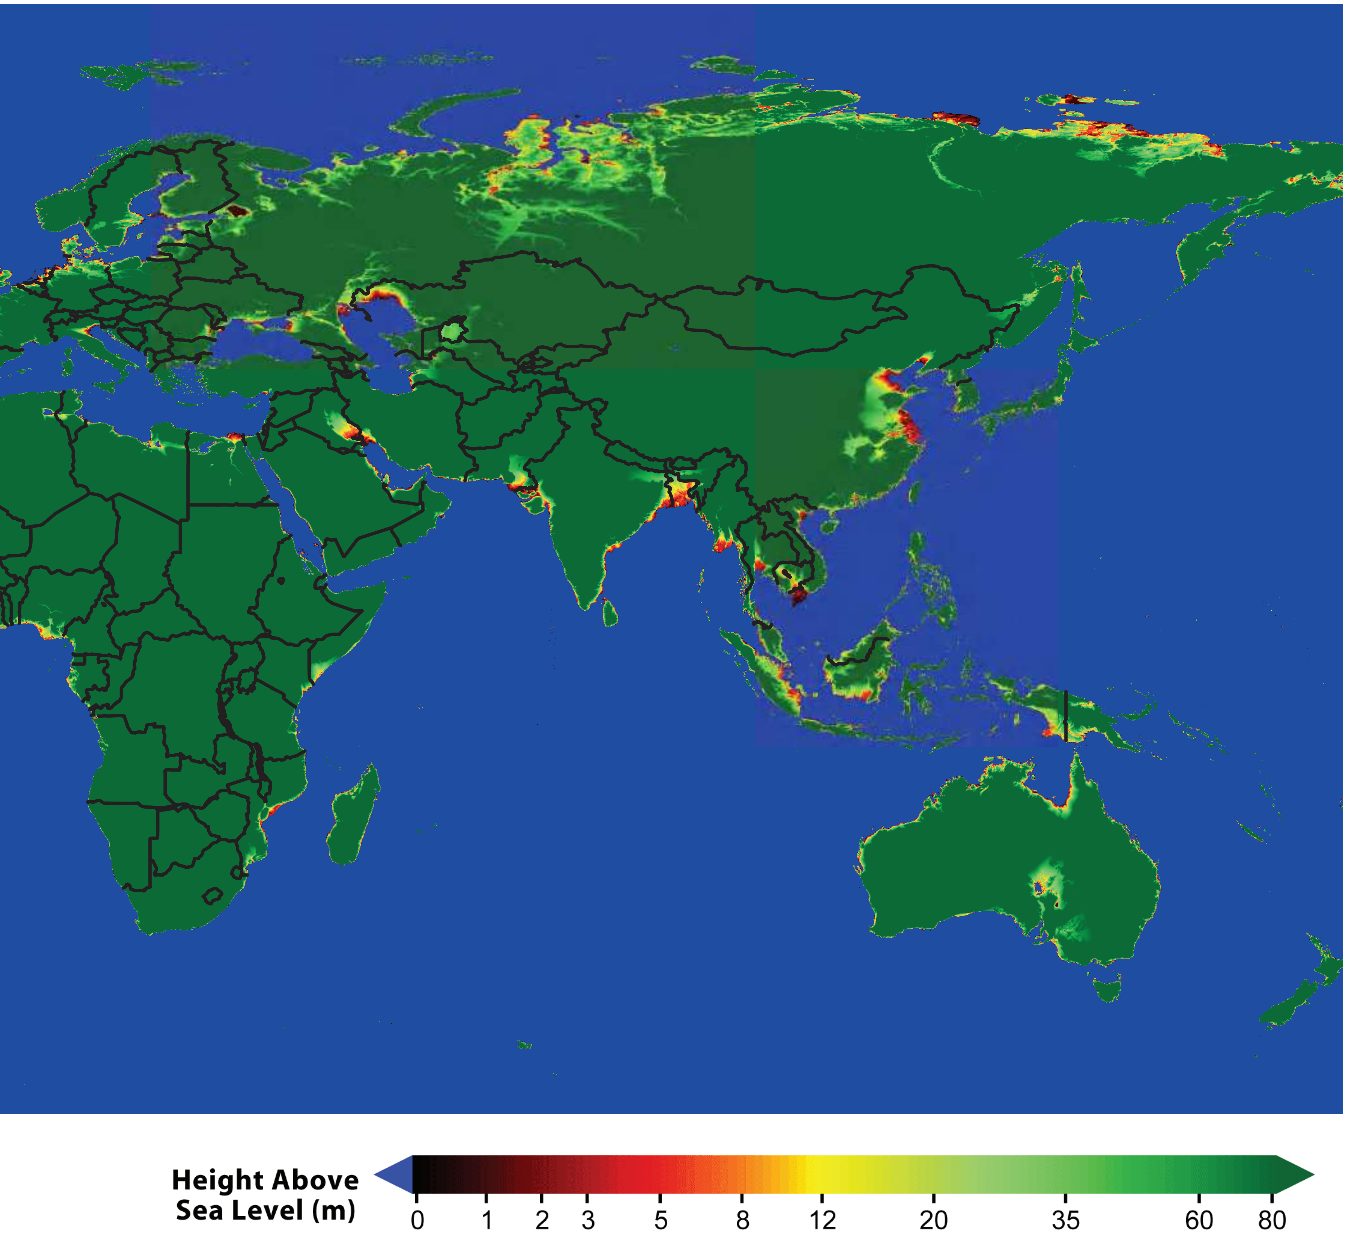
HURRICANE PATHS: A plot of the intensity and paths of hurricanes and typhoons. How global warming will affect the development and strength of storms is a subject of debate and study.



POTENTIAL FLOODING: This is a topographic map designed to emphasize regions near sea level that could potentially be vulnerable to sea level rise, though over centuries rather than decades.

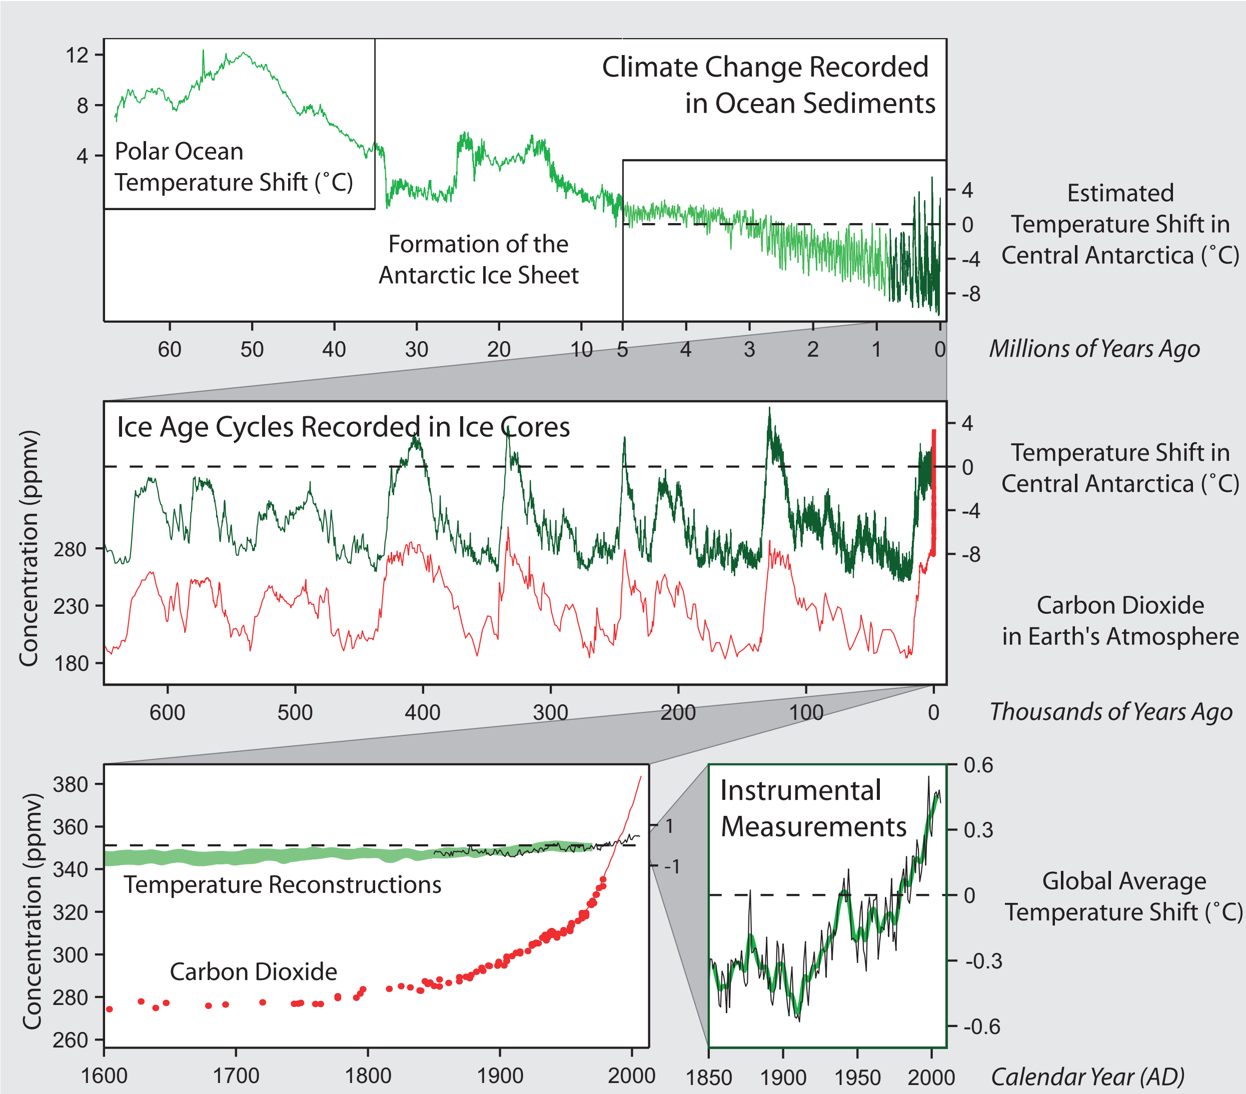
promotes the growth of glaciers. Hence, the appearance of continental glaciers was one of the feedbacks that amplified the response to Milankovitch variations in sunlight. Trapped in those glaciers are bubbles of air that tell us about past changes in the atmospheric composition, past variations in the atmospheric composition of carbon dioxide. As yet it is not known why the concentration varied, or to what degree the variations contributed to the temperature fluctuations.

Solving the puzzle of the Ice Ages will be a major contribution to our ability to anticipate future climate changes, because the solution will tell us a great deal about the sensitivity of the Earth's climate to changes in the atmospheric concentration of carbon dioxide. In the meanwhile, familiarity with the data can give us a valuable perspective on global warming by giving us a geological context for our activities over the past century. From a geological perspective, the present is a special moment



in the history of our planet for at least two reasons. The first is that the Earth is currently in an era of high sensitivity to small disturbances. Starting approximately 3 million years ago, the Earth's response to slight variations in sunlight, the Milankovitch cycles, have included enormous climate fluctuations associated with recurrent Ice Ages. Only some of the feedbacks that are involved have been identified. The second reason why the present is special is that we are currently enjoying the temperates of one of the brief interglacial periods that separate prolonged Ice Ages.

The previous interglacial was more than 100,000 years ago but, at that time, we humans were few in numbers, and had very limited capabilities. We were ready when the current interglacial started, some 10,000 years ago, and proceeded to advance with astonishing rapidity, inventing agricultures, domesticating certain animals, developing cultures, and building cities. We developed so rapidly that we are now



HISTORY OF CLIMATE CHANGE: A compound graphic depicts Earth's climate change across the millennia and centuries. Top: Global cooling over the past 60 million years. Middle: Recurrent Ice Ages over the past 600,000 years. Bottom: Rise in temperature and carbon dioxide over the past four centuries. The information in the top panel comes from cores drilled into the ocean floor, where sediments contain remains of primitive organisms that live near the ocean surface. The information in the middle panel comes from Antarctica, where the accumulated snowfall of hundreds of millennia created deep glaciers.

geologic agents, capable of interfering with the processes that make this a habitable planet. For more than a century, we have caused the atmospheric concentration of carbon dioxide to grow exponentially. This, surely, is a time for circumspection and caution.

Chronology

4.5 billion years ago
The Earth, newly formed, had the hottest climate in the planet's long history. Temperatures were hot enough to liquefy rock. Radioactive elements in Earth's core generated heat and pressure as they decayed, pushing molten rock toward Earth's surface. Volcanoes also brought molten rock to the surface, liberating heat. Volcanoes spewed carbon dioxide into the atmosphere, causing the Greenhouse Effect.

3.8 billion years ago
As the mass of radioactive elements in Earth's core diminished, the climate cooled and the first rock formed. The cooling of the atmosphere liquefied water vapor, which fell to Earth as rain.

3.5 billion years ago to 3 billion years ago
The origin of life enhanced the cooling of the climate, for among the first life were single-celled photosynthetic algae. Like plants, these algae consumed carbon dioxide and exuded oxygen. The reduction of carbon dioxide in the atmosphere weakened the Greenhouse Effect. With the reduction in carbon dioxide, temperatures dropped below freezing, causing the planet's first ice age 3 billion years ago.

2.9 billion years ago
The retreat of the glaciers inaugurated a long period of warm climate. The sun, burning steadily brighter, bathed Earth in its heat. Warm inland seas covered Earth, moderating the climate. Ocean currents circled the globe, spreading warm water from the equator to the poles.

800 million years ago to 550 million years ago
Glaciers covered the oceans as well as the land, killing photosynthetic algae that lived in the ocean. With algae in small numbers they were able to remove only a fraction of carbon dioxide from the atmosphere. With no check on its accumulation, carbon dioxide increased in the atmosphere, causing the Greenhouse Effect. The Greenhouse Effect ended the Late Proterozoic Ice Age roughly 550 million years ago, inaugurating a new warm period.

350 million years ago to 280 million years ago
The lush plant growth of the Carboniferous Era confirmed that the climate was warm and that carbon dioxide, essential for plant growth, was abundant.

230 million years ago
The continents gathered into a single landmass called Pangea. Because it was near the equator, Pangea's climate was tropical.

135 million years ago to 65 million years ago
Temperatures soared 20 degrees Fahrenheit warmer than today's temperatures during the Cretaceous Era.

Forests covered Antarctica. Ocean currents again carried warm water to the poles.

65 million years ago
An enormous meteor impacted Earth, ejecting a gigantic cloud of debris and dust. It ignited widespread fires, which pumped ash into the atmosphere. The debris, dust, and ash blocked out much of the sun's light, chilling the climate. So severe was the reversal in climate that the dinosaurs and a large number of marine species, unable to cope with the new conditions, perished.

55 million years ago to 35 million years ago
Temperatures declined 20 degrees F (11 degrees C). Glaciers formed on Antarctica.

130,000 years ago
The climate was again warmer than it is today. The water from melting glaciers flowed to the oceans, raising the sea level 60 ft. (18 m.) higher than it is today.

100,000 years ago
The climate cooled yet again and glaciers once more spread across the continents, plunging Earth into its most recent ice age.

16,000 to 13,000 years ago
The glaciers were in retreat, temperatures rose nearly 15 degrees Fahrenheit.

12,900 and 11,500 years ago
Temperatures during the Younger Dryas fell 50 degrees Fahrenheit in only a decade

7,000 years ago
Temperatures peaked at 2–3 degrees F (1–1.5 degrees C) above current temperatures. The climate remained warm and wet for another 3,000 years.

1,000 to 1,300 C.E.
The Medieval Warm Period rewarded peasants with bountiful crops. With food in surplus, human population increased.

1400 to 1840
The Little Ice Age covered the globe with record cold, large glaciers, and snow. This massive climate change triggered disease, famine, and death. Today, many scientists around the world believe that global warming caused by the Greenhouse Effect will be the fastest warming of the Earth since the termination of the Little Ice Age.

1824
French mathematician and physicist Jean Baptiste Joseph Fourier established that a buildup of carbon dioxide in Earth's atmosphere warms the climate.

1859
Irish scientist John Tyndall discovered that some gases block infrared radiation. He suggested that changes in the concentration of the gases could bring climate change.

1863
Tyndall announced that water vapor is a greenhouse gas.

1875
British scientist James Croll established that ice and snow reflect sunlight into space and cool the Earth.

1896
Swedish scientist and Nobel laureate Svente Arrhenius coined the phrase *Greenhouse Effect* and predicted that the Earth's climate is slowly warming. Arrhenius published the first calculation of global warming from human-induced emissions of carbon dioxide.

1897
British scientist Thomas C. Chamberlin established the link between ice ages and low concentrations of carbon dioxide and between warm climates and high concentrations of carbon dioxide.

1920 to 1925
The opening of Texas and Persian Gulf oil fields inaugurated an era of cheap energy. The burning of petroleum releases greenhouse gases into the atmosphere, warming the climate.

1924
German climatologist and geologist Alfred Wegener posited that the continents move slowly across Earth. When they are near the equator their climate is warm, while near the poles their climate is cold.

1930
Serbian geophysicist Milutin Milankovitch proposed that changes in the eccentricity of Earth's orbit cause climate change, including ice ages.

1932
Meteorologist W.J. Humphreys elaborated the conditions for a return to an ice age. He believed that an increase in debris in the atmosphere and the reflection of sunlight by ice and snow might return Earth to an ice age.

1933 to 1935
The drought of the 1930s created dust storms on the Plains. The worst dust storm of the Dust Bowl gripped the Plains on what later becomes known as Black Sunday. President Franklin Roosevelt established the Soil Erosion Service in response to the devastation of the Dust Bowl and as a part of his New Deal programs to create jobs. The Soil Erosion Service was the predecessor of the Soil Conservation Service established in 1935, which is known today as the Natural Resources Conservation Service (NCRS).

1937
Royal Meteorological Society president George Simpson posited that an increase in solar radiation might cause an ice age. By warming the poles more than high altitudes, the increase in solar radiation would intensify the circulation of the atmosphere, carrying moisture to high latitudes, where it would fall as snow. If enough snow accumulated, a new ice age would ensue.

1938
Amateur scientist G.S. Callendar recorded an increase in temperatures in the Artic and posited the Greenhouse Effect as the cause.

1939
Simpson announced that the atmosphere seems to keep the climate nearly constant by regulating the amount of clouds. The more clouds, the lower the temperature, and the fewer clouds, the warmer the temperature.

1940
Many scientists dismissed Callendar's claims. However, in response to his theory scientists began to develop new ways to measure the history of and current conditions of Earth's climate.

1945
The U.S. Office of Naval Research began generous funding of many fields of science, some of them useful for understanding climate change.

1950
American scientist Charles F. Brooks announced that Artic ice might be melting and that, once started, the melting might shrink the ice to a vestige of its former size and raise sea levels.

1950s
The development of new technology led to an increased awareness of global warming and the Greenhouse Effect. Researchers began to show that the level of carbon dioxide in the atmosphere was rising each year and people became concerned about pollution.

1956
American scientists Maurice Ewing and William Donn posited that the last ice age had rapidly descended on Earth when the North Pole wandered into the Arctic Ocean, triggering the accumulation of snow and ice in this region. American scientist Norman Phillips produces a somewhat realistic computer model of the global atmosphere. Canadian physicist Gilbert Plass calculated that adding carbon dioxide to the atmosphere would affect the radiation balance.

1957
Launch of Soviet Sputnik satellite. Cold War concerns support the 1957–58 International Geophysical Year, bringing new funding and coordination to climate studies. U.S. oceanographer Roger Revelle warned that humanity is conducting a "large-scale geophysical experiment" on the planet by releasing greenhouse gases.

1958
Astronomers identified the Greenhouse Effect on Venus, where temperatures are far above the boiling point of water.

1960
A report found that global temperatures had declined since the early 1940s. American scientist Charles David Keeling set up the first continuous monitoring of carbon dioxide levels in the atmosphere. Keeling soon finds a regular rise in temperatures.

1961
Soviet meteorologist Mikhail Budyko warned that the burning of fossil fuels, and the attendant accumulation of greenhouse gases in the atmosphere, would warm the planet.

1963
Fritz Moller calculated that a doubling of carbon dioxide in the atmosphere might increase temperatures 50 degrees Fahrenheit.

1965
Climatologists gather in Boulder, Colorado, to discuss climate change. Edward Lorenz and others point out the chaotic nature of the climate system and the possibility of sudden shifts.

1966
Italian scientist Cesare Emiliani's analysis of deep-sea cores showed that the timing of ice ages was set by small orbital shifts, suggesting that the climate system is sensitive to small changes.

1967
The International Global Atmospheric Research Program was established, mainly to gather data for better short-range weather prediction. Computer modelers Syukuro Manabe and Richard Wetherald predicted that an increase in the number of clouds might hold heat in the atmosphere and so increase temperatures.

1968
Mikhail Budyko derived two mathematical models. One predicted an increase in temperatures due to the Greenhouse Effect. The other predicted the return of the ice age. Budyko favored the first model. Other models were also contradictory. Studies suggested that the Antarctic ice sheets might collapse, raising sea levels catastrophically.

1969
American climatologist William Sellers predicted that a 2 percent decrease in solar radiation, whether from a fluctuation in solar output or the result of debris in the air, might plunge Earth into a new ice age. Like Budyko, Sellers feared that the burning of fossil fuels might warm Earth. Nimbus III satellite begins to provide comprehensive global atmospheric temperature measurements.

1970
The First Earth Day. The environmental movement attains strong influence, spreading concern about global degradation. The creation of the U.S. National Oceanic and Atmospheric Administration was the world's leading funder of climate research. Aerosols from human activity were increasing in the atmosphere. American scientist Reid Bryson claimed they counteracted global warming and may actually cool the Earth.

1971
The Study of Man's Impact on Climate (SMIC), a conference of leading scientists, reported a danger of rapid and serious global change caused by humans and called for an organized research effort. The American Mariner 9 spacecraft found a great dust storm warming the atmosphere of Mars along with indications of a radically different climate in the planet's past.

1972
Budyko predicted that a 50 percent increase in greenhouse gases in the atmosphere might raise temperatures enough to melt all the ice on Earth, whereas a 50 percent reduction might plunge Earth into an ice age. Budyko favored the first scenario and predicted that temperatures might rise enough to melt all the ice by 2050. Ice cores and other evidence showed that the climate changed in the past in the space of 1,000 years or so, especially around 11,000 years ago.

1972 to 1974
Serious droughts and other unusual weather since 1972 increased scientific and public concern about climate change, with cooling from aerosols suspected to be as likely as warming. Journalists wrote about ice ages.

1975
Concern about the environmental effects of airplanes led to investigations of trace gases in the stratosphere and the discovery of danger to the ozone layer. Manabe and collaborators produced complex but plausible, computer models, which predicted an increase of several degrees Fahrenheit for a doubling of carbon dioxide.

1975 to 1976
Studies showed that chlorofluorocarbons (CFCs) (1975) and also methane and ozone (1976) contribute to the Greenhouse Effect. Deep-sea cores show a dominating influence from 100,000-years ago. Milankovitch's prediction of orbital changes emphasized the role of feedbacks. Deforestation and other ecosystem changes were recognized as major factors in the future of the climate. American meteorologist Amos Eddy showed that the absence of sunspots in past centuries corresponded with cold periods.

1977
Scientific opinion tended to converge on global warming, not cooling, as the chief climatic risk in next century.

1978
Attempts to coordinate climate research in United States ended with an inadequate National Climate Program Act, accompanied by rapid, but temporary, growth in funding. American scientist James Hansen predicted that the accumulation of aerosol particles in the atmosphere might reflect sunlight back into space and so reduce temperatures.

1979
The second oil energy crisis. A strengthened environmental movement encouraged the development of renewable energy sources and the reduction of technologies that burn fossil fuels. The U.S. National Academy of Sciences estimated that a doubling of carbon dioxide might increase temperatures 35 to 40 degrees Fahrenheit. The World Climate Research Program was launched to coordinate international research on climate change.

1980
The election of President Ronald Reagan caused a backlash against the environmental movement. Political conservatism is linked to skepticism about global warming. Some scientists predicted greenhouse warming should be measurable by about the year 2000.

1982
Greenland ice cores revealed temperature oscillations over a single century in the distant past. Strong global warming since the mid-1970s was reported, with 1981 the warmest year on record.

1983
Reports from U.S. National Academy of Sciences and Environmental Protection Agency spark conflict, as greenhouse warming becomes prominent in mainstream politics.

1984
Theories about global warming and the Greenhouse Effect became more prevalent, gaining attention from the mass media. However, many people believe the threat is not imminent and some doubt that global climate change is a danger.

1985
The Center for Atmospheric Science Director Veerabhadran Ramanathan and collaborators announced that methane and other trace gases together could bring as much global warming as carbon dioxide itself. The Villach conference in Indonesia declared consensus among experts that some global warming seems inevitable and called on governments to consider international agreements to restrict emissions of greenhouse gases. Antarctic ice cores show that carbon dioxide and temperature went up and down together through past ice ages, pointing to powerful biological and geochemical feedbacks. American scientist Wallace Broecker speculated that a reorganization of North Atlantic Ocean circulation could bring swift and radical climate change.

1987
This was the warmest year since humans began to keep records. The 1980s were the hottest decade on record, with seven of the eight warmest years recorded up to 1990. Even the coldest years in the 1980s were warmer than the warmest years of the 1880s. The Montreal Protocol of the Vienna Convention imposed international restrictions on the emission of ozone-destroying gases.

1988
Global warming attracts worldwide headlines after scientists at Congressional hearings in Washington, D.C., blamed the U.S. drought on its influence. A meeting of climate scientists in Toronto subsequently called for 20 percent cuts in global carbon dioxide emissions by 2005. The United Nations set up the Intergovernmental Panel on Climate Change (IPCC) to analyze and report on scientific findings. News media coverage of global warming leapt upward following record heat and droughts. The Toronto conference called for strict, specific limits on greenhouse gas emissions. British Prime Minister Margaret Thatcher is the first major leader to call for action. Ice-core and biology studies confirmed that living ecosystems give climate feedback by way of methane, which could accelerate global warming. The level of carbon dioxide in the atmosphere reached 350 parts per million.

1989
Fossil-fuel suppliers and other industries formed the Global Climate Coalition in the United States to lobby politicians and convince the media and public that climate science is too uncertain to justify action.

1990
American meteorologist Richard Lindzen predicted that an increase in carbon dioxide in the atmosphere might not cause a concomitant increase in water vapor. Consequently, the Greenhouse Effect might be less severe than some were forecasting. The first IPCC report stated that the world has been warming and continued warming seems likely in the future. Industry lobbyists and some scientists disputed the tentative conclusions.

1991
Mount Pinatubo erupted. Hansen predicted that the eruption would cool Earth, verifying (by 1995) computer models of aerosol effects. Global warming skeptics emphasized research indicating that a significant part of 20th-century temperature change was due to solar influences. Studies from 55 million years ago show the possibility of the eruption of methane from the seabed causing enormous warming.

1992
A conference in Rio de Janeiro produced the United Nations Framework Convention on Climate Change, but the United States blocked calls for serious action. The study of ancient climates revealed climate sensitivity in the same range as predicted by computer models.

1993
Greenland ice cores suggested that great climate changes (at least on a regional scale) could occur in the timespan of a single decade.

1995
The second IPCC report detected the "signature" of human-caused Greenhouse Effect warming, declaring that serious warming is likely in the coming century. Reports of the breaking up of the Antarctic ice sheets and other signs of current warming in polar regions began to affect public opinion.

1997
Japanese automobile manufacturer Toyota introduces the Prius in Japan, the first mass-marketed electric hybrid car. Engineers progressed in the design of large wind turbines and other energy alternatives. An international conference in Japan produced the Kyoto Protocol, setting targets to reduce greenhouse gas emissions—if enough nations would approve and sign the treaty.

1998
The warmest year on record globally averaged (1995, 1997, and 2001-2006 were near the same level). Borehole data confirmed extraordinary warming trend. Qualms about arbitrariness in computer models diminish as teams model ice-age climate and dispense with special adjustments to reproduce current climate.

1999
A National Academy Panel dismissed criticism that satellite measurements showed no warming. V. Ramanathan detected massive "brown cloud" of aerosols from South Asia.

2000
The Global Climate Coalition dissolved as many corporations grappled with the threat of warming, but the oil lobby convinced the U.S. administration to deny the problem. Various studies emphasized variability and the importance of biological feedbacks in the carbon cycle that are liable to accelerate warming.

2001
The Third IPCC report stated that global warming, unprecedented since the end of last ice age, is "very likely," with possible severe surprises. The National Academy panel marked a "paradigm shift" in scientific recognition of the risk of abrupt climate change (decade-scale). Warming is observed in ocean basins. These observations match computer models, giving a clear signature of Greenhouse Effect.

2002
Studies found surprisingly strong "global dimming," due to pollution. This factor had retarded greenhouse warming, but dimming is now decreasing.

2003
Numerous observations raised concern that the collapse of ice sheets (West Antarctica, Greenland) might raise sea levels faster than most had believed. A deadly summer heat wave in Europe deepens divergence between European and U.S. public opinion.

2004
In a controversy over temperature data covering the past millennium, most scientists concluded that climate variations were substantial, but not comparable to post-1980 warming. The first major books, movies and artwork feature global warming.

2005
The Kyoto Treaty, signed, by all major industrial nations except the United States, took effect. Work to retard greenhouse emissions accelerated in Japan, Western Europe, U.S. regional governments, and corporations. Hurricane Katrina and other major tropical storms spurred debate over the impact of global warming on storm intensity.

2006
An Inconvenient Truth premiered at the 2006 Sundance Film Festival and opened in New York and Los Angeles on May 24, 2006, earning $49 million.

2007
The fourth IPCC report warned that serious effects of warming have become evident. The cost of reducing emissions would be far less than the damage they will cause. Al Gore shared the Nobel Peace Prize for his efforts to spread knowledge about global warming. The level of carbon dioxide in the atmosphere reaches 382 parts per million.

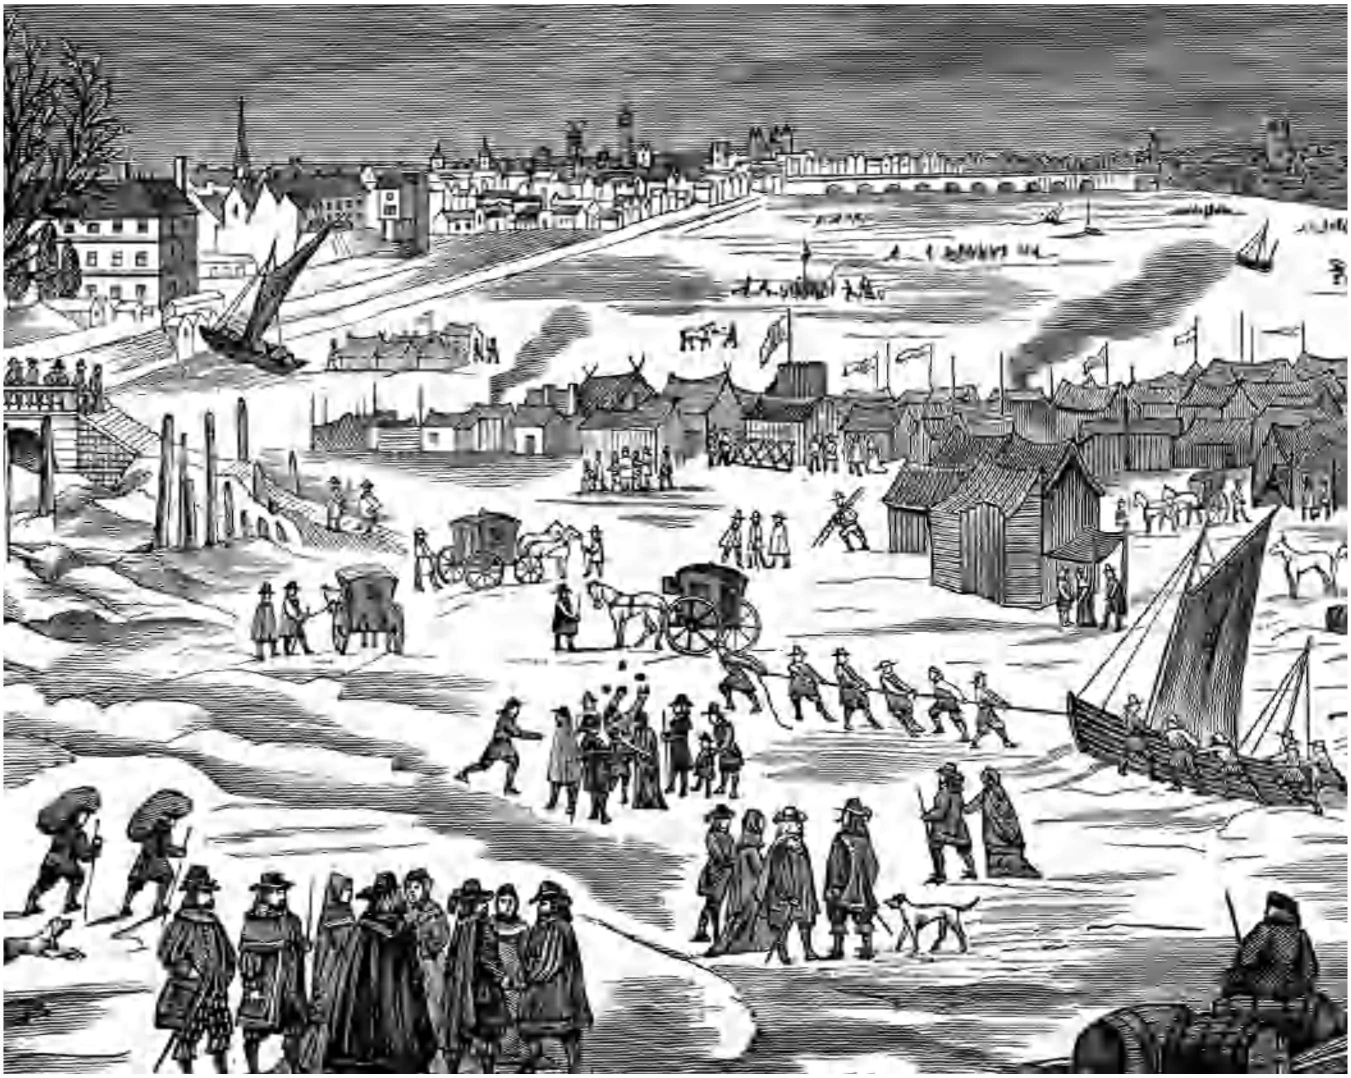
Abrupt Climate Changes

THROUGHOUT RECORDED HISTORY, and in studies of geological and other records from much earlier periods of the Earth's history, there have been a number of abrupt climate changes. These significant and widespread shifts in climate heavily impacted many parts of the world. Current studies of these changes draw from details revealed from ice core samples, especially from Greenland and northern Canada, and also from records compiled showing signs of geological changes. More recent information has emerged from examinations of the fluctuations in the size of tree rings, and also from historical accounts.

The quantity of these abrupt climate changes has led some academics, often labelled climate change skeptics, to explain the current global warming in terms of these trends. They suggest or state that the current changes are, or could be, merely a part of a cycle of global warming and cooling, similar to those that have occurred over hundreds of thousands of years.

Explaining global warming in the 1990s and 2000s by studying these abrupt climate changes gained much publicity around the world through the article "A Pervasive Millennial-Scale Cycle in North Atlantic Holocene and Glacial Climates," which was written by ten leading scientists, Drs. G. Bond, W. Showers, M. Chesby, R. Lotti, P. Alamsi, P. de Menocal, P. Priore, H. Cullen, I. Hajdas, and G. Bonani, and published in the journal *Science* in November 1997. This article, and related work, led to a substantial body of research on abrupt climate changes—when the Earth's temperature has either significantly increased or decreased over a short period of time—and also the possible causes of these changes.

A development of this theory came from two other scientists associated with those skeptical of global warming, S. Fred Singer of the University of Virginia, and Dennis Avery of the Hudson Institute in New York. They raised the possibility of a 1,500-year climate cycle, especially in the North Atlantic region, with hot temperatures every 1,500 years, The present global warming could be a part of this cycle. Certainly a part of this theory clearly rests on the extreme weather patterns experienced around the world during the years 535–36 C.E. They are recorded by the Byzantine historian Procopius, and also in Irish annals, as well as in records kept in China—all showing that the climate change occurred across a large number of areas.



The Little Ice Age, which lowered world temperatures from about 1600 to 1750, froze large rivers and canals in Europe. This engraving depicts a fair held on the ice of the frozen River Thames in London in 1683.

These historical accounts are confirmed by a tree ring analysis undertaken by the dendrochronologist Mike Baillie from Queen's University of Belfast, Northern Ireland, which showned little growth in Irish oak trees during this period. Similar data emerging from a study of tree ring samples conducted on trees from Scandinavia, California, and Chile. The rise in temperature during these years seems to have led to a widespread series of famines around the world, and the collapse or destruction of a number of empires including that of the Persians, and the Mesoamerican city of Teotihuacan.

There is no accepted cause of this instance of abrupt climate change, although there has been the suggestion that it could have been caused by the large-scale eruption of a volcano, such as Krakatoa, off the coast of Java (modern-day Indonesia); this idea formed a central part of the work of David Keys in his book *Catastrophe: A Quest for the Origins of the Modern World* (1999). It should, however, be noted that other scientists have been critical of these conclusions.

HISTORY

Going back further in history, there was a prolonged drought in the 22nd century B.C.E., which had a dramatic effect on the Old Kingdom of Egypt. It led to about 40 years of famines and social dislocation, which produced the emergence of the unified Kingdom of Egypt as a new political identity capable of financing irrigation projects and the like to overcome these problems. There have also been more recent changes in temperature, with suggestions that the collapse of the Mayan Empire in Mexico in the 8th and 9th centuries was possibly caused by a regional abrupt climate change, although others have pointed to the greater likelihood that this stemmed from overpopulation, foreign invasions, epidemics, and internal insurgencies. The idea of localized problems is reinforced by the fact that there is little evidence of an abrupt climate change elsewhere in the world at that time.

There have also been studies of what has been deemed the Little Ice Age, which took place from about 1600 until about 1750, with the freezing of rivers such as the River Thames in England, of canals in the Netherlands (shown in contemporaneous paintings), and the southern section of the Bosphorus in 1622. As the process seems to have been gradual, it might also have been responsible for the end of the Viking colonies in Greenland during the 15th century.

Certainly the concept of abrupt climate change goes back far further than recorded history. The last Ice Age in the Pleistocene period, which ended in about 10,000 B.C.E., ended a period of cold weather that is believed to have started with a long glacial advance from about 70,000 B.C.E., reaching a peak in 18,000 B.C.E., when most of northern Europe and considerable portions of modern-day Canada were covered with glaciers.

THE DEBATE

As a result of these studies, there are scientists who argue that global warming is just a phenomenon that has taken place before, and will take place again. They believe that global warming is not caused by the emission of increasing amounts of carbon dioxide and other greenhouse gases. There are also many who suggest that while warming is a regular phenomenon, it has been exacerbated by increasing greenhouse gas emissions.

Although abrupt climate changes have happened throughout history, scientists who argue that global warming is extremely serious, point to the rapidity of recent climate changes, and that they are occurring at an increasing rate throughout the world. In contrast to the changes that have been studied, measured, examined, and analyzed over the last 20 years, events such as the Little Ice Age took place gradually over at least 120 years, if not longer. Some date the start of the period back to 1250, when the Atlantic Pack Ice started to grow, and suggest it was a cause of the Great Famine of 1315–17, with the serious glacial expansion taking place only since 1550, and the first significant climatic changes in non-Arctic Europe beginning in the early 17th century.

By contrast, similar fluctuations in temperature (rising now, instead of falling as in the 1600s) in recent decades, have happened over a very short time, and the loss of large amounts of Antarctic ice have been evident over a 10-year period. The ability to track many of these changes from satellites has allowed geographers and scientists to identify other problems, such as the "Ozone Hole." .

The theory of abrupt climate change clearly indicates that there are many forces that contribute to global warming around the world, in addition to human-caused carbon dioxide and other emissions. However, researchers have been increasingly able to monitor these changes since the early 1990s, and the fact that the symptoms of climate change and global warming are currently being recorded around the planet, and are accelerating, has led many scientists to suggest global warming cannot be solely explained by the theory of abrupt climate change. It has further led to the theory that these man-made causes might be coinciding with a cyclical period of abrupt climate change, leading to a worsening of problems being faced by people in most parts of the world.

Adaptation

ADAPTATION IN SOCIAL, cultural, and economic contexts is also an important component of thinking about societal response to climate change. As such, adaptation is defined in many ways. It can be defined as a process that enables people to minimize the adverse effects of climate on their health and well-being. It also refers to the capacity of people or societies to take advantage of the changes that the climate might provide. Adaptation can also mean the adjustments in behavior and economic structures that will reduce societal vulnerability to climate change impacts.

This can include changes to social and cultural structures or mores within society, so that vulnerability to climate variability and potential extreme events is reduced. The Intergovernmental Panel for Climate Change (IPCC) defines adaptability as "the degree to which adjustments are possible in practices, processes, or structures of systems to projected or actual changes of climate," and notes, "adaptation can be spontaneous or planned, and can be carried out in response to or in anticipation of a change in conditions."

Of great interest to policymakers, however, is the ability of societies to implement adaptations. The IPCC reiterates that adaptation is more than just finding a technical "fix," but should incorporate a combination of strategic and technical options. This is generally discussed in the literature as *adaptive capacity*. The IPCC report (2001) on adaptive capacity notes that the capacity to adapt, as with vulnerability, is a result of the integration of wealth, scientific and technical knowledge, information, skills, infrastructure, institutions, and equity. This report also states that adaptations will be more beneficial if they are incorporated into existing strategies such as coastal zone management, disaster mitigation, land use planning, and sustainable development programs, a process referred to elsewhere in the literature as mainstreaming.

TYPES OF ADAPTATION

Adaptation can take many forms. It can work from the bottom up or top down. It can be reactive to changes or impacts, or it can be predictive, as in responding in advance to anticipated impacts. Adaptations can also be differentiated by whether or not they are autonomous or planned, occur in natural or socioeconomic systems, are anticipatory or reactive, and take technological, institutional, or behavioral forms. Adaptation can also be structural, such as the building of dykes or levees to combat flooding or sea level rise associated with climate change. Adaptation can also take the form of policy measures or approaches such as integrated coastal zone management.

An example of adaptation in practice is the adaptive management of sea-level rise. The six most important bio-geophysical (or natural system) effects of sea-level rise are: increasing flood-frequency probabilities, erosion, inundation, rising water tables, saltwater intrusion, and biological effects. Without adaptation, the consequences of global warming and sea-level rise would be disastrous, a point reiterated by the IPCC in its Fourth Assessment Report, 2007.

There are a number of technical options designed to respond to sea-level rise: retreat, accommodate, or protect. Retreat involves the removal of all artificial structures from the potentially affected area, providing the shoreline with space to move. Accommodation is where coastal developments try to adapt to sea-level rise by doing things such as introducing building standards, and only allowing removable homes to be built in high risk areas.

Protection, also called defense, includes not only the erection of coastal defense structures such as seawalls and dikes, but also leaving all existing structures in potentially affected areas, and even encouraging more development to be built. However, there are environmental, social, and economic aspects of all three options that have to be considered carefully before approving or discarding any of them.

In 2001, the United Nations Environment Programme (UNEP) adopted a seven-step adaptation framework for addressing the problems of sea-level rise and climate change: define the problem, select the method, test the method, select scenarios, assess the bio-geophysical and socioeconomic impacts, assess the autonomous adjustments, and evaluate adaptation strategies. While the UNEP specifically outlines a suite of strategic responses to sea-level rise, it cautions that before applying these strategies, policymakers must decide if their adaptation is to be autonomous or planned, and reactive or pro-active.

Policy makers can also use adaptive measures to manage climate change. One adaptive strategy is known as the no-regret or win-win approach. This approach allows policy makers to implement strategies that benefit all parties, and are politically feasible because of minimal risk. Another strategy is the precautionary strategy, where adaptation becomes part of ongoing management planning, thus ensuring that any future impact of climate change is anticipated. For example, local governments might factor in requirements for development applications to plan for climate change, even before the predicted effects of climate change occur in that region.

RESEARCH AND ADAPTATION

Some researchers interpret adaptation by examining the relationship between human and organizational behavior and adaptation strategies. For example, research based on nine case studies of companies in the United Kingdom showed that adaptation processes have many synergies with organizational learning. Researchers demonstrate that business adaptation techniques that affect organizational adaptive behavior provide lessons to policymakers for implementing climate change actions. Suggested business adaptation techniques include: changes to the firm's commercial strategy (commercial adaptation), changes to technologies used to provide products or services (technological adaptation), changes in financial management systems (financial adaptation), changes in data-gathering and monitoring trends, and information and monitoring of climate stimuli and search processes for adaptation measures.

Some policy makers construct adaptation as a space, providing the opportunity to implement well-established adaptation options, as well as options that are novel and not yet fully explored. The adaptation space is conceptualized as dynamic, growing, and evolving as new options are generated. Within the adaptation space, four alternative climate adaptation strategies can be identified. These include the wait and see approach, which is a strategy of deferral, based on skepticism or uncertainty about the possible impact of climate change and the benefits of adaptation.

Risk assessment and options appraisal is another strategy designed to evaluate options in preparation for adaptation of organizational routines. Bearing and managing risks is a strategy of handling risks and opportunities arising from climate impacts employing organizational resources and capabilities. The fourth strategy is one of sharing and shifting risks, a process of seeking to externalize risks associated with climate impacts through insurance and collaboration.

ADAPTATION AND UNCERTAINTY

Implementing adaptation strategies for climate change requires decision makers to incorporate and deal with the issue of uncertainty. Uncertainty is one of the key difficulties for policy makers in assessing both how climate change will manifest and the resulting extent, diversity, regularity, distribution, and magnitude of its impacts. Uncertainty arises from insufficient, inaccurate, or unavailable data; external developments and cross-boundary issues; and the unpredictability of human behavior. Part of the solution to dealing with uncertainty lies in ensuring that adaptation policy is robust, and anticipates future impacts based on a wide array of predictions. By building social and economic capacity to respond to diverse sets of circumstances, it is possible to incorporate uncertainty in planning frameworks. Adaptation strategies are, thus, a very important part of climate change management.

A protective approach to the adaptive management of sea-level rise retains old structures and even backs more development.

ADAPTIVE MANAGEMENT

Building on the notions of adaptation and adaptive capacity is the concept of adaptive management. It is a process that embeds greater fluidity and flexibility within conventional environmental management systems. Adaptive management is based on the assumption that as circumstances change, so must management strategies. It is a technique that provides a framework for continually improving management practice and delivering environmental outcomes within socioeconomic contexts.

Adaptive management also builds on environmental assessment techniques to deal with uncertainty, and access information sets on partially-known processes, making it ideal for climate change management. The fluid nature of adaptive management also suits the dynamics of working with the changing quality of environmental processes. Adaptive management means management that is flexible and based on the principle of continuous improvement. Employing adaptive management techniques enables policy makers to focus on variation over time within policy, rather than the more conventional spatial variation. For example, within local government, planners can use adaptive management techniques to review their planning schemes periodically, and ensure that they deal with variations over time. Adaptive management can be viewed as a process with consecutive stages including: information collection, systems analysis and vision, plan making, implementation of management actions, and monitoring and reviewing.

ADAPTATION ASSESSMENT

In planning for what types of adaptation to use at any given time, decision makers must consider these aspects: adaptation to what, who or what adapts, and how adaptation occurs. Decision makers must also determine the attributes for differentiating adaptations, such as purposefulness, timing, temporal and spatial scope, effects, form, and performance. In this context there is a distinction between two types of adaptation assessment: positive and normative. Positive assessment is predictive; the likelihood of adaptations that will be required is based on the assessment of likely impact scenarios. Normative assessment builds on the positive approach by evaluating likely adaptation options, and enables input into policy recommendations.

Many techniques can be applied to determine which adaptation type to implement. For example, adaptation trials in Egypt show that multi-criteria analysis and decision-matrix approaches based on questionnaire surveys to determine adaptation priorities and options, are useful tools. Other studies use participatory vulnerability assessment (PVA) tools to identify the adaptation strategies most appropriate for communities that will allow incorporation of political, cultural, economic, institutional, and technological factors. PVA also facilitates a dynamic interplay among various exposures, sensitivities, and adaptive capacities over time, because what is vulnerable in one period is not necessarily vulnerable (or vulnerable in the same way) in the next.

The choice and implementation of different adaptive measures is also contingent on the decision processes that frame them. Decision-making processes must ensure that adaptation and knowledge of climate impacts are both considered. Also, it is important that adaptation decisions are not impractical or prohibitively expensive. For example, in low-lying areas subject to flooding as a result of sea-level rise, the cost of adaptation could amount to at least 5 to 10 percent of Gross Domestic Product. The appropriate mechanism for implementation of adaptation strategies also depends on the particular response. One response within the United Kingdom to sea-level rise has been to develop shoreline management plans (SMP). The English coastline is divided into 11 cells, which are divided further into sub-cells. The divisions are made according to the transport of sand and other sediments. For each sub-cell a SMP has been defined. Each SMP is designed to take a strategic view of shoreline defenses and is based on a decision to pursue one or a combination of the following adaptation options: do nothing, advance the line, hold the line, or retreat the line. In Bangladesh, soft adaptation measures have been tried, such as the planting of mangroves along vulnerable coasts, beach nourishment, and coral transplanting. Hard measures include the building of seawalls and coastal dykes, such as in Japan or the Netherlands.

Ensuring the most appropriate adaptation in each case is the key. For example, in some places beach nourishment is implemented as a short-term, flexible strategy as an alternative to building sea walls. In cases where saline water intrusion threatens groundwater supplies, longer-term adaptation strategies, such as demand reduction initiatives like the improved maintenance of water reticulation systems to prevent and remedy leaks, conservation education, and plumbing, might be more appropriate.

LESSONS LEARNED FROM ADAPTATION

Climate change adaptation strategies have been tried worldwide. A number of key lessons have been learned that will help future decision makers when planning for, and adapting to, climate change. These lessons include: adaptation should build on previous experiences in relation to disaster management; adaptation can be autonomous or planned, reactive or proactive; adaptation takes time and, therefore, should not be postponed; there is a need to build diverse information/knowledge bases that will support adaptation processes; social vulnerability needs to be canvassed; adaptation technologies need to be developed and applied; institutional arrangements must support adaptation; and priority should be given to adaptation in catchments where the water is close to full utilization.

Aerosols

AEROSOLS ARE SOLID or liquid particles that are small enough to remain suspended in the atmosphere for hours to days. They are created by both natural and human-caused processes, and are either directly emitted from sources or are formed in the atmosphere from the condensation of gases. Aerosols can perturb climate either directly, by the scattering or absorption of radiation, or indirectly, through the modification of clouds and precipitation. The effects of aerosols on climate represent the single largest source of uncertainty in the understanding of global warming. While the magnitude of the effect is unclear, most observations and models agree that the impact of aerosols is to cool the earth.

Typically, particles that comprise aerosols range in size from the length of a large molecule (one nanometer) to one-tenth the width of a human hair .0004 in. (10 microns). The number of these particles in a cubic centimeter of air at the Earth's surface is highly variable in time and space, and ranges from 100 to 100,000. "Primary aerosols" are formed directly at the source, examples of which include mineral dust, sea salt, and combustion products such as soot and black carbon. "Secondary aerosols" are those formed in the atmosphere from reacted gases, and are often complex mixtures of oxygen, hydrogen, sulfur, nitrogen, and carbon. Most aerosols contain a mix of primary and secondary constituents. Aerosols are the major part of smog, and, in addition, contribute to many environmental and human problems such as acid rain and human respiratory ailments.

The impact of aerosols on climate has been classified in two ways. The direct radiative effect describes the scattering and absorption of sunlight and the earth's radiated heat energy by aerosols. Indirect radiative effects include the suite of possible impacts of aerosols on climate through the modification of cloud properties.

Scientists quantify the impact of an external agent such as aerosols on climate by its radiative forcing, expressed in units of Watts per square meter (W m-2). A positive radiative forcing tends, on average, to warm the Earth's climate, whereas a negative forcing tends to cool the Earth.

The direct radiative effect of aerosols is closely related to "global dimming," which is the observed reduction of sunlight received at the surface of the Earth in areas where pollution aerosols play a role. Recent assessments of the direct effect have benefited greatly from improvements in satellite and surface-based observations, which provide near-global coverage of aerosol optical properties. These observations have been matched by improvements in, and are often integrated into, global atmospheric computer models that can provide estimates of direct radiative forcing of aerosols. The most recent estimate places the value of direct effect radiative forcing between minus 0.9 and minus 0.1 W m2.

The indirect effect highlights a key role that aerosols play in the atmosphere as the seeds upon which water vapor condenses to form clouds. Variations in the number of these seed particles, known as cloud condensation nuclei (CCN), result in changes in the radiative properties, amounts, and lifetime of clouds. The effectiveness of an aerosol to act as a CCN is a function of its size, composition, shape, and surrounding environment. These details are known best about liquid water clouds, whereas knowledge of ice clouds is limited.

Several types of indirect effects have been identified. The first is the albedo effect, also known as the Twomey or 1st indirect effect. Albedo is a measure of the reflectivity of a cloud, and the albedo effect refers to an increase in the number of CCN, which leads to the formation of more numerous, but smaller, cloud droplets. This leads to an increase in cloud reflectivity, resulting in a negative radiative forcing estimated to be between minus 0.3 and minus 1.8 W m2.

The cloud lifetime effect or 2nd indirect effect, describes how increased CCN can modify the hydrological cycle and cause feedbacks that ultimately affect the earth's climate. Examples include drizzle suppression, increased cloud height, and increased cloud lifetime. Drizzle suppression, for example, can result in increases in wind-blown dust, which would lead to increased aerosol concentrations that would directly and indirectly impact climate. A third classification, the semi-direct effect, refers to certain types of aerosols, such as black carbon, that absorb sunlight and heat the atmosphere, which suppresses cloud formation. There are no estimates available for the impact of these other indirect effects.

The overall impact of aerosols on climate includes direct, semi-direct, and indirect effects. All model simulations agree that the total effect is greater over the Northern Hemisphere than the Southern Hemisphere. Direct and semi-direct effects in models are generally smaller compared to indirect effects. The average overall forcing ranges from minus 0.2 to minus 2.3 W m2, and the resulting effect on precipitation ranges from 0 to minus .05 in. (1.3 mm.) day-1. No climate simulation accounts for all aerosol-cloud interactions, therefore the net aerosol effect on clouds deduced by models is inconclusive.

Afforestation

AFFORESTATION INVOLVES TAKING action to plant trees in an area that has never been a forest area or to restore a deforested area. The trees may be planted from seeds or from seedlings. Legally, afforestation includes the setting aside of forest land, or land to be reforested by law. Many national forests have been created in the last century. These forest

On some land, such as this farm in Israel, afforestation will not occur naturally and requires mass planting programs.

areas may be designated as wilderness areas or as forest areas. In the case of the latter, they are usually multiuse areas. Some of the area in the forest will be used for recreation or for hunting, and other areas for timber operations.

The 18th and 19th centuries were times of enormous expansion of farming operations. In North America and in many places around the world, vast forests were cut down to create farms. In many areas of the eastern United States, the deforestation was extensive. In Vermont, for example, by 1900 about 80 percent of the land was being used for agricultural production, in particular for sheep herding. However, by 2000, farming had been greatly reduced and the state was over 80 percent forested. Some of the afforestation was due to the movement of people away from farming and into urban or town life.

Reforestation of Palestine began with the return of the first Jewish settlers in the late 1880s. After the creation of the state of Israel, a major tree-planting program began. The Kingdom of Jordan has also engaged in a widespread tree-planting effort. The deforestation there occurred under the Ottoman Empire because the Turks needed wood for their railroad steam engines. In Jordan, afforestation programs often encounter human resistance, as poor people see the forest as a resource for fuel and food for their goats. In Israel, Jordan, and other countries, afforestation cannot occur naturally as it can in an already well-watered area such as Vermont or the eastern half of the United States and Canada, generally. Deforestation in some places devastates the land because the removal of trees that held in moisture are no longer present, so the soil dries out so much that it is difficult for trees to re-establish themselves naturally. In tropical areas, the loss of forest cover may cause the soil to become so hard that water cannot penetrate it.

In some regions, deforestation, either followed by, or accompanied by, overgrazing, has led to desertification. In other areas, forests cannot be replanted because of the presence of people using the land for other purposes. Often, these uses are not as economical there as they would be if relocated. In Canada, Russia, and Iceland, afforestation programs have been used to replace the boreal forests.

It has been suggested that afforestation is a solution to global warming. However, there are a number of challenges to this claim. One challenge is that people, especially in third world countries, have little incentive to protect forests from destruction in order to save the planet from global warming. A second challenge is that, while forests lock up huge quantities of carbon dioxide, carbon dioxide emissions from many industrial sources are choking them. A third challenge is that while planting boreal forests will soak up vast quantities of carbon dioxide, the forests will also add to the heat of the planet because they absorb and retain energy.

Afghanistan

LOCATED IN CENTRAL Asia, with no maritime borders, Afghanistan covers a land area of 251,772 sq. mi. (647,500 sq. km.) and has a population of 31,889,923. It has a population density of 119 people per sq. mi. (46 per sq. km.). About 12 percent of the country is arable land, with 46 percent of the land area being used as meadow or pasture. Only three percent of the country is forested. Officially some 80 percent of the population make a living from agriculture.

At war since the late 1970s, there are numerous environmental problems facing Afghanistan, especially involving unexploded ordnance and a poor infrastructure. Parts of Afghanistan have faced severe shortages of food, alleviated by foreign aid, initially from the Soviet Union, later from parts of the Islamic world, and from the West, which supports the government of President Hamid Karzai. There have also been campaigns to eradicate the production of opium poppy and cannabis, with attempts to substitute the planting of food crops.

The arid countryside and resulting low level of agricultural production has been highlighted as a serious problem for Afghanistan, with the rising global temperature likely to lead to further declines in farming. Since fighting began in 1978, Afghanistan has lost over 70 percent of its forests, leading to soil erosion, a decline in soil fertility, and a rise in salinization. In addition, a dramatic fall in water tables has affected the electricity production in the country, 64 percent of which comes from hydropower, with the remaining 36 percent from fossil fuels. One important hydroelectric plant is located at Sarobi on the Kabul River, and provides much of the power for the capital. Prior to the use of hydropower, there was heavy reliance on wind power, with "horizontal" windmills located on the tops of buildings between Herat and the Iranian frontier from as early as the 7th century C.E. These windmills were primarily used to grind grain. The sulfur industry operates around the city of Maimana in the northwest of the country, and a small oil industry exists near Herat in the west of Afghanistan.

In 2001, Afghanistan recorded the warmest winter on record, with crop production decreasing. The Afghan refugee crisis, created by the war, continues, with many people unable to subsist in their villages. Because the country is so underdeveloped, it has one of the lowest carbon dioxide emissions per capita in the world, with 0.2 metric tons per capita in 1990 falling to negligible levels in 1997, and in 2007 was estimated to be 0.03 metric tons per capita, with only Chad and Somalia recording lower levels.

The Afghan government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, which took place less than a month after the overthrow of the pro-Russian president, Mohammad Najibullah. Under the Taliban government, there was little participation in any of the international forums, and the government of President Hamid Karzai has not expressed an opinion on the Kyoto Protocol to the UN Framework Convention on Climate Change.

Agriculture

FARMERS PRODUCE MUCH of the human food supply; raw inputs such as cotton, leather, and wool for textiles; and an array of fibers, chemicals, and pharmaceuticals that serve myriad manufacturing processes. Agriculture is a complex system of human activity that is intertwined in the economic, environmental, and social processes on the Earth.

The importance of agriculture to human well-being explains why influential national and international government and nonprofit agencies have focused so much attention on the impact of climate change on agriculture. There is a clear recognition on the part of agencies such as the United States Department of Agriculture (USDA), the International Panel on Climate Change (IPCC), the United Nations Food and Agricultural Organization (FAO), and the World Bank clearly recognize that climate change could have profound effects on the future. Global climate change may have some positive impacts on agriculture. On the other hand, there may be deeply negative impacts if climate change triggers droughts or other catastrophic events that hurt the global food supply. Resource scarcity could, in turn, cause famines and geopolitical conflicts with grave humanitarian consequences.

AGRICULTURAL IMPACTS OF CLIMATE CHANGE

Given that crops and livestock thrive in a relatively narrow set of environmental parameters, it makes sense to explore how climate change will affect agricultural productivity. Factors considered include the impacts of rising temperatures, increased production of carbon dioxide and other greenhouse gases, water supply fluctuations, soil quality variations, sea-level increases, and the introduction of new pests, diseases, and weeds, which could hurt agricultural output. These

One of the ways agriculture contributes to greenhouse gases is by shipping produce hundreds of miles to markets.

changes can have different impacts depending on the geographic scale of analysis. Climatic change will have different manifestations at local, regional, and global scales. Impacts will also vary according to the agricultural products under consideration. Some plant or animal species may be very resilient to environmental changes. Others may not adapt so well to change.

Temperature increases will affect crop and livestock production in various ways. A warming climate will extend the frost-free growing season at higher latitudes. Regions that are too cold to support commercial agriculture in northern Canada, Alaska, Scandinavia, and Russia, may become viable agricultural areas if temperatures increase. On the other hand, temperature-sensitive crops may no longer be commercially viable in regions that become too hot or dry. Also, rising temperatures could increase the heat stress on livestock.

Climatic change models predict that regional temperature variations may alter precipitation patterns and the supply of water for agriculture. Areas that are currently too dry may receive more moisture in the future. Areas that are productive now without irrigation may suffer as temperatures increase, because of increased plant evapo-transpiration. Farmers will have to find ways to offset the rising temperatures and corresponding moisture loss if they are to survive. Furthermore, many meteorologists suggest that weather events such as thunderstorms, tornados, and hurricanes may become more intense and occur with greater frequency. This may bring more rain to some regions. On the other hand, severe storms cause strong winds and flooding, which could cause large-scale crop damage.

Many regions of the world, such as the Indian Subcontinent, the Andes region of South America, Kazakhstan, California, and the American High Plains, rely on melt water from glaciers and heavy winter snows to feed streams and rivers that provide water for irrigation. These high altitude water sources have traditionally been viewed as renewable resources that can be depended upon to provide moisture during the growing season and are then replenished by snow falls during the frigid winters. However, rising temperatures have caused glaciers to shrink or disappear and have been linked to reduced snow pack at high altitudes.

A related problem is that many of the most productive rivers to fuel hydroelectricity are fed from the melt water of high altitude glaciers and snow pack. The Yangtze River in China is important for agriculture, and with the Three Gorges hydroelectric power plant, it is also an important energy producer. However, the Yangtze River, like the Colorado River in the United States and the Ganges River in India, is replenished by melt water from glaciers and snowmelt. This shows the complex impacts of rising temperatures that will reduce water for agriculture, but also produce a renewable form of energy to offset carbon dioxide production from fossil fuels. Melting glaciers may also increase sea levels, which could jeopardize agriculture by flooding and accelerated soil erosion in many low-lying areas around the world.

Global warming is caused by increased concentrations of carbon dioxide, nitrous oxides, methane, and other gases produced by the combustion of fossil fuels. The impact of having more carbon dioxide in the atmosphere is difficult to gauge with certainty. Plants consume carbon dioxide in the production of oxygen through photosynthesis. Theoretically, increased levels of carbon dioxide could spur plant growth because increased atmospheric concentrations of carbon dioxide mean that there is more available for plants to use during photosynthesis. In addition, there is a synergistic relationship between carbon dioxide and water uptake. Plants are more efficient users of water as ambient concentrations of carbon dioxide increase.

Unfortunately, there are many factors that could offset the potential productivity gains to agriculture from increased carbon dioxide concentrations. The conditions that increase the growth of commercial crops also increase the growth of traditional weeds and could accelerate the growth of new invasive plant species. Also, increased temperatures will prompt the growth of plant diseases and insects. In order to reduce the impact of pests and pathogens, farmers will have to apply more pesticides, herbicides, and other chemicals, many of which are manufactured from petrochemicals.

Soil dynamics will also be affected by changing temperature regimes. Rising temperatures will increase the rate at which organic material decomposes and possibly decrease the level of moisture in soils. This will lower soil productivity, thus prompting the increased use of fertilizers. This might be mitigated, though, by the growing presence of nitrogen oxides that are also increasing as a result of fossil fuel combustion. Increased temperatures might also accelerate soil erosion in agricultural areas, rising temperatures increase the severity of thunderstorms. Without appropriate adaptation by producers, soil erosion could accelerate as the increased flow and force of water droplets dislodge soil. This is a problem because soil erosion is itself a cause of carbon dioxide release into the atmosphere.

CONTRIBUTIONS TO CLIMATE CHANGE

While agriculture is affected by climate change, agricultural processes also contribute directly and indirectly to global warming. This occurs for many reasons. A direct contribution is agriculture's reliance on the combustion of fossil fuels such as gasoline, diesel, and propane to power farm equipment, including tractors, combines, grain elevators, grain dryers, and transport trucks for shipping feed and livestock. Agriculture also relies on petrochemicals in the form of herbicides and pesticides. Estimates suggest that agriculture uses 8 percent of all energy consumed in the United States.

In order for farming to occur, land must be cleared of trees and other vegetation. The problem is that forests represent a "sink" or reservoir of carbon that would otherwise be part of the earth's atmosphere. The process of deforestation releases the sequestered carbon back into the atmosphere as the fallen trees decompose. This process is often accelerated as farmers burn the wood. In rainforest areas, traditional cultures use a farming process called "slash and burn" or swidden agriculture, whereby farmland is carved from the rainforest by cutting down trees. The trees are set on fire and the resulting ash nourishes the soil. After a couple of years, the nutrients are leached out of the soils because of the heavy precipitation in the rainforest. Farmers then move to a new site and repeat the process.

However, the impact of swidden agriculture is small compared to the destruction of tropical and temperate rainforests for the purposes of agriculture and timber production. Brazil is effectively competing with the United States in soybean production by turning its forests into fields. By turning its rainforests into cropland, Brazil is increasing greenhouse gases through deforestation. It also contributes to greenhouse gases because it has heavily invested in the American model of industrial agriculture, which relies on the consumption of fossil fuels to power farm equipment and to manufacture fertilizers, pesticides, and herbicides. While it is easy to blame tropical countries for cutting down their forests to make way for farming, temperate countries in North America and Europe have also plowed under biodiverse prairies and cut down broadleaf forests to make way for agriculture. The United States has the most productive agricultural system in the world. This productivity comes at a cost to the environment.

Agriculture accounts for about 7.4 percent of all carbon dioxide emissions in the United States. In addition to carbon dioxide, agricultural operations contribute more methane and nitrogen oxides to the atmosphere than any other economic sector. Enteric fermentation generates most of the methane released. In simpler terms, this refers to the flatulence released from ruminant livestock, such as cattle, as they digest feed grains. The production of rice also creates enormous amounts of methane. When the rice paddies are flooded, the organic material in the water-covered soils decomposes, anaerobically releasing methane in the process. The fact that rice is a staple crop for hundreds of millions of people around the world explains why it contributes so much methane to the atmosphere.

Nitrous oxides are an important input to industrial agriculture. Crop production depletes the nutrients in the field. Prior to the industrial revolution, farmers managed soil nutrients by rotating their crops. Different crops use different soil nutrients at different rates. Hence, crop rotation from year to year reduced the overall rate at which nutrients were depleted. Farmers also periodically left fields fallow. The nutrients in these fields were replenished as organic material on the soil surface decomposed.

In modern industrial agriculture, crop rotations play a moderate or minor role in the management of soil fertility. Farmers survive on low profit-margins. Hence, they tend to specialize in only one or two crops to achieve economies of scale in production. In the American Midwest, the crops tend to be corn or soybeans. Farmers are not likely to rotate beyond these two crops, nor are they likely to leave fields fallow. This means that farmers must maintain soil productivity through the application of nitrogen to the soils. Nitrogen oxides form when the nitrogen designed to work below the soil comes in contact and binds with oxygen molecules. Farmers also use animal waste as a way to increase nutrients in the soils. Hence, animal waste management practices also contribute to nitrogen oxides in the atmosphere.

Finally, agriculture contributes greenhouse gases because of the national agricultural system and a global agricultural market that depends on shipping commodities hundreds and even thousands of miles to markets. This requires the combustion of gasoline and diesel to operate trucks and refrigerated storage facilities.

AGRICULTURAL SOLUTIONS TO CLIMATE CHANGE

There are many strategies that farmers, businesses, and consumers can adopt to reduce greenhouse gases related to agriculture. First, farmers can replace fossil fuels such as gasoline and diesel with biofuels such as ethanol or biodiesel. Ethanol is a fuel alcohol that is produced by a fermentation process that uses yeast to convert the sugars found in plants into a combustible alcohol fuel. Ethanol can offset varying amounts of fossil fuel–generated carbon dioxide depending on the material used to produce the ethanol. For example, Brazil, located in a tropical climate, can efficiently grow sugarcane. Sugarcane is an excellent source material for ethanol because the sugars in sugarcane can be easily converted into alcohol. In the United States, corn is the primary feedstock for ethanol. It is more costly to convert corn into sugar because the sugars are bound up in long starch molecules. These carbohydrates must be broken down in order to free up the sugars to be converted into alcohol. Therefore, researchers in the United States are working hard to discover ways to lower the costs of producing corn-based ethanol.

Researchers are also studying how to use other plant materials to produce fuel. Cellulosic ethanol is not yet a commercially-viable strategy, but many predict that it will be in the near future. Cellulose is the fibrous or "woody" part of many plants. For example, high concentrations of cellulose are found in the stock and leaves of corn. It would be beneficial to use this part of the corn for ethanol production because it is usually considered a waste product. Cellulosic ethanol would allow the corn kernel to be used for food rather than as a source material for ethanol. The challenge is that the sugars in the cellulose are tightly bound to starch molecules. Consequently a more expensive, enzyme-driven process must be used to convert the sugars into alcohol. Therefore, cellulosic ethanol is not commercially viable now, but many countries, including the United States, are spending hundreds of millions of dollars to discover how it could become a commercially viable fuel.

In addition to ethanol, research is being conducted on other plant-based alcohol fuels such as methanol and butanol. These fuels can also be produced from organic materials including grains and wood fibers. They are currently not commercially viable, but some researchers claim that they may be even better than ethanol as an alternative fuel. Diesel produced from plant material can also reduce greenhouse gases. Crops known as oilseeds, such as cottonseed, sunflower, soybeans, and canola, can serve as the source material to produce a diesel product that has performance characteristics similar to petroleum-derived diesel, without emitting the same volume of greenhouse gases.

Farmers can also modify their management practices so that farmland can serve as a sink to sequester carbon dioxide. For example, farmers can create buffers comprised of trees, shrubs, and natural grasses along rivers to prevent soil erosion and the loss of nutrients due to runoff. The Conservation Reserve Program in the United States pays farmers to take marginal cropland out of production as a way to reduce soil erosion.

Farmers can also create windbreaks near farmhouses and outbuildings. Windbreaks can create a microclimate that can moderate temperature extremes by blocking cold winds or providing shade on hot summer days. This can lower energy use and costs on farms. Windbreaks can also serve as carbon sinks, whereby trees and other plants absorb carbon dioxide. Farmers can also adopt conservation tillage strategies that leave part of the organic residue on the field after the harvest. This material slows runoff, thereby reducing soil erosion and nutrient loss. The decomposing material also replenishes the nutrients in the soil. All of these practices can reduce the energy used, and greenhouse gases produced, on the farm.

Livestock producers can reduce the impact of their operations by changing how they manage animal waste such as methane and manure. Some farmers are experimenting with anaerobic digesters that convert manure into more manageable waste solids that can be used as an organic fertilizer. The digester also creates methane as a byproduct, which can be captured and used as a renewable fuel.

Finally, some writers argue for a move away from large-scale industrial agriculture to place more emphasis on so-called civic agriculture as a way to slow global warming. Civic agriculture includes local food systems and organic foods. Local food systems reduce greenhouse gases by reducing transportation costs. Traditional food supply chains can stretch thousands of miles from the point of production to the place of consumption. Local food advocates suggest that food could be grown and consumed locally. Organic agriculture reduces the use of greenhouse gases because organic farmers cannot use petroleum-based herbicides or pesticides.

Agulhas Current

THE AGULHAS CURRENT is the major western boundary current of the Southern Hemisphere. It completes the anti-cyclonic gyre of the South Indian Ocean, and because the African continent terminates at a relatively modest latitude, it becomes a mechanism for the climatologically important inter-ocean exchange between the Indian and Atlantic Oceans. The southwestward flowing Agulhas Current only becomes fully constituted along the east coast of southern Africa at a latitude somewhere between Durban (South Africa) and Maputo (Mozambique). It increases in speed and volume flux downstream.

On average, its volume flux is 70 × 106 m.3/s, with only small temporal changes. Its depth, by contrast, can vary from 6561 ft. (2,000 m.) to the sea floor at 9,842 ft. (3,000 m.) over a period of months. It is underlain by an opposing undercurrent at a depth of 3,937 (1,200 m.), with a maximum velocity of about 0.2 m./s and carrying about 4 × 106 m.3/s equatorward. An offshore profile of the surface speed of the current shows a peak of about 1.5 m./s close inshore, slowly tapering off to about 0.2 m./s at a distance of roughly 62 mi. (100 km.) offshore. The temperature of its surface waters is about 11 degrees F (6 degrees C) higher than ambient waters and decreases from 80 to 71 degrees F (27 degrees C to 22 degrees C) from summer to winter.

Using its flow characteristics, the Agulhas Current can be clearly divided into northern and a southern parts. The northern part follows the continental shelf edge very closely, meandering less than 9 mi. (15 km.)

to either side. Downstream of Port Elizabeth, in its southern part, it starts meandering with increasing distances to either side of its mean trajectory, producing large shear edge eddies and plumes on its landward side in the process. The path stability of the northern Agulhas Current is interrupted at irregular intervals by a major perturbation, called the Natal Pulse, which is triggered just upstream of Durban. Triggering is thought to come about when offshore eddies interact with the current. This singular meander grows as it travels downstream at a rate of about 12 mi. (20 km.) per day. It has an embedded cyclone on its landward side. Natal Pulses have been perceived to play an important role in inter-ocean exchange.

Once the southern Agulhas Current overshoots the tip of the continental shelf south of Africa, it retroflects, with most of its water heading zonally eastward as the Agulhas Return Current, more or less parallel to the Subtropical Convergence. The Agulhas Return Current is largely steered by the bathymetry and exhibits large meridional meanders. The retroflection loop itself is unstable, and at irregular intervals it occludes, forming a large ring 155 mi. (or 250 km. diameter) of warm Agulhas Current water. These rings may extend to the sea floor. After such an event the newly-formed retroflection loop starts prograding into the South Atlantic Ocean once more. There is evidence that nearly all ring shedding events are set off by the arrival of a Natal Pulse from farther upstream.

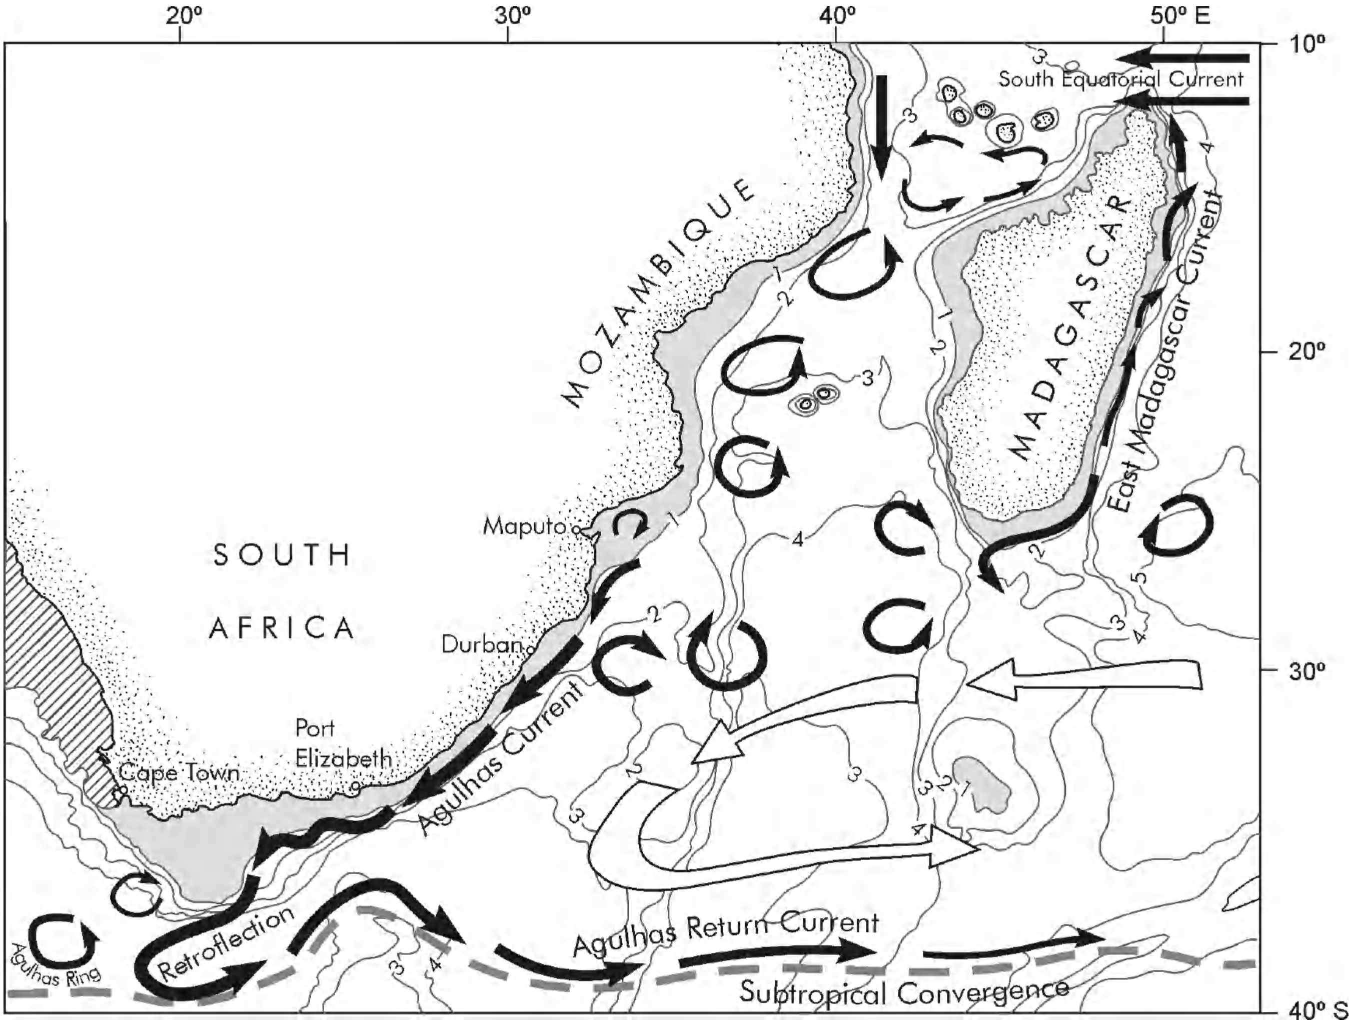
Having formed, most rings dissipate in the mixing cauldron of the Cape Basin northwest of Cape Town. Here, Agulhas rings have to contend with previously-formed rings, as well as Cape Basin cyclones. The few that survive this interaction move northwestward across the South Atlantic Ocean, slowly shedding their anomalous heat, salt, and vorticity to the ambient waters. The inter-ocean fluxes brought about by the ring-shedding process have been estimated to lie between 5 and 20 × 106 m.3/s. By this process and others, the Agulhas Current becomes a profound factor in local weather and in global climate.

It has been demonstrated that the presence of the Agulhas Current enhances coastal rainfall along South Africa's east coast. Wherever the current is further offshore, this enhancement is reduced. The enormous ocean-to-atmosphere heat fluxes at the Agulhas retroflection and from Agulhas rings and Agulhas eddies; the latter shed across the Subtropical Convergence by the Agulhas Return Current, directly affect the overlying atmosphere and, thus, local weather.

Even more important climatologically, is the role the Agulhas Current plays in the global thermohaline circulation. The westward heat and salt flux south of Africa is a crucial link in this chain of currents and fluxes. The Atlantic Ocean is the only ocean basin where there is a net heat flux northward across the equator; this has been assumed by some to be the result of the net westward heat flux south of Africa. Modelling studies have shown that a forced decrease in this flux is linearly related to a decrease in the meridional overturning of the whole Atlantic Ocean. Studies of temporal changes of inter-ocean fluxes, such as changes in the bottom sediments, have shown substantial variation in the penetration of Agulhas Current water into the South Atlantic over the past 500,000 years, which has never shut off completely. Furthermore, analyses of bottom sediments have demonstrated conclusively big surges of Agulhas Current water into the South Atlantic at the end of each glacial period.

Understanding significant changes in the inter-ocean exchanges requires a look at how the Indian Ocean controls Agulhas ring shedding. The main factor controlling the horizontal circulation system in the ocean gyres to either side of South Africa is the wind stress pattern. The succession of trade winds and westerlies drives a subtropical ocean gyre system both in the South Indian and Atlantic Oceans. This subtropical circulation is connected south of Africa, largely by the Agulhas rings. Meridional shifts of the wind pattern or variations in their strength lead to variations in this connection. Modelling studies suggest that a large southward shift opens the Agulhas valve and results in a supergyre that flows unobstructed through both oceans. Similarly, the wind patterns shifting northward, reduces the flux from the Indian to Atlantic Ocean. Data from the paleo record indicate that such fluctuations of the inter-ocean exchange have occurred.

Less dramatic variations of the exchange have been observed over the past decades. They seem to be controlled by the tropical and subtropical climate modes over the Indian Ocean. Associated wind variations force anomalies over the central and eastern Indian Ocean that propagate as planetary waves from east to west across the Indian Ocean. On encountering the



Agulhas rings that reach the South Atlantic Ocean and shed their heat, salt, and vorticity to the ambient waters are part of what makes the Agulhas Current a profound factor in both local weather and the global climate.

island of Madagascar, the anomalies interact with the background current system, involving swift boundary currents along the east coast of Madagascar and jets that separate from both the northern and southern tips of the island. This leads to instabilities in the flow, with mesoscale eddies formed both in the Mozambique Channel and south of Madagascar. The resulting eddy trains propagate to the African coast where they either trigger the formation of Natal Pulses or move into the Agulhas retroflection region. In both cases, they seem to regulate the frequency of Agulhas ring shedding. The rate of eddy formation around Madagascar has been observed to vary with the appearance and strength of the Indian Ocean (sub)tropical climate modes. The whole chain of events takes several years to propagate from the tropical and subtropical region to the Agulhas retroflection.

Air Force, U.S.

THE U.S. AIR Force began as the Aeronautical Division of the U.S. Army Signal Corps. This division was established on August 1, 1907, to manage air machines, military ballooning, and other military matters of the air. Since then, the Air Force has become an institution independent of the U.S. Army, and with its vast increase in size and fuel usage has a considerable effect on the environment. The U.S. Air Force is conscious of greenhouse gas emissions and their potential link to global warming. For example, the Air Force voluntarily purchased over one billion kilowatt-hours of green energy in 2006: 39 percent biomass, 38 percent wind, 16 percent geothermal, and 7 percent other. The power was purchased from several sources, including American Electric Power, Rocky Mountain Generation Cooperative, and Sterling Planet.

The estimated quantity of emissions spared via the green energy is equal to the emissions of just over 250,000 cars annually. This purchase led the U.S. Environmental Protection Agency (EPA) to name the Air Force the leading green energy purchaser in the United States in 2006. By July 2007, the Air Force had fallen to the number five position, behind PepsiCo, Wells Fargo & Company, Whole Foods Market, and The Pepsi Bottling Group, Inc. The Air Force had purchased nearly .5 billion kilowatt-hours of green energy, which supplied only 4 percent of its total electricity needs. Other renewable purchases and on-base renewable energy generation raised that percentage to nearly 10 percent. The Air Force is also on the Environmental Protection Agency's Top Ten Federal Government Green Power Partners list, in the highest position for three years in a row: 2005, 2006, and 2007.

Another facet of environmental protection pivotal to the Air Force is cleaning and restoring the environment surrounding Air Force Bases, especially during closings or realignments. A special office that helps to manage these issues is the U.S. Air Force Center for Environmental Excellence (AFCEE). The AFCEE is headquartered at Brooks City-Base, San Antonio, Texas. It is an Air Force Civil Engineer field-operating agency, created in 1991 in response to a need for assistance to Air Force commanders when establishing environmental or construction programs. Several rearrangements of the organization and offices have taken place since 1991; however, the vision and purpose of the AFCEE has remained the same. According to its mission statement, "AFCEE provides a complete range of technical and professional services in environmental and installation planning and engineering, and military housing construction and privatization." Within one year, the AFCEE base was managing numerous environmental clean-ups, specifically those needed after a sweep of closures and realignments of many bases.

Because there are many leading environmental engineers and green construction experts who are not in the Air Force, the AFCEE employs both civilians and military personnel in dealing with the environment and construction management. As of 2007, approximately 300 civilians and 50 military personnel belonged to the AFCEE. These members included contractors around the nation. A civilian director, assisted by an executive director, manages the AFCEE. The civilian director is a member of the senior executive service, while the executive director is a colonel in the Air Force. In addition, the executive director acts as commander of the military personnel at the AFCEE. Four support directorates assist the AFCEE in the spectra of Contracting, Mission Support, Operations & Development, and Staff Judge Advocate (Legal). Additionally, AFCEE directors manage four business line directorates: Installation and Support Worldwide, Installation and Support for Air Force-related Matters, Housing, and Base Conversion. Finally, there is a technical directorate and three regional offices for the environment. These offices are located in Atlanta, Georgia; Dallas, Texas; and San Francisco, California.

An additional step made by the Air Force to reduce fuel usage is the purchase of flight simulators to reduce the fuel requirements of training. Novel technology is also being used to better align fuel (and thus weight) carried with fuel needed per flight. Streamlining fuel weight to just the amount needed will reduce fuel usage overall, as a lighter plane uses less fuel per unit of distance and speed. While these changes were for the sole purpose of saving money on fuel and, thus, using tax dollars more efficiently, the reduced burning of fuel also has a positive impact on the environment.

Alabama

ALABAMA IS 52,237 sq. mi. (135,293 sq. km.) wide, with inland water making up 962 sq. mi. (2,491 sq. km.), and coastal water 519 sq. mi. (1,344 sq. km.) Alabama's average elevation is 500 ft. (152 m.) above sea level, with a range in elevation from sea level on the Gulf of Mexico to 2,405 ft. (733 m.) at Cheaha Mountain. Alabama's varied topography includes plateaus, uplands (northeastern section of the state), forested ridges, rolling prairie, and fertile valleys. Most drainage flows to the Gulf of Mexico, or, as in the case of the Tennessee River, drains into the Ohio River, then drains into the Mississippi River. The bodies of water in Alabama are mostly reservoirs. Alabama's coastline on the Gulf of Mexico is only 53 mi. (85 km.) long; Mobile Bay, an inlet 35 mi. (56 km.) long at the mouth of the Mobile River, along with smaller bays and inlets, creates a much longer shoreline. Barrier islands block part of the entrance to Mobile Bay. Other islands extend along Alabama's western coast.

Alabama's temperate subtropical climate means its long summers are hot and humid, while winters are mild. Temperature extremes are unusual, though the highest temperature recorded in the state was 112 degrees F (44 degrees C) on September 5, 1925, and the lowest temperature recorded in the state was minus 27 degrees F (minus 33 degrees C) on January 30, 1966.

In winter, mild humid air masses from the Gulf alternate with cold air masses from the north. Snow occasionally falls in the north. The average annual precipitation is 56 in. (1.4 m.); most rainfall occurs in winter and spring with droughts common from August through October. River overflow and flooding occurs one time per year on average. Tornadoes occur November to May, and March to April is the most frequent storm season. Hurricanes occur between July and November.

Fossil fuel is important to Alabama's economy, with coal mining (in the north-central region, especially near Birmingham), natural gas, and petroleum, along with thousands of acres offshore leased for oil and gas. Agriculture is also important. A variety of crops (cotton, corn, and hay) are grown, though in some places the soil requires fertilization. In 1980, Alabama instituted a conservation program of forest management and replanted 22 million acres of forest for logging. Alabama is already experiencing the effects of higher temperatures and rising sea levels (9 in. in the last century) and hurricane and other major storms have increased in intensity and duration by about 50 percent since the 1970s, noted in the devastation from Hurricane Katrina in 2005.

While climate models vary, temperature increases for Alabama, from 1–4 degrees F (0.5–2 degrees C) in winter and summer, from 1–5 degrees F (0.5–2.7 degrees C) in spring, and from 2–7 degrees F (1–4 degrees C) in fall, are predicted by the end of the century. Potential risks include anticipated rising sea levels of an additional 20 in. (51 cm.) (causing flooding, loss of coastal wetlands, beach erosion, saltwater contamination of drinking water, and damage/decreasing stability of low-lying property and infrastructure), possible increase in frequency and intensity of summer thunderstorms, decreased water supplies, population (both human and animal) displacement, changes in agriculture (cotton yield unaffected, but rising corn and hay yields), and forest loss with persistent drought, as well as loss of trees unsuited to higher temperatures.

Human health risks include contracting certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents. Warmer temperatures increase the incidence of heat-related illnesses and lead to higher concentrations of ground-level ozone pollution, which could cause respiratory illnesses (diminished lung function, asthma, and respiratory inflammation), especially in Birmingham, which sometimes already exceeds the national standard for ozone.

Based on energy consumption data from EIA's State Energy Consumption, Price, and Expenditure Estimates (SEDS) released June 1, 2007, Alabama's total CO_2 emissions from fossil fuel combustion in million metric tons CO_2 for 2004 was 140.48, including contributions from: commercial 2.08, industrial 24.57, residential 3.1, transportation 34.89, and electric power 75.84. Alabama joined the Climate Registry in 2007, and by doing so agreed to develop and manage a greenhouse gas emissions reporting system as well as provide an accurate assessment of greenhouse gas emissions.

The Geological Survey of Alabama is taking part in the Southeastern Regional Carbon Sequestration Partnership (SECARB) investigating the potential for using coal as a sink for carbon dioxide. They will perform field-testing and monitoring in the Black Warrior basin; an assessment indicated more than 5.9 trillion cu. ft. of CO_2 could be sequestered in established coal bed methane fields. Air quality water, and land protection and conservation in the state falls under the Department of Conservation and Natural Resources. However, in terms of climate change initiatives, more is being done on the local level and in the private sector.

The Alabama Power Company and the Tennessee Valley Authority (TVA) are working to improve greenhouse gas emissions. The Alabama Power Company is updating technology for reducing CO_2 discharges. TVA must meet federal and other environmental statutes and regulations for air and water quality, as well as managing the disposal of wastes (including hazardous materials). These regulations are becoming more stringent with clean air requirements and reducing greenhouse gas emissions.

Alaska

THE LARGEST AND the coldest of the 50 American states, Alaska is already experiencing the effects of climate change. The state, which is located in the extreme northwestern portion of the North American continent, normally experiences temperatures ranging from minus 60 degrees F (minus 51 degrees C) in the winter to more than 90 degrees F (32 degrees C) in interior areas during summer months. Over the last three decades, Alaska's average temperature has risen 5 degrees F (2.7 degrees C). Around the world, glaciers are melting at unprecedented levels, threatening animal and plant ecosystems. In Alaska, warmer temperatures are causing the breaking up of portions of Porter Glacier. Alaska shares an eastern border with Canada and is surrounded on three sides by the waters of the Gulf of Alaska, the Beaufort Sea, the Bering Sea, the Bering Strait, and the Chuckchi Sea, all of which are also filled with ecosystems that are vulnerable to changing temperatures.

Sea levels are rising around the world, and Alaska is seeing the effects of these changes to varying degrees. The most significant changes have been along the coasts of the Bering Sea, the Chuckchi Sea, and the Beaufort Sea. The coastal communities of Kivalina, Shishmaref, and Newtok are in the process of relocating because of erosion and flooding. According to the U.S. Army Corps of Engineers, more than 160 other rural communities in Alaska are vulnerable to coastal erosion. Alaska has over 100 acres of state parks and forests, and scientists have observed decreased tree growth in interior areas as a result of climate change. The state also has a large mammal population whose survival depends on preserving existing ecosystems. Alaska has experienced an increase in the number of forest fires in the state in response to warmer temperatures, and spruce bark beetles are destroying forests.

In much of Alaska, permafrost causes the ground to remain frozen year-round. Some 85 percent of Alaska is built on foundations of permafrost. When events occur to disrupt the thermal balance, the permafrost melts and the ground above it collapses in a process known as thermokarst slumping. Maintenance costs are already increasing for roads, pipelines, and other facilities built on permafrost. Two Alaskan scientists, who have identified holes as deep as 200 ft. (61 m.) in some areas, report that the permafrost south of the Yukon River is nearing thawing point. Another scientist has observed that permafrost in the far north remains relatively stable, but acknowledges that considerable warming has occurred since the 1990s. If permafrost melts, it may lead to slumping roads, slanting floors, forest sinkholes, disappearing trees, and the presence of new lakes.

Although the state government has acknowledged the need to respond to changes that are taking place in Alaska, there is still controversy over whether or not climate changes are due to global warming, and on defining specific actions that are necessary to deal with the issue. In the spring of 2007, three groups of Alaska Natives, the Inter-Tribal Council, the Council of Athabascan Tribal Governments, and Resisting Environmental Destruction on Indigenous Lands, filed an *amicus curiae* (friend of the court) brief in a global warming lawsuit filed by 10 states, three cities, and a number of citizen advocacy groups, in an effort to force the U.S. Environmental Protection Agency (EPA) to regulate greenhouse gases and identify them as contributors to global warming and climate change. The state government of Alaska has joined 10 other states and industries in formally protesting the suit, arguing that forcing the EPA to reduce carbon dioxide (CO_2) emissions from new vehicles would not solve the overall problems of global warming.

When compared with other states, Alaska produces 0.3 percent of the nation's alternative fuels and 0.1 percent of ethanol. The state produces 0.2 percent of total CO_2 and 0.4 percent of nitrogen oxide emissions. Alaska does not produce significant amounts of sulfur dioxide. Alaska has the 14th lowest level of CO_2 emissions in the United States; but because of Alaska's sparse and widely distributed population and its dependency on coal-generated power, the level of CO_2 produced per person is the highest in the nation and six times that generated by the state of New York, which has a population approximately 29 times the size of Alaska's. Because the land area of Alaska is 570,374 sq. mi. (917,928 sq. km.), residents spend much time traveling by air, and Anchorage, the largest city in the state, ranks second in air cargo traffic in the United States.

ENERGY PRODUCTION

Alaska ranks second in oil production in the United States, outranked only by Texas. A total of 14 of the largest American oil fields and two of the largest natural gas fields are found on the Alaska North Slope. Prudhoe Bay yields around 400,000 barrels a day, and the Trans-Alaska Pipeline is capable of pumping 2.1 million barrels of crude oil daily. The Alaskan ecosystems are still not completely recovered from the oil spill that occurred in 1989 when the *Valdez*, an oil tanker owned by Exxon, inadvertently spilled 260,000 barrels of oil into Prince William Sound. Because Alaska does not use all of the natural gas that is produced during oil production and there is no viable means of piping it into the American mainland, much of it is pumped back into the ground. In order to make use of this cheap and readily available natural gas, a number of petrochemical industries, which produce ammonia and urea fertilizer, have located in Alaska.

Some 50 hydroelectric plants supply the most heavily populated areas of Alaska with power. Around three-fifths of Alaska's energy is fueled by natural gas. Two-tenths of the energy requirement is met by petroleum and coal. In many isolated areas, diesel-fueled electric generators supply power. Renewable energy is replacing fossil fuels in some areas, and a geothermal plant has been built in Chena Hot Springs. Small wind farms have been set up in the rural areas of Healy and Kotzebue. Anchorage is home to one of the largest fuel cell systems in the United States.

ENVIRONMENTAL PROGRAMS

The Alaska Department of Environmental Conservation (DEC) is chiefly responsible for responding to environmental issues that affect global warming and climate change in Alaska. The Division of Air Quality, the Division of Environmental Health, the Division of Information and Administrative Services, the Division of Spill Prevention and Response, and the Division of Water are all sub-branches of ADEC. The Department of Fish and Game and the Department of Natural Resources also have environmental obligations.

In the fall of 2007, Governor Sarah Palin created the Climate Change Sub-Cabinet by executive order and charged the group with consolidating existing knowledge on climate change and making recommendations for policy and initiatives designed to reverse climate change trends that are already evident in Alaska. Three workgroups have been set up to pursue the goals of the Sub-Cabinet: Immediate Action, Alternative Energy Conservation, and Research Needs. The Sub-Cabinet is made up of department commissioners from Commerce, Community and

Economic Development, Natural Resources, Fish and Game, Transportation and Public Facilities, and Environmental Conservation.

The group was requested to work with the University of Alaska to investigate the development of renewable energies, including geothermal, wind, hydroelectric, and tidal resources. The Climate Change Sub-Cabinet cooperates with the Joint Alaska Climate Impact Assessment Commission set up by the legislature, Arctic Climate Impact Assessment (ACIA), and the University of Alaska's Alaska Center for Climate Assessment and Policy. Alaska has observer status at the Western Climate Initiative, which the governors of Arizona, California, New Mexico, Oregon, and Washington established in February 2007, to develop regional responses to climate change.

Because the population of Alaska is widely scattered and travel is often difficult, the needs of rural Alaskans are different from those of larger, more populated areas. A number of programs, such as RurAL CAP, have been established to meet these distinct needs. Alaska Environmental Resource Hub Online serves as an interactive environmental educational tool and provides a forum for addressing issues that include compliance, solid waste management, air quality, environmental justice, and health. RurAL CAP works closely with the local Indian General Assistance Program. The Alaska Village Indoor Air Quality Program provides education on environmental issues in rural communities and advises Alaskans on reducing exposure to domestic hazardous waste, installing carbon monoxide alarm systems, and using non-toxic green cleaning kits. RurAL CAP and RAVEN AmeriCorps members use the Savin Raven Game to teach children about environmental issues.

There are a number of other programs designed to protect Alaska's environment and slow the progress of climate change in the state. For instance, the Alaska Environmental Monitoring and Assessment Program samples coastal and fresh waters to maintain clean water and protect vulnerable ecosystems. The Environmental Quality Incentives Program serves the Alaskan agricultural sector by promoting voluntary conservation and offering financial and technical help to enable farmers to meet national guidelines for responsible agricultural practices.

Grassroots groups are also an essential element in pursing environmental policies designed to mitigate the effects of global warming and climate change. Citizens' groups include Alaska Action Center, Alaska Boreal Forest Council, Alaska Center for the Environment, Alaska Clean Water Alliance, Alaska Community Action on Toxics, Alaska Conservation Foundation, Alaska Forum for Environmental Responsibility, Alaska Friends of the Earth, Alaska Marine Conservation Council, Alaska Natural Heritage Program, Alaska Rainforest Campaign, and Alaska Wilderness League.

Alaska Climate Research Center

THE ALASKA CLIMATE Research Center is a research and service organization at the Geophysical Institute at the University of Alaska, Fairbanks. Established and funded by the State of Alaska, the center conducts research focusing on the climate of Alaska and other polar regions. It also houses an archive of Alaska climate data. The primary concern of the center is to supply information concerning the meteorology and climatology of Alaska to public, private, and government agencies. It also assists researchers around the world.

Most of the climate data available for Alaska have been accumulated in Fairbanks and by the state climatologist in Anchorage at the Alaska State Climate Center. The Alaska Climate Research Center archives digital climate records, develops climate statistics, compiles monthly weather summaries, and conducts research on a number of high latitude meteorological and climate issues.

The center found itself in the spotlight of national debates over global warming in 2002, when a *New York Times* editorial praised Californian legislation that set stricter standards for CO_2 emissions from automakers. The article cited a report by journalist

Timothy Egan about Alaska, claiming that a dramatic 7-degree increase in average temperatures over the past 30 years has led to “melting permafrost, sagging roads, dying forests, unexpected forest fires and disruption of marine life.” The article concluded by quoting Alaska Republican Senator Ted Stevens’s concern about “global warming’s potential cost to his home state” and “Washington’s indifference.” The Alaska Climate Research Center entered the debate by issuing a note that challenged and openly countered the data reported by Timothy Egan. The statement read:

> the article ‘Alaska, No Longer So Frigid, Starts to Crack, Burn, and Sag’ written by Timothy Egan, stated that the average temperature has risen seven degrees in the last 30 years. This statement was repeated in an editorial by Bob Herbert of 24 June 2002. This statement is incorrect. The correct warming for Alaska is about 1/3 of the quoted amount for the last climatological mean 1971 to 2000.... It should be pointed out that ... data [come] from first class weather stations, which are professionally maintained and generate high quality data. The three stations, Barrow, Fairbanks, and Anchorage, represent a cross section of Alaska from north to south. Further, Barrow, situated in Northern Alaska, which gave the largest temperature increase, is the only long-term first class meteorological weather station in Northern Alaska. All changes are based upon the time period 1971 to 2000 and are compiled from a linear trend.

Albania

ALBANIA IS A small and relatively underdeveloped country in southeast Europe. Since the collapse of the Communist government there in 1991, Albania has transformed itself from an isolated country to one whose government has sought to take an active part in European affairs. The country has a population of 3.6 million (2007), and covers 11,100 sq. mi. (28,748 sq. km.), with a population density of 318.6 per sq. mi. (134 per sq. km.). Some 21 percent of the land is arable, with 5 percent under permanent cultivation, and 15 percent as meadow or pasture. In addition, some 38 percent of the country is forested; most of the trees are oak, elm, pine, or birch.

There are a number of environmental problems facing Albania, mainly with pollution. The country is largely self-sufficient in food, and its petroleum industry produces some 100,000 barrels per day. Because much of the country is underdeveloped, Albania has a relatively low carbon dioxide emission level per capita, with 2.2 metric tons emitted per person in 1990, 1.2 metric tons in the following year, and falling off markedly to 0.7–0.8 metric tons per capita in the 21st century, showing one of the more dramatic declines of any country in the world. Albania is now 139th in the world in terms of carbon dioxide emissions per capita, the second lowest in Europe; only Georgia has a lower emission level. Similarly, the sulfur dioxide, nitrogen oxide, and the carbon monoxide emissions from Albania are all very low.

The main reasons for the low carbon emissions in Albania are relatively low private ownership of cars, heavy use of public transport, and a reliance on hydroelectric power. Only 3 percent of Albania’s total electricity production comes from fossil fuels, with the remainder from hydropower generated from the dams along the Drin River, especially from where Vau I Dejes runs to the junction of the White Drin and Black Drin rivers at Kukës.

The building of the hydroelectric power network at Kukës resulted in some of the villages in the region being submerged in the early 1970s, with the building of a new town called Kukësi i Ri (“New Kukës”). The dam located at Fierzë led to the formation of the largest artificial lake in the country at 28 sq. mi. (73 sq. km.), further adding to hydroelectric power. There are also other dams operated by the Albanian Energy Corporation (K.E.S.H.) that help in hydroelectric production, such as the Bovilla Dam. Not only does hydropower help Albania, but it also provides much electricity for Greece, helping reduce Greek carbon emissions.

The Albanian government of Sali Berisha, which came to power in April 1992, took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, as part of a move to involve Albania more with the West. However, it was not until the presidency of Alfred Moisiu that Albania accepted the Kyoto Protocol to the UN Framework Convention on Climate Change, which took place on April 1, 2005, coming into force on June 30, 2005.

Albedo

ALBEDO ORIGINATES FROM a Latin word *albus*, which means white. Albedo is the amount of sunlight (of all wavelengths) that is reflected back from an object or a substance. The more the amount of light reflected back, the brighter the color of the object. A lesser amount of light is reflected back from darker objects. The albedo of an object varies from 0–1. Black objects have zero albedo, while white objects have an albedo of one. Sometimes it is also expressed in terms of percentage, 1–100. An ideal white body thus has an albedo of 100 percent, while an ideal black body has an albedo of zero percent. Some standard amounts of sunlight reflected from certain objects are shown in Table 1.

Usually, albedo is used in the field of astronomy to describe reflective properties of planets, satellites, and asteroids. There are two types of astronomical albedo: normal and bond albedo. Normal albedo is a measure of a surface's brightness when illuminated and observed vertically, while bond albedo is defined as the fraction of total solar light reflected back to space and is a measure of a planet's energy balance. The value of bond is defined over the entire range of wavelengths.

Surface reflectance values vary across the globe, mainly because of variation in presence or absence of snow, ice, or clouds, which increases albedo values in those areas. The presence of ice and snow, for example, on poles and the absence of snow and ice on the equator reflects the difference in albedo values at the poles and equator. It is interesting to note that the reflectance value (and hence the albedo value) changes with the change in dust concentration, thickness of the clouds (or amount of cloud cover) and zenith of sunlight falling in that zone, which is also reflected in seasonal variation in albedo value for the same region. This can be observed best at higher altitudes, where in winter the surface is covered significantly by snow (or ice), thus increasing the surface reflectance values, while in spring, when most of this snow (or ice) melts, the surface (bare soil) absorbs a lot more sunlight, thus decreasing the albedo values for the same place.

Table 1: Reflectivity values of various surfaces

Surface	Details	Albedo
Soil	Dark and wet Light and dry	0.05 0.40
Sand		0.15–0.45
Grass	Long Short	0.16 0.26
Crops		0.18–0.25
Tundra		0.18–0.25
Forests	Deciduous Coniferous	0.15–0.20 0.05–0.15
Water	Small zenith angle Large zenith angle	0.03–0.10 0.10–1.0
Snow	Old Fresh	0.40 0.95
Ice	Sea Glacier	0.30–0.45 0.20–0.40
Clouds	Thick Thin	0.60–0.90 0.30–0.50

Sources: Oke; Ahrens.

Albedo is an important concept in climatology. When albedo is expressed in percentages, snow has an albedo of 90 percent and charcoal has an albedo of 4 percent. When seen from a distance, the ocean surface has a low albedo as do most forests, while desert has one of the higher albedo values.

The role of the concept of albedo in climate change can be seen in the following example: ice reflects back more sun radiation than water; with the snow cover getting smaller and the water in lakes (and seas and oceans) increasing, the amount of sunlight absorbed (and, hence, heat retained) is increasing, leading to further increases in the temperature of lake, sea, and ocean water. On the other hand, if more snow is formed, a cooling cycle starts. The amount of sunlight (radiation) absorbed or reflected back causes fluctuations in temperature, wind, ocean currents, and precipitation. In a way, the hydrological cycle changes with the fluctuations in temperature (which is related to how much evapo-transpiration takes place). Also, the climate system equilibrium is dependent on the balance between the amount of solar radiation absorbed and the amount of terrestrial radiation emitted back to space.

Thus, Earth's albedo values are important in shaping both local and global climate through their radiation budget (difference between the amount of absorbed short-wave radiation and outgoing long-wave radiation). For example, clouds have an impact on the amount of energy (sunlight/radiation) that reaches the Earth's surface. Because cloudiness varies geographically, with the lowest values of cloudiness observed in the subtropics and the highest values observed in mid- to high-latitudes, this has an impact on surface reflectance globally. The variation in surface reflectance determines how much of the sunlight is absorbed or reflected back. Approximately half of the solar energy is absorbed by the Earth's surface, which causes evapo-transpiration and precipitation, and thus, impacts the hydrologic cycle as well.

Table 1 shows albedo values for different landforms and covers. Land areas have a higher albedo value than oceans, mainly due to cloud contributions over land. Human activities such as clearing of forests for farming, human settlements, urbanization, and industrialization have changed the landscape and, in turn, have changed the albedo value of different places. Since forests/trees have a low albedo, removal of forests/trees tends to increase the albedo, thereby cooling the planet. In winter, in snow-covered areas, the albedo of treeless areas is about 10 to 50 percent higher than forested areas (where snow does not cover the trees that readily). Studies have also shown that new forests in tropical or mid-latitude areas tend to be cooler, while new forests in higher latitudes are more neutral or may be warming. Scientists have also focused on planting forests and carbon sequestration and its use in dealing with climate change.

Urbanization, especially, has led to changes in natural albedo values, because many human-built structures absorb light before the light actually reaches the Earth's surface. Studies have shown that cities in the northern part of the world are relatively dark, with an average albedo of 7 percent, which increases a bit during summer, while cities in tropical countries have an average albedo of 12 percent. Some of the reasons for this difference may include different natural environments of cities in tropical regions, such as the presence of darker trees. Also, city buildings are built with different materials, and in warmer regions might be made of light-colored material to keep structures cooler; asphalt (used in the building of roads in urban areas) also changes the albedo value of the surface. Remote-sensing technology is generally used to measure surface reflectance and albedo. Values observed through satellites are fed into mathematical models to get the albedo values.

Algeria

ALGERIA IS A North African country that was occupied by France until 1962. It experienced a major insurgency from 1992 until 2002, resulting in the deaths of up to 160,000 people. It covers a land area of 919,595 sq. mi. (2,381,741 sq. km.) and has a population of 33,333,216 (2007 est.), of which 96 percent live in the north of the country, which covers only 17 percent of the overall area. Approximately 45 percent of the population live in urban areas. Thus, although the population density for the entire country is 26 people per sq.

mi. (13.6 people per sq. km.), the density the north of the country is considerably higher.

Only 3 percent of the country's land is arable, yet in spite of this, intense cultivation, developed by the French, has resulted in Algeria becoming self-sufficient in food. In 1960, the government started a program of soil restoration, and although this ended in 1965, many of the ideas and concepts were incorporated into the program of the Agrarian Revolution of 1971, which helped Algeria retain its self-sufficiency in food in spite of the large rise in population. In Algeria, some 13 percent of land is used for meadows and pastures, with only 2 percent forest, which includes 1.2 million hectares of Aleppo pine and cork oak trees.

The major ecological problem facing the country is continued desertification, with the heavy reliance on petroleum production and exporting resulting in Algeria being reliant on the world consumption of fossil fuels. Much of Algeria's oil production has traditionally been used for airline fuel, tying the country's wealth closely to an industry that has been at the forefront of greenhouse gas pollution.

In fact, carbon dioxide emissions per capita in Algeria have steadily increased, from 3 metric tons in 1990, to 6 metric tons in 1998, and falling slightly to 5.1 metric tons per capita in 2003, nearly 250 percent more than its neighbor Tunisia. This is largely because the oil wealth of Algeria has led to a much higher standard of living, with the widespread use of air conditioning.

In addition, there is heavy private use of cars, with public transport being extremely limited. Buses are operated by the national bus company. The last tramway service in Algeria, located in Algiers, closed in 1959. Although there is a relatively good railway network, it only covers some parts of the country, forcing most businesses to use road haulage on a regular basis. Traditionally, the price of gasoline has been low. In addition, in an attempt to open up the country, the government contributes further to greenhouse gas emissions by subsidizing many internal airfares.

The start of the insurgency in 1992 led to the formation of a High State Committee to run the country. Anxious to continue engagement with the West, it took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. The Algerian government of Abdelaziz Bouteflika ratified the Kyoto Protocol to the UN Framework Convention on Climate Change on April 28, 2004, through a presidential decree, although the official date for the country acceding to the Kyoto Protocol was February 16, 2005; it took effect on May 17, 2005. Since then, the Algerian government has promoted policies to reduce carbon levels, with the rising world temperature likely to increase desertification significantly, although the per capita emissions have risen with the increased use of gaseous fuels in the country.

Alliance of Small Island States

THE ALLIANCE OF Small Island States (AOSIS) is an umbrella lobby and negotiating body representing the interests of low-lying and small island states at the level of the United Nations. AOSIS has played an important role in shaping international climate change policy by ensuring that the concerns of small island developing states are represented on an international level.

Specifically, AOSIS has been a leading advocate for reductions in global greenhouse gas emissions. Operating on an ad hoc basis and primarily through the diplomatic missions of its member countries, AOSIS has no formal charter, no regular budget, and no secretariat organizing the group's work. Decisions are made based on consultation with member states, with major policy decisions made in ambassadorial plenary sessions. The alliance operates on a consensus basis, requiring all members to be in agreement before a decision can be formalized.

AOSIS traces its inception to the 1989 Small State Conference on Sea Level Rise, held in the Maldives, where a proposal to establish an action group to address issues related to small island developing states was presented. AOSIS first met as an official group in 1990 during the Second World Climate Conference. Though the alliance was first formed to address sea level rise and other threats caused by climate change, its focus has broadened over time to include a variety of development or trade-related issues.

With an initial membership of 24 states, as of 2007 AOSIS had grown to a coalition of 43 members and observers from around the world. The members and observers of AOSIS originate from three regions: the Caribbean, the Pacific, and the African, Indian Ocean and South China Seas (AIMS). Many of the alliance's members also belong to the United Nation's Group of 77 and China (G77), an intergovernmental organization composed of developing states within the UN system.

The AOSIS, begun in the vulnerable Maldives, began calling for a 20 percent reduction of CO_2 emissions as early as 1994.

The AOSIS member and observer states are heterogeneous. They vary along geographic, economic, social, linguistic, and political lines; yet despite these differences, they face many of the same development challenges, including their geographic isolation, small political voice, and limited economic clout. However, the characteristic that unites AOSIS states is their potential to be severely affected by climate change and sea-level rise. Though small island states produce relatively minute amounts of carbon dioxide, methane, and other greenhouse gases, these countries will be profoundly affected by climate change, given their low elevations. As many of the countries participating in the alliance are located only a few meters above sea level, climate change and its effect on rising sea levels has historically been one of the key issues addressed by the alliance.

Traditionally, due to their weak political influence, small island states have had difficulty being heard internationally. As a result of their position within the international system, concerns specific to small island and low-lying states have often been lost amongst other international issues. AOSIS seeks to mitigate this situation by providing a collective voice for its members and applying greater pressure to the rest of the international community. As a group, small island states have a greater international voice and are in a better position to effect change than as individual negotiators. As a result, ASOSIS has increased the representation of small island developing states and lowland areas within the UN system.

Historically, AOSIS has favored and pursued legally-binding agreements or hard laws to address issues such as sea-level rise, while the remainder of the international community has generally favored soft law agreements, especially with regards to climate change and the environment more broadly. In this regard, AOSIS has led or been involved with numerous international treaties, conferences, and negotiations.

The Alliance of Small Island States was one of the first groups to submit a draft protocol addressing climate change under the UN Framework Convention on Climate Change. This proposal, submitted in 1994, called for a 20 percent reduction of CO_2 emissions by 2005.

Further, AOSIS's involvement and awareness-raising activities surrounding the negotiations of the Kyoto Protocol facilitated the incorporation of issues of concern to small island development states, such as capacity-building and dispute resolution mechanisms.

Aside from climate change negotiations, AOSIS has also lobbied for greater recognition of the special needs of small island developing states. As a result of AOSIS activities, a program of work on small island developing states was adopted during the UN Conference on Environment and Development in 1992. These activities were increased in 1994 with the adoption of the Barbados Program of Action for the Sustainable Development of Small Island Developing States, which provided a framework for the sustainable development of small island states.

In 2004, at the Small Island Developing States Inter-Regional Meeting, a draft document entitled "Alliance of Small Island States (AOSIS) Strategy for the Further Implementation of the Barbados Program of Action for the Sustainable Development of Small Island States" was presented. This strategy further advanced the cause of small island states on the international stage.

Alliance to Save Energy

ESTABLISHED IN 1977, the Alliance to Save Energy (ASE) is a nonprofit coalition of business, government, environmental, and consumer leaders. The ASE supports energy efficiency as a cost-effective energy resource under existing market conditions and endorses energy-efficiency policies that reduce costs to society and individual consumers, and that limit greenhouse gas emissions and their impact on the global climate. To achieve these results, the ASE undertakes research, educational programs, and policy advocacy; plans and implements energy-efficiency projects; promotes technological innovation and collaboration; and sets up public-private partnerships, both in the United States and in other countries.

The alliance's mission is to promote "energy efficiency worldwide to achieve a healthier economy, a cleaner environment and greater energy security." Its corporate statement describes the ASE as leading "worldwide energy-efficiency initiatives in research, policy advocacy, education, technology deployment, and communications that impact all sectors of the economy." Leaders from academia, business, government, and other fields serve on the board of directors.

HISTORY

Republican Senator Charles Percy and Democratic Senator, former Vice President, and presidential nominee Hubert Humphrey founded the ASE in 1977. In the same year, U.S. President Jimmy Carter also established the Department of Energy. Since its founding, the ASE has been a bipartisan endeavor. It had to face the energy crisis of the late 1970s, when the United States recognized its oil dependency and the economic importance of energy. In those years, the Iranian Revolution generated a second, severe oil crisis worldwide (the first had occurred in 1973 with the Organization of the Petroleum Exporting Countries [OPEC] oil embargo). The crisis caused the doubling of oil prices. The Three Mile Island accident exposed the risks of nuclear energy. The ASE started its first major campaign in 1978, mounting a national television public-service advertising campaign that used Gregory Peck to promote energy conservation. The slogan of the campaign was "Don't Blow It America."

During Ronald Reagan's presidency, characterized by drastic reductions in federal efficiency activities, the alliance restructured its organization by initiating new research programs and pilot demonstrations that outlined innovative methods to promote energy efficiency in private markets. In the first half of the 1980s, the ASE came to the forefront in national debates on energy efficiency. In 1982, it promoted the adoption of utility demand-side management, designing the first methodology to evaluate efficiency as an energy resource for Arkansas Power and Light. Two years later, the ASE began to explore the use of energy-saving performance contracting, producing workbooks and hosting seminars on innovative, private sector financing techniques for energy-efficiency projects. The alliance also promoted legislation to allow governors to shift fuel assistance funds into energy-efficiency upgrades in low-income homes. Encouraged by then-alliance chairman Senator John Heinz, this piece of legislation devoted nearly $2.5 billion into energy-efficiency investments.

The nuclear accident at Chernobyl in 1986 renewed interest in energy saving at a time when the collapse of oil prices had given a false impression of abundance. The following year, President Reagan first vetoed, but then signed, the National Appliance Energy Conservation Act, fixing federal energy-efficiency standards for many commonly used appliances. The alliance began to arrange the energy-efficiency industry so that its voice could be heard on national energy policy issues.

The 1990s opened with the Gulf War, which again called public attention to energy issues. In 1991, the alliance indicted the federal government's poor performance in reducing energy use in the government's own facilities. The ASE calculated that the federal government wasted more than $1 billion annually of taxpayers' money. The ASE worked closely with the energy-efficiency industry to propose legislative responses to the problem. Thanks to the lobbying of the ASE and other associations for energy efficiency, President George W. Bush signed the comprehensive Energy Policy Act, including major terms to improve federal energy management, building codes, equipment standards, and home energy ratings.

Beginning in 1993, the alliance played a major role in the creation of the Business Council for Sustainable Energy, the Building Codes Assistance Project, the Export Council for Energy Efficiency, the Northwest Energy Efficiency Council, and the Hungarian Energy Consumers Association. Recognizing that the need for energy efficiency was becoming a global emergency, the alliance also launched an international program resulting in projects in Russia, Ukraine, Central Europe, Mexico, Ghana, and China. As the U.S. dependence on imported oil reached a new record in 1994, the ASE started to cooperate more closely with the energy-efficiency industry to undertake educational and market development export missions to Mexico, then to Portugal and China. New business deals created American jobs while promoting a cleaner global environment.

RAISING PUBLIC AWARENESS

In 1995, the ASE successfully blocked the attempts of the new Congress to eliminate federal efforts at energy efficiency. Faithful to its original public education role, the ASE began a new television and radio public service campaign to increase public awareness of the importance of energy efficiency in saving the Earth, jobs, and money. In 1996, the expansion of the alliance beyond American borders became a reality as the organization opened offices in Kaliningrad, Russia, followed by offices in Ukraine and Hungary (1997).

In the late 1990s, the ASE's public outreach campaign achieved an important series of successes, including three animated television spots that garnered $2.2 million in broadcast time in 49 states; four radio spots airing in 45 states; the Power$mart consumer booklet; an animated, interactive consumer website; and a new educator website with free energy lesson plans. The campaign earned the ASE a National Energy Resources Organization award for public education.

The ASE's 1999 report *Leading by Example: Improving Energy Productivity in Federal Government Facilities* was instrumental in persuading President Bill Clinton to issue an executive order calling for the federal government to reduce its energy use 35 percent by 2010, compared to 1985 levels. The order also pledged the government to cut its greenhouse gas emissions to 30 percent below 1990 levels by 2010. Greenhouse gas emissions and global warming have become the focus of several of the ASE's initiatives, including the organization of the First Climate Summit in Washington, D.C., in 2006.

Alternative Energy, Ethanol

WITH INCREASING UNCERTAINTY in the global fuel market, the search for gasoline substitutes is becoming more and more important. One viable option is using ethanol as an alternative fuel, unlike fossil fuels, it is a renewable energy source. There are many chemical compounds that make up ethanol; the molecules contain a hydroxyl group, and are bonded to a Carbon atom. Ethanol that is made from cellulosic biomass instead of the usual starch crops is known as Bioethanol. Ethanol is in a liquid state, and is clear and colorless. As a diluted aqueous solution, it has a somewhat sweet flavor, but in more concentrated solutions, it has a burning taste.

The shift toward ethanol-based fuel has positive social, economic, and environmental effects. The combination of better efficiency with cleaner emissions yields makes it a promising future source of fuel. For transportation, ethanol can be blended with petroleum-based gasoline or can be used on its own. It has a chemical component that consists of ethyl alcohol, grain alcohol, and EtOH; it is also ethane with a hydrogen molecule replaced by a hydroxyl radical. When ethanol alone is used as fuel, it is mixed with a small amount of water, usually 5 percent of the total mixture.

SOURCES AND PRODUCTION PROCESSES

Ethanol is derived from several sources. Food products such as corn, wheat, sugar cane, and rice are all viable candidates for ethanol production. Ethanol is produced through the fermentation of the sugars supplied from these foods. Materials used in ethanol production are wood chips, yard waste, crop residues, and solid animal waste. It can be made from just about any feedstock that has ample amounts of sugar, or materials that can be converted to sugar, such as sugar beets, sugar cane, or organic materials containing high levels of sugar such as starch and cellulose. Corn is widely used to produce ethanol. There are certain elements that are not as easily converted to sugar, such as trees and grasses, which are made of cellulose. Ethanol is also made from a wet-milling process. Many larger ethanol producers use this process, which also yields products such as high-fructose corn sweetener. These other materials are viewed as potential sources of low-cost ethanol production, because corn may not always be practical for ethanol because land needed to grow corn is needed for food and feed corn.

There are several ways to produce ethanol. One method is to convert lignocellulosic materials to ethanol. This method involves two processes. The first step is the hydrolysis of cellulose in the lignocellulosic materials to fermentable reducing sugars. After hydrolysis comes the fermentation of the sugars to ethanol. Another mode of production involves cereal grains. The grains are milled, which produces amylase and heat. The results go through a gelatinization process, resulting in amyloglucosidase and yeast. Next, saccharification and fermentation are conducted, and the product is heated, and then distilled. This produces ethanol, as well as stillage. When heat is added to the stillage, dry grain is produced.

Ethanol can be manufactured from a variety of different naturally-growing carbon-based organisms. For instance, in India, sugar cane molasses, a byproduct of the sugar industry, contains 45–50 percent fermentable sugars, allowing India to efficiently produce a significant amount of ethanol. Fermentation represents an ideal way to produce ethanol, as it is easy to ferment these sugars, and quite cost effective.

USES AND EFFECTS

Ethanol is used mainly as a fuel additive, replacing methyl tertiary butyl ether (MTBE). Thailand's government has passed regulations to reduce MTBE emissions, and they are looking to ethanol for the answer. A 10 percent ethanol fuel mixed with gas, coined *gasohol*, is currently used, decreasing the amount of toxic volatile organic compound emissions. Diesel engines can use a 15 percent mixture of ethanol and gasoline, resulting in a visible reduction in fumes.

It is not feasible to completely replace gasoline with ethanol. It costs more for the United States to produce ethanol than gasoline. Turning to ethanol as a substitute, and possibly a primary fuel, has the potential to positively affect the environment, however. Ethanol burns cleaner than gas, releasing fewer volatile organic compounds into the atmosphere. Ethanol also runs up to one-third more efficiently than gasoline, while polluting less. Pure ethanol fuel (95 percent ethanol, 5 percent water) has numerous benefits because of low pressure and the reduced emission of ethanol into the atmosphere, along with clean burning characteristics. Although there is some environmental benefit from using ethanol, there are also some environmental concerns, because ethanol is listed as a carcinogen for humans. The use of ethanol can lead the raising of peroxyacl nitrates (PAN), which is extremely toxic for plants. Ethanol combustion emits formaldehyde, also dangerous to humans. Health issues related to this include eye irritation, respiratory complaints, and nervous disorders.

The large-scale production of ethanol would have other effects. Because cars will need specialized parts, workers will be required to make and install them, Ethanol could create jobs in rural areas. There could also be a large swing from oil to agriculture if ethanol becomes a highly-sought resource. Different forms of agriculture may be developed to handle the demand for corn to produce ethanol. One such form is called biotech; however, its corn has not been proven healthy. There are limits to its production, also, as only a few companies comprise the entire ethanol business, and only one company in California holds the patent.

Another agricultural issue deals with the land requirements for corn production. One study estimated that almost one-fourth of the United States would need to be used to produce enough ethanol to replace gasoline. This raises issues of converting land from other uses to that of corn production. While the change from gasoline to ethanol is partially environmentally stimulated, the destruction of other environmental sites such as forests seems counter-productive.

Besides Thailand, many countries around the world are using ethanol in combination with gasoline. In the United States, Michigan produces and consumes the most ethanol. Many states are adopting a requirement that ethanol to be used as a fuel additive in place of MTBE. Brazil is a large producer and consumer of ethanol. Ethanol use in the United States is 10 percent, and 22 percent in Brazil.

Brazil and the United States intend to create an ethanol market to meet the needs of citizens. Last year, the United States produced 5.3 billion gallons of ethanol and imported another 720 million gallons, almost two-thirds of it from Brazil. Both the United States and Brazil have begun spreading agriculture and ethanol refinement technology to parts of the Caribbean and Central America to enhance sugar cane production, which, in turn, will enhance the production of ethanol. There are also many other sources of ethanol throughout the world; the top five areas are the United States, Brazil, China, France, and India. The United States not only imports from Brazil, but also from Jamaica, El Salvador, China, and Costa Rica. By 2010, it is estimated that Brazil will provide key ethanol resources with at least 77 more ethanol plants; this will help boost the production of ethanol by one-third, for a total of 7 billion gallons a year.

BENEFITS AND DRAWBACKS

Despite its advantages over MTBE, ethanol does have limitations. It has a lower BTU than gasoline, making it less powerful. It costs more to produce a gallon of ethanol fuel than it does to produce a gallon of gasoline. Ethanol is also corrosive to some metals, gaskets, and seals, and ethanol air mixtures can be explosive in the ambient temperature range. Land space is also a limiting factor, as large amounts of land are required for corn production.

Also, the substitution of ethanol has been noted to cause negative impacts on climate change. Despite the fact that it does not emit carbon dioxide into the atmosphere, it does release other toxins, and it does not reduce air pollution. Brazil's air quality worsened during the big ethanol push in the 1970s. Compared to gasoline, ethanol produces less benzene and butadiene when burned, but more acetaldehyde and formaldehyde.

Driving the strong political backing for ethanol are energy security concerns, agricultural interests, and environmentalists. In the future, a drive for better efficiency could force ethanol to compete with electric cars and fuel cells, as well as gasoline. The trend for fuel seems to be shifting toward ethanol. In India, the blend of ethanol in gas is expected to double in the next few years. Brazil, because of their efficient sugar cane production, already produces ethanol for about 40 percent less than gasoline. More testing is needed on the health and environmental issues surrounding ethanol. As testing increases, cheaper ways of producing ethanol will be implemented. Engines will likely become more efficient, and more cars are likely to come with ethanol-ready parts.

Ethanol also enhances the performance and maintenance of many old and new cars. Since ethanol burns at cooler temperatures than gasoline, it does not burn valves. It may loosen noxious wastes and residues, usually in older cars, which have been deposited by previous gasoline fuels. However, changing the fuel filter will correct the problem and increase the performance of the car. Ethanol is used in aircraft as well, because it offers a low volatility, high-octane fuel to replace gasoline. Unlike many other fuel types, such as regular unleaded, unleaded plus, diesel, and premium, it can be used in any type of engine. Ethanol decreases the amount of water accumulated in an engine while providing better engine longevity. However, many people question whether ethanol provides good performance if used without gas line antifreeze.

Ethanol appears to be viable as an alternative fuel. Once solutions are found to its pollutant problems, ethanol may become even more desirable. It appears to be better for the environment than gasoline. It may create jobs, and free the United States from dependence on foreign oil. An electric hybrid using ethanol fuel may be the future of the automobile industry. Ethanol as an alternative fuel is a good, currently available solution to the problem of diminishing fossil fuel supplies.

Alternative Energy, Overview

WE USE ENERGY to grow our food, power our vehicles, and run the appliances in our homes, schools, and workplaces. Over the past two centuries, industrial societies have used inexpensive, and readily available, sources of energy to fuel urbanization and economic development. This growth has created, at least in some countries, the highest level of human development in the history of civilization. A question to ponder, though, is if this level of development can be sustained indefinitely. Many of the great civilizations of the past declined, at least in part, due to environmental change caused by human activities.

Starting in the late 18th century with the Industrial Revolution, the global economy has increasingly relied on fossil fuels such as coal, petroleum, and natural gas. In the future, the global economy will run out of these fuels. In the meantime, some scientists argue that dependence on fossil fuels has contributed to global warming. The Intergovernmental Panel on Climate Change (IPCC), founded in 1988 by the World Meteorological Organization and the United Nations Environment Programme, argues that measurable global warming has occurred, and that humans are at least partially to blame.

Some scientists and commentators from across the political spectrum downplay the significance of global warming—especially the role humans might play in climate change. However, even famous skeptics such as author Michael Crichton, or contrarian scientist Bjørn Lomborg, agree that the Earth is getting warmer, but do not believe that humans are to blame. The heavy reliance on fossil fuels raises several questions. First, how long into the future will these resources last? Second, to what extent do fossil fuels contribute to climate change? Third, are there alternative fuels that are less likely to influence the climate and that will last into the foreseeable future? Alternative energy strategies based on wind, biomass, geothermal, solar and photovoltaics (PV), hydrogen fuel cells, and improved fuel efficiencies could ameliorate climate change.

ALTERNATIVES TO FOSSIL FUELS

The phrase *Alternative energy* implies that these energy sources are alternatives to nuclear and traditional fossil fuels such as coal, petroleum, or natural gas. Alternative energy, therefore, is a catchall category of energy sources that proponents argue can replace traditional fossil fuels in daily life, while causing less harm to the environment.

Alternative energy is increasingly important for at least three reasons. First, fossil fuels are nonrenewable; eventually, they will be exhausted. The United States is already witnessing a decline in its petroleum production. In 1950, the United States was largely self-sufficient in fossil fuels, producing 32,562,667 billion Btus of energy. At the same time, Americans consumed 31,631,956 billion Btus of fossil fuels. The United States therefore enjoyed a slight fossil fuel surplus. Now, fossil fuel consumption in the United States far outstrips production. In 2006, the United States produced 56,032,329 billion Btus of fossil fuels, but consumed 84,760,343 billion Btus. Advocates of alternative energy argue that alternative energy sources need to be developed now, so that when fossil fuels are gone, there will be other dependable energy resources.

Second, many advocates of alternative energy argue that as oil production declines, Americans and others around the world will become increasingly reliant on foreign sources of oil. This will require heavy investments in the military to ensure that fossil fuels continue to flow, especially from politically unstable regions of the world such as the Middle East.

Third, alternative energy has received increased attention because of a scientific consensus that the average temperature of the planet is rising. Scientists argue that a leading cause of global warming is the emission of so-called greenhouse gases such as carbon dioxide, methane, various nitrous oxides, hydrofluorocarbons, sulfur oxides, and particulate matter. These gases come from the combustion of fossil fuels in vehicles, in the production of electricity from coal or natural gas, and in many other processes.

Carbon dioxide and other greenhouse gases are not inherently bad. In fact, these gases naturally occur in the atmosphere and help moderate the global climate to support living organisms, including humans. In this process, the Earth's surface is first warmed directly during the day by incoming solar radiation. At night, this energy is radiated back into the atmosphere as latent heat energy, some of which is absorbed by atmospheric gases such as carbon dioxide. The problem, say many scientists, is that the growing use of fossil fuels is increasing the concentrations of carbon dioxide, methane, and other gases, which, in turn, increase the capacity of the atmosphere to absorb latent heat energy. The National Aeronautical and Space Administration (NASA) notes that the atmospheric concentration of carbon dioxide has increased 35 percent 1750–2007. At the same time, the Earth's average temperature has increased between 1.1 degrees F to 1.6 degrees F (0.6 degrees C to 0.9 degrees C) and that warming continues at an accelerating rate. The only way to slow global warming is to reduce greenhouse gases. This means that the use of fossil fuels will have to be reduced.

Reducing the reliance on fossil fuels will not be easy. The United States relies on fossil fuels for 85 percent of its energy needs. Nuclear energy accounts for another 8 percent. Hence, only 7 percent of the energy consumed in the United States comes from renewable sources such as biomass, hydroelectric, wind, or solar power. Another way to look at the heavy reliance on fossil fuels is to see the amount of energy consumed in absolute terms—data show that Americans consumed more fossil fuels in 2006 than they did in 2002. However, renewable energy is playing a slightly larger role in the U.S. energy portfolio.

DEFINITIONS

To maintain the current standard of living in the industrial world, and promote human and economic development in the less prosperous regions of the world, alternative forms of energy must be found. Some scientists use the phrases *alternative energy* and *renewable energy* interchangeably. International agencies such as the IPCC and World Bank, as well as government agencies such as the U.S. Department of Energy

A hyrdoelectric plant in Tennessee. Once the water level reaches a high enough level, a gate is opened in the dam, allowing gravity to carry water down toward the generator. The force of the water falling spins the turbine and generator, creating electricity.

(DOE) or the U.S. Environmental Protection Agency (EPA), offer separate, but somewhat overlapping definitions for alternative versus renewable energy.

The word *alternative* can be seen as somehow marginalizing the importance of the concepts it embodies. However, an argument can be made for its use because of the need for a clear distinction between the various forms of energy. In the future, alternative energy may, in fact, become the dominant form of energy used. Maybe a better term is *sustainable energy,* to focus on its potentially mainstream status and renewable nature. However, for the time being, these energy sources represent only a small fraction of the energy used.

USE OF ALTERNATIVES

The World Bank definition for alternative versus renewable energy differs. It uses a hierarchical strategy to categorize energy forms. Alternative energy represents the broadest category of energies that are not based on fossil fuels or nuclear energy. These energy forms are thought to produce fewer greenhouse gases than the fossil fuels they are intended to replace. Within this broad category, there are two subcategories of energy sources or strategies for greenhouse gas reduction: renewable energy and improved energy efficiencies.

Renewable energies can be further sorted into energies used to generate electricity and energies used for transportation. While there is certainly overlap between these two categories (for example, solar energy can generate electricity for distributed use in homes and it can also be used to power vehicles), it makes sense to examine the efficacy of renewable energies by starting with these two categories.

Electricity is produced by finding a way to convert kinetic energy (energy associated with movement) into electrical energy. A generator typically does this. A generator consists of a rotating magnet, called a rotor, and a stationary coil of copper wires known as a stator. By turning the rotor continually past the stator, an electrical current is generated. The challenge is to find a source of energy to move the rotor. In simplified form, a rotor is attached to some type of turbine or propeller that is forced to turn by some external force, usually water, steam, or air. Fossil fuels such as coal, natural gas, and oil, and nuclear fission can be used to generate heat. This heat is used to convert water into steam within a confined space. As steam is created, it expands, creating pressure. This pressure can be directed at a turbine, and when released in a controlled manner, can cause the turbine to turn.

The problem with using fossil fuels for generating electricity is that the combustion of fossil fuels to create the heat needed to rotate turbines creates carbon dioxide and other greenhouse gases. Furthermore, these forms of energy are nonrenewable, and the extraction of fossil fuels through mining and oil drilling itself requires considerable amounts of fossil fuels. The process also transforms the landscape in profoundly destructive ways.

HYDROELECTRICITY

The major renewable forms of energy include hydroelectric, solar, and wind power. These energies produce electricity, but do not use the combustion of fuels to spin a turbine. For example, hydroelectricity works by converting potential energy into kinetic energy. A hydroelectric generating station uses a dam on a river to create a reservoir. As the reservoir fills up with water behind the dam, the water level rises above the turbine, which is located on the downstream side of the dam. There is a large pipe called a penstock, which connects the reservoir above to the turbine below. Once the water level reaches a high enough level, a gate is opened in the dam, allowing gravity to carry water down the penstock toward the generator. The force of the water falling from the height of the reservoir spins the turbine and generator, creating electricity.

A similar mechanism operates to generate electricity from tidal power. In places where there are large tides, such as the Bay of Fundy in Canada, the rapid flow of incoming and outgoing tides can be used to spin a turbine. Annapolis, Nova Scotia, hosts an operating example of a tidal power plant generating electricity from tides that fluctuate 40 or more ft. between low and high tide. The tidal plant operates using a reversible turbine that generates electricity as the tide rises. The turbine then reverses to generate power as the tide goes back out.

From a global warming perspective, hydroelectricity and tidal power are low-impact ways to generate electricity. However, they have limitations. They only work in certain geographic and climatic areas. Hydroelectricity can only be generated where there is sufficient precipitation to keep the reservoirs full. It also works better in areas of rugged topography where rivers flow through steep valleys. This makes the construction of dams and reservoirs more cost-effective. Reservoirs also cause considerable damage, as land previously occupied by towns, or used for agriculture, is flooded. This is a particularly sensitive topic in countries such as India and China that have rapidly-expanding energy needs, but also have large populations that will be displaced by any large-scale hydroelectric project.

Tidal power may be even more restricted in the places where it can work economically. In many parts of the world, daily tidal variations may be only a few feet, which is too small to merit large-scale investments in tidal power. Furthermore, the tidal power plants require that dams or so-called “barrages” be built across estuaries in order to channel the force of the tides through the generator. Barriers of this sort can disrupt ocean ecosystems and hinder boat navigation.

WIND POWER

Electricity generated by wind power relies on air moving past a propeller to spin a turbine. Wind is created as a result of the differential heating of the earth’s surface of the sun. Air masses move from areas of high atmospheric pressure to low atmosphere pressure. Wind energy creates very few greenhouse gases and will exist as long as the sun shines and winds blow. There are challenges to implementing wind energy, though. Wind energy, like other forms of renewable energy, operates effectively only in certain geographic areas and climates. Wind speeds and direction can vary hourly, daily, and seasonally. For example, winds are typically stronger during the day than at night. In temperate climates, the wind tends to be stronger during the winter than during the summer. Hence, a wind turbine only makes economic sense if, on average, the wind blows at a certain minimum average velocity, usually at least 10 to 12 mi. (16 to 10 km.) per hour for much of the calendar year. Winds lower than that cannot move the large propellers to spin the turbine.

A wind turbine also needs a relatively open space, so that trees or buildings do not affect wind speeds. Critics of wind farms also argue that wind turbines can harm migrating birds and bats, are an aesthetic blight on the landscape, and cause irritating "flicker" as sunlight reflects off of the rotating propeller blades.

SOLAR POWER

Solar power can reduce greenhouse gases in several ways. First, passive solar energy can be used for heating. Dark surfaces absorb energy from the sun better than light surfaces. This principle can be used to heat water or warm a house. Water stored in a dark container or cistern on the roof of a house can become very hot. This water can be used for showers, laundry, or cleaning. Similarly, a dark exterior on the roof or walls of a house can help warm the house on a cold winter day. This helps reduce greenhouse gases, because like all renewable energies, its use offsets the use of fossil fuels.

Second, active solar energy can generate electricity through the use of photovoltaic cells. This technology relies on semiconductors to take direct light from the sun and convert it into electricity. This form of energy production is renewable.

However, it has several limitations, including the daily fluctuations in light, as well as regional variations in the amount of annual sunshine received. Solar energy is more economical in the American southwest, where sunshine is abundant. It is less viable in areas that have more cloud cover. However, solar energy is viable in most parts of tropical and mid-latitude regions.

Geothermal energy can be used to offset fossil fuels in several ways. First, the energy can be used to heat and cool buildings. Typically, a residential geothermal system relies on the fact that the Earth's temperate remains constant at about 55 degrees F (12.7 degrees C) at about 12 ft. (3.6 m.) below the surface. During the summer, the heat from the house is drawn down into the ground through a closed system, where it dissipates into the cool ground. During the winter, the relatively warm temperature of the ground is brought to the surface and used to help heat the house on a cold day.

HYDROGEN AND BIOMASS

Many researchers tout hydrogen as the ultimate renewable energy source, because it is the most common element in our universe. Hydrogen-based fuel cells operate by reacting pure hydrogen with oxygen to generate electricity. Energy is released that is then converted into electricity, with water as the only by-product. Unfortunately, pure hydrogen must be created through the hydrolysis of water. This is an expensive process that relies largely on conventional energy sources. Hence, there are significant technological barriers to the widespread adoption of hydrogen power.

Biomass, or plant material, can also be a significant source of energy for the production of electricity and for transportation. The DOE identifies three biomass sources: wood, waste, and biofuels. Wood can be cut and burned directly for home heating. The by-products of processing wood into paper products can also be co-fired with fossil fuels to make coal-fired electrical plants burn cleaner. Combustible biomass can also come from municipal solid waste, industrial waste, and landfill gas. Biomass can be used to create alcohol fuels such as ethanol, or diesel fuels, such as soy diesel. Advocates of these fuels, used largely for transportation, argue that their production and use creates fewer greenhouse gases than conventional fossil fuels.

Critics argue that biofuels must still be burned and therefore still generate greenhouse gases. They also argue that the increased production of corn and soybeans for ethanol or soy diesel will increase food prices, while degrading soil quality. This will require more use of petroleum-based fertilizers. Finally, skeptics suggest that biofuels are not a viable alternative because the energy it takes to produce ethanol is more than the energy contained in the fuel.

COST OF ALTERNATIVES

The high cost of production and related technological barriers affect all alternative energy sources. A comparison of production costs shows that fossil fuels are simply cheaper to produce than alternative fuels, which often need government subsidies to make them economically feasible. For example, it costs approximately 4.0 cents per kilowatt hour (¢/

kWh) and around 5.0 ¢/kWh to produce electricity from natural gas and coal, respectively. Electricity from large-scale hydroelectric generators can cost between 5.0 and 12.0 ¢/kWh. Electricity from nuclear fission can cost between 11.0 and 15.0 ¢/kWh.

Great technological strides have been made in the advance of renewable fuels. Electricity from wind, which cost over 40.0 ¢/kWh in 1980, now costs in the range of 4.0 to 6.0 ¢/kWh. However, that makes it barely competitive with coal. Electricity from solar photovoltaics still costs almost 20.0 ¢/kWh, while that from hydrogen-powered fuel cells costs $4.00 per kWh. That is why some scientists suggest that while research is done over the long term to reduce the costs of producing energy from wind, solar, biomass, or hydrogen, the focus should be on increasing the efficiency of current systems. Environmentalist Amory Lovins argues that existing technologies can help reduce energy needs. Examples include more fuel-efficient vehicles, homes with better insulation to reduce heating and cooling costs, and more efficient appliances. The refrigerator exemplifies this progress in energy efficiency. In 1980, a 20 cu. ft. refrigerator used about 1,300 kWh of electricity per year. In 2001, a comparably sized unit used 500 kWh of electricity per year.

Alternative energy can be an important part of a strategy to reduce global warming if the commitment to energy efficiency can be increased in the short term, with continued research on alternative energy technologies in the long term. It may also mean combining energy types to maximize the amount of work that can be done. Increasing investments by the public and private sector in research and development can help make this happen.

Alternative Energy, Solar

SOLAR ENERGY REFERS to forms of energy emitted by the sun, including light, radio waves, and x-rays. Accounting for 99.8 percent of the mass in our solar system, the sun is a self-sustaining nuclear fusion reaction by which hydrogen is converted to helium. Every second, the sun converts over 4 million metric tons of matter into solar energy. This matter is converted and released from the sun in the form of radiation waves that travel through the void of space and eventually reach earth. The radiant energy that eventually reaches the earth's surface is estimated around 1,000 watts per sq. m. The sun is similar to a fusion reactor that emits 3,800 million, million, million, million watts of energy each second, which is 20,000 times the energy requirement of the world.

Solar power, as an alternative fuel, involves transforming some of the sun's massive thermal energy into electricity. Individuals driven by environmental and other concerns encourage the implementation of policies that require the use of solar and other renewable energies. Solar energy can be broadly classified in two categories on the basis of its use: active and passive.

ACTIVE SOLAR ENERGY

Active solar energy can be converted to electricity and used directly, as in the case of solar heating applications and solar photovoltaic (PV) applications. In a PV cell, sunlight strikes a layer of semiconductors, which in turn creates an electrical current. By 2005, this proven technology was being used to provide heat and power to well over 650,000 homes, primarily in the United States, Germany, and Japan. Electricity can be produced from solar power by placing solar panels on roofs. These panels consist of PV cells that can convert sunlight directly into electricity. Moreover, electricity produced as solar power during the day may be stored in batteries for use at night.

Another method of electric generation employs the use of turbines. In turbines, the sun's heat can be used to convert water into steam and then this steam is used to run turbines. The turbines, in turn, run generators, which produce electricity. Solar PV applications have found many uses in rural areas for multiple activities besides home lighting. Remote villages deprived of grid power can be easily powered using solar photovoltaic technology. The economics of rural electrification can be attractive considering the high cost of power transmission and erratic power supply in rural areas. From portable indoor uses such as calculators, to generating plants alongside railways and roads, PVs are adaptable. They easily function across most areas in both the Northern and Southern Hemispheres.

PASSIVE SOLAR ENERGY

Passive solar thermal technology is employed for collecting and converting the sun's energy to heating applications such as water and air heating, cooking and drying, steam generation, and distillation. To accomplish this, a solar thermal collector device absorbs and stores heat. Solar thermal technology requires good heat conducting materials, insulation, and reflectors. Solar geysers, solar concentrators, and solar cookers are some examples of devices based on solar thermal technology.

Also, solar energy can be put into use by incorporating appropriate designs in buildings to maximize utilization of solar energy for various purposes such as lighting, air conditioning, and water and space heating/cooling and thereby reduce external energy inputs. PV cells require high exposure to direct sunlight. To assure maximum exposure to the sun throughout the day, a phyrheliometer is used to calculate how much sun exposure a location experiences. This information is useful in determining whether or not a specific location is suitable for solar energy, as well as what direction the cells should face. In many cases, these cells are placed on rooftops.

USE AND DEVELOPMENT

Increasingly, PV cells are being added to residential and commercial structures. This approach to using solar energy is modular, as panels can be added to any existing structure with sufficient exposure to sunlight. In addition, photovoltaic cells are able to tie directly into the existing electrical grid, thus avoiding the need to build additional transmission lines. In cases where the solar energy provides more energy than any one location can use, it can actually supplement the electrical grid with additional power to be used elsewhere. In such cases, the electric company is required to pay the individual the same amount they would charge per unit of electricity. Therefore, rather than being billed for using electricity from the grid, the individual could actually receive a check from the electric company for any power that was sold to the grid. This helps offset the initial cost of installing solar cells.

Different groups perceive the issue of solar energy differently. Advocates see solar energy simply as another fuel to plug into the existing energy system and do not feel that it carries any social or political relevance. They argue that the removal of conventional impediments to the diffusion of solar power, such as financing or getting high-quality installation on new devices, leads to substantial growth in the solar energy market. Solar advocates tout the technology as environmentally benign, and believe it will be an important part of the solution to the structural problem of energy-related pollution. Other groups maintain that there are too many barriers for solar energy to be a large-scale option in the immediate future.

Economic barriers have stood in the way of using solar energy because of the high price of solar equipment. However, technological advances and economies of scale are making PV electricity production steadily more cost-effective. The market for solar power is growing, primarily overseas, where two billion people, most in developing countries, still live without electricity. In countries where energy from the sun is abundant, a small PV panel on a house can create enough power for two light bulbs, a television, and a radio. With installation costs of

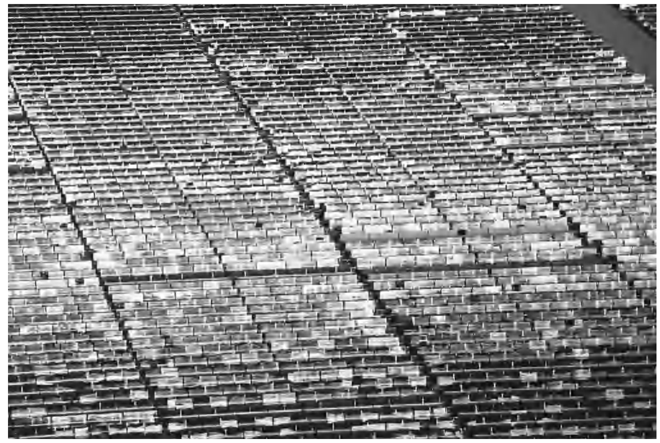
$400–$600 per house and low maintenance, these solar panels already appoint thousands of rooftops in India, Indonesia, Mexico, and Brazil. In addition to residential buildings, many commercial buildings are now starting to add photovoltaic cells, as well. Large areas such as rooftops of office buildings are ideal places for these cells, as they are otherwise wasted space. They are also high enough to avoid any obstructions that might block exposure to the sun.

GROWTH OF A NEW INDUSTRY

The solar PV industry grew at an annual rate of over 20 percent worldwide in the past decade, and 40 percent from 2007–07, reaching an annual PV module production of 100 megawatts (MW) in the United States and about 400 MW globally. Worldwide, in 2001, photovoltaics were a $2 billion business. In the United States alone, the industry employs about 20,000 people in high-value, high-tech jobs. In the swimming pool sector of solar thermal, according to the Florida Solar Energy Center, the equivalent of 594 MW of power was installed last year in the United States. For solar hot-water heating for general home use, one utility, Hawaii Electric, has installed systems that produce approximately 60 MW per year, and it continues to add around 12 MW of capacity annually.

The "power tower" in California uses a field of mirrors focusing on a boiler atop a tower. A working fluid is heated, which in turn makes steam to drive a turbine. The hot fluid also may be stored to generate electricity at night. A simple but promising idea is the solar pond, developed in Israel. If the bottom layer of water is heated by the sun and then prevented from rising, then heat can reach usable temperatures and be stored in the pond. Electricity can be generated, or, for that matter, any low-temperature heat demand can be met.

Although geography, daylight, and weather present major barriers to the use of solar power, high cost is still its biggest impediment. Most new technologies need initial research and development support to get established, which represents a major institutional hurdle, especially because governments are the most probable source of initial support. There are likely to be disagreements about which projects should be funded and over how projects should be developed. In addition, there may be resistance to new developments from those with vested interests in the existing range of technologies, and a lack of commitment from decision-makers to press ahead with what may seem to be risky and long-term development programs.



Fields of solar mirrors in California collect some of the 100 MW of solar power produced in the United States every year.

The growing energy demand is mounting pressure on conventional energy supplies, such as oil, coal, and natural gas. By 2025, worldwide electricity use is projected to increase. Solar energy could provide a large percentage of the future electricity used. Solar energy is expected to form a significant share of the U.S. energy market by 2020, and by 2030 is expected to meet 10 percent of U.S. peak energy demand. For this statement to become a reality, millions of homeowners and businesses would have to switch to solar energy. This is possible only if solar power becomes affordable.

It is expected that some of the technologies, such as roof-mounted systems, solar dishes, and concentrating PVs, will also play a role in America's energy future. Experts predict that the main use for solar energy in the future will be for space heating. Currently, houses are being designed to make maximum use of solar heat so that the needs for space heating could be met almost entirely by solar energy in populated regions of the world as far north as Boston.

ENVIRONMENTAL AND ECONOMIC IMPACTS

Perhaps the greatest benefit of using solar energy is the environmental impact. The beauty of solar energy is that it simply uses existing energy. No hydrocarbons need to be burned in order to release the energy required for doing other forms of work. Energy from the sun is simply collected and used. In essence, the sun is doing all of the work that a conventional nuclear reactor would be doing on Earth. However, the sun takes care of this process without fuel or maintenance. There are costs and environmental impacts associated with manufacturing PV cells to harness this energy, though. Initially, these cells would need to be manufactured in facilities powered by a conventional source of energy, such as coal or nuclear power.

Although progress is being made in the field of solar energy, one of the major concerns holding solar energy back is the high cost. Currently, solar cells must be viewed as an investment in order to justify the initial cost of the cells, and the installation. However, the government does offer incentives at both the state and federal level for those interested in adding solar cells to homes.

The economic impact of solar energy is huge. Because solar energy is dispersed more evenly throughout the globe than fossil fuels, no one country or government would be able to control it. This would ultimately lead to a more stable infrastructure for countries whose energy needs are dependent on foreign nations. Solar energy would not only alleviate the pressures of oil dependence, it would also bring seemingly free energy to developing regions of the world, where conventional forms of energy are either too expensive or impractical. For instance, there are regions of the world that do not have any sort of power grid. For places such as these, the modular design of solar cells allows for the construction of cells on a case-by-case basis.

Solar energy does have its limits. While the distribution of solar energy is much more homogeneous than that of fossil fuels, there are portions of the world that experience more or less solar exposure. For instance, during winter, the sun does not shine for months at a time at the North pole. For the rest of the world, there is the dilemma of night. Solar energy alone cannot provide power 24 hours a day. To overcome this barrier, batteries are required to store the energy overnight until they can be recharged the next day. Also, because PV cells are constantly exposed to the elements, they are susceptible to damage from high winds or hail storms. However, solar energy will continue to gain momentum as a practical source of energy in the coming decades. As more and more manufacturing facilities are built to handle the demand, the cost of such cells will be reduced, and solar energy will become more practical for the average consumer.

Alternative Energy, Wind

WIND IS A source of solar energy that does not rely on the condition of the sky. Unlike fossil fuels, wind energy can be collected during storms, snow, or the night. Wind power is the alteration of wind energy into more purposeful forms, usually electricity using wind turbines, and is a form of renewable energy. Wind power is greenhouse gas extenuating, clean, abundant, infinitely renewable, domestically produced, widely distributed, and supportive of rural economies.

The International Energy Agency (IEA) projects that, 2000–30, global energy consumption will increase and electricity use could double, placing pressure on nonrenewable resources, public health, international stability, and the natural environment. One solution lies in finding and utilizing alternative energy sources. Renewable energy sources pose lower costs, whether environmental or health-related. The use of alternative energies to generate electricity is especially advantageous to developing countries, because of the new employment opportunities it will create, as well as the stimulation of local economies by attracting investment. One of the resources leading the way to a more sustainable future through the use of alternative energy is wind power.

People have been harvesting the wind for hundreds to thousands of years, with functions varying from sailing, to grinding grain, to pumping water. Windmills have been found dating back to 10th century Persia, while their appearance in Europe is believed to have begun around the Middle Ages. It was not until the 20th century that people became interested in using the wind to generate electricity. In 1941, the 1,250 kilowatt (kW) Smith-Putnam wind turbine was constructed in the United States. There are records of 100 kW turbines in the former Soviet Union in 1931, and other innovative designs originating in Germany during the 1950s to the 1960s. However, after the 1950s, lower-cost fossil fuels made wind energy technology economically unprofitable, and only in the 1970s did rising fuel prices bring it back into popularity.

MECHANICS

Wind energy moves over the Earth's surface as kinetic energy. This energy is received by the blades of a turbine, which is attached to an electrical generator that sits atop a collection tower. Collection sites consist of a single turbine, or many, constituting a wind farm.

Projects like this wind farm in California may help the U.S. Department of Energy's Wind Powering America Initiative reach its goal of generating 5 percent of the nation's electricity through wind power by the year 2020.

Each turbine consists of a tower structure, rotor with blades attached to the hub, shaft with mechanical gear, electrical generator, yaw mechanism, and sensors and control. Modern structures must come equipped with a control system for operational and safety functions.

Certain terms are necessary to understanding of the wind industry. The gearbox increases the turbine speed from around 45 rotations per min. (rpm) to about 14,500 rpm. The rotor connects to the nacelle, which sits atop the tower and contains the gearbox. Upwind refers to a turbine operating facing the wind in front of the tower. Downwind turbines run facing away from the wind behind the tower. Finally, the yaw drive maintains the direction of the upwind turbine facing the wind.

The tower is the support structure. It can be steel or concrete, and tubular or lattice. They must be at least 82 ft. (25 m.) tall to capture adequate energy. The turbines range in size from a few kW to a few megawatts (MW), used for utility-scale power generation. Turbines usually consist of two or three aerodynamic blades constructed to capture the most energy possible. The blades operate using the Bernoulli principle. A lift is created by the difference in pressure on the sides of the blades when the wind flows over it. The lift rotates the blades around the hub. A drag force is created that acts perpendicular to the blades and slows down the rotor. The purpose of this design is to achieve the highest drag to lift ratio, optimizing the turbine's power.

IMPACTS

When assessing the introduction of wind energy conversion to a new area, it is important to consider the environmental, economic, and social impacts. Birds feel the environmental consequences of collecting wind energy, and humans experience noise emissions and the visual impact of the turbines. The presence of turbines may alter the breeding and feeding patterns of some avian species. Some birds have been killed or injured from collisions with blades. Some may be sucked into the draft created by the rotating blades, but some may just be attracted to the hum of the machine. However, the 300 birds killed in Altamont Pass, California, in the 1980s do not seem as significant when compared with the millions of birds killed by U.S. hunters and the one billion birds killed annually by flying into glass windows. To combat these occurrences, certain measures have been put in place, such as avoiding migration routes and using fewer, larger turbines.

The visual aspect may not be considered an important environmental impact, but it has generated public concern. The elements that must be considered are the number and design of turbines, the turbine arrangement, their color, and the number of blades. The wind turbines may not be aesthetically pleasing, but it is hoped that with the knowledge of the technology and services they deliver, they will become more acceptable.

Noise emission due to wind energy is another consequence that is relative to the public's perception. Its impacts can range from annoyance, to sleep interruption, to effects on hearing. A 600 kW wind turbine will produce around 55 decibels (dB) of noise when a receptor is 164 ft. (50 m.) away. This amount will decrease as the distance increases. This level falls in between that of the noise produced in the average office (50 dB) and that of an average factory (60 dB). While this may seem a tolerable amount, it is dependent on individuals' personal discretion and tolerance. Because an individual's level of tolerance of noise is subjective, there is no way to please everyone; hopefully public education about the technology will increase acceptance.

The economic impact of employing wind technologies is beneficial. This would be especially helpful in developing countries where billions of people still lack access to electricity and other modern forms of energy. Limited access to fossil fuels and the abundance of renewable, sustainable sources has led to the creation of 100,000 jobs in the wind industry worldwide. In 2003, $9 billion was invested in the wind industry globally.

This influx could greatly assist weaker, developing economies. The decreasing costs of the operation and services provided by wind energy are also appealing to poorer countries. By 2020, the cost may even be reduced to 2.6¢/kW hour.

One of the factors determining the economic worth of wind energy production is siting. The strength of wind spectra is one of the critical factors in deciding the cost of wind-generated electricity. Therefore, as the velocity of the wind increases, the cost is reduced. Also included in site-specific factors are the cost of land, installation, and environmental factors such as climate and harmful substances in the atmosphere.

Machine parameters include the cost of the turbines themselves. The cost of wind-generated electricity can be reduced with an increase in turbine size. When the size is scaled up from 20 kW to 50 kW, the cost/kW is reduced by 18 percent. Other factors that influence the cost are the existing energy market and policy issues, including incentives and exemptions. With the goal of promoting clean and easily accessible energy sources, several governments are giving financial support to the development of renewable energies.

WIND POWER IN ACTION

Despite the limitations and boundaries that wind energy may extend, Germany has proven to be a success story and has become the world leader in wind power. In the early 1990s, Germany started out with almost no renewable resource industry, and it seemed unlikely that it would ever be considered a leader in these technologies. The decision of the German government, in 1990, to pass a law that required utilities to purchase the electricity generated from all renewable technologies, and to pay a minimum price, was governed by the public's increased concern about the security of energy supplies and its environmental impact.

The results that Germany has experienced are staggering. The average cost of manufacturing wind turbines fell 43 percent 1990–2000. In 1997, Germany surpassed the United States to become the world leader in wind energy production. The percent of total electricity accounted for by wind power has increased from 3–6 percent 2001–07. In 2002 the renewable resource industries totaled $11 billion in sales. Nearly 45,000 Germans were employed in the wind industry alone in 2003. The country is taking further steps by pledging to reduce its CO_2 emissions by increasing its use of renewable energy. The government aims to meet 25 percent of national electricity needs by 2025 and at least half of its total energy needs with renewable resources by 2050.

The world can learn a lesson from Germany's innovative renewable energy technologies, especially wind power, and many nations are taking the initiative. Countries such as Spain and Denmark have established similar laws as Germany. Spain is a leading turbine producer, generated 5 percent of its electricity from wind in 2003, and has some of the world's largest turbine manufacturers. In Denmark, 20 percent of its electricity has been generated by wind. In the United States, at least 38 states have enacted similar laws.

These numbers are projected to increase. Major oil companies, including BP and Shell, are investing hundreds of millions in renewable energy. The U.S. Department of Energy's (DOE) Wind Powering America Initiative intends, by the year 2020, to have 5 percent of the nation's electricity generated through wind power. The European Wind Energy Association (EWEA) has developed a program, Wind Force 12, to produce 12 percent of the world's electricity by wind for the year 2020. Some countries may expect wind to contribute to larger percentages of their total energy by 2010.

For years, the exploiting and burning of fossil fuels has caused emissions of harmful gases and severe degradation of the environment. People worldwide are becoming conscious of the consequences of their actions for the environment. Only with a suitable amount of time, money, and energy invested in wind power can countries reap its full benefits. It does not emit pollutants into the air or water. There is no chance of hazardous waste as a byproduct of its use. The wind is a sustainable, natural, renewable resource which can never be diminished, unlike the finite supply of natural gas, coal and oil.

American Council for an Energy-Efficient Economy

THE AMERICAN COUNCIL for an Energy Efficient Economy (ACEEE) is a nonprofit organization located in Washington, D.C. Its staff is comprised of scientists, lawyers, engineers, and policy analysts. Its mission is to increase the economic well being of the world and foster a cleaner environment through energy efficiency. ACEEE is not a membership-driven organization; however, it does send out conference information, publications, and online newsletters to over 30,000 registered individuals.

Since its inception in 1980, ACEEE has helped to save American energy consumers over $50 billion and 60 billion kilowatt hours (kWh) annually. These savings are brought about by standards and policies recommended by the American Council for an Energy Efficient Economy and included in the energy policies of the last four U.S. presidents. ACEEE promotes five main program areas: energy policy, buildings, utilities, industry, and transportation. The goals of these programs are to educate consumers, businesses, policy makers, and program managers through collaboration and publications. ACEEE often works with energy experts, universities, national laboratories, and those in the private sector.

The first of ACEEE's projects was to influence energy policy. In 2006, the United States used approximately 100 billion British thermal units (Btu) of energy. ACEEE seeks to decrease this amount by lobbying Congress to include efficiency measures in national legislation. The organization has worked with Congress on major laws, such as the National Appliance Energy Conservation Act of 1987, the Energy Policy Act of 1992, the Energy Policy Act of 2005, and draft bills of comprehensive energy legislation in both the U.S. House of Representative and U.S. Senate.

ACEEE is also an established leader in creating ways to improve the efficiency of buildings, thereby decreasing overall impacts on global climate change. It has been instrumental in creating voluntary and mandatory labeling programs. ACEEE also consults with the U.S. Environmental Protection Agency (EPA) and Department of Energy (DOE) on the Energy Star program to achieve program targets. Finally, ACEEE is working to engender new, more stringent state-regulated building codes, which will require a greater emphasis on energy-efficient technologies.

ACEEE also works with the utility sector to design and implement efficiency policies and programs. They accomplish this by working with states and utilities on an individual basis, advocating for funding for end-user and system-wide efficiency programs, and creating sound policy advice. ACEEE also offers strategies for implementation, such as "reliability-focused" energy-efficiency, which promotes energy savings during times of high demand.

AnotherACEEE program area is industry. The goal of this program is to promote and analyze new technologies and polices that bolster energy efficiency while also increasing the competitiveness of businesses and agriculture. Staff members review energy-use trends, options for implementing energy and cost-saving technologies, and potential productivity and capital gains from such implementation options. ACEEE believes that sustainable businesses usually have the strongest bottom lines; therefore this nonprofit organization works to facilitate communication among businesses, government, and the environmental community. ACEEE accomplishes this by hosting a Summer Study in Energy Efficiency in Industry each year.

Another area that ACEEE works to improve is the transportation sector. ACEEE advocates for incentives for green vehicles, stronger Corporate Average Fuel Economy (CAFE) standards, market initiatives to promote greater vehicle efficiency, and more research and funding for new, clean technologies. ACEEE maintains a website for consumers to research the most fuel-efficient vehicles, read recent publications, and find tips for greener driving at www.greenercars.org.

ACEEE works with international companies and foreign nations to support energy efficiency programs. Most of this work is in conjunction with developing countries such as Brazil, China, and Thailand. In Brazil, ACEEE helped to establish PROCEL, the national energy conservation program. PROCEL has received over $100 million from the World Bank and the Global Environmental Facility. ACEEE's work in China has led to the establishment of the China Green Lights Program and the China Motor Systems Energy Conservation Program. These efforts helped

China to adopt national efficiency standards and integrated resource planning. ACEEE is expanding their international efforts to include the Czech Republic, Egypt, India, Poland, and the Slovak Republic. In addition to their Summer Study institute, the group also publishes several consumer guides, including the *Consumer Guide to Home Energy Savings*.

American Electric Power

AMERICAN ELECTRIC POWER (AEP) was founded in 1906, and served electric utilities in various parts of the United States for over 100 years. The company was originally formed from a utility holding-company in 1899, but began its electric utility service business in Albany, New York, on December 20, 1906, as American Gas and Electric (AG&E), acquiring its first utility properties on January 2, 1907. In 1917, AG&E operated the first super power plant on the Ohio River at Wheeling, Ohio, and named it the Windsor Plant. It was the first major steam plant built at the mouth of a coal mine, eliminating the need to haul coal over long distances. It provided a significant amount of power over the nation's first long-distance 138,000-volt transmission line. The AG&E made the greatest expansion in its history 1922–27. It acquired a number of major properties such as Indiana Michigan Electric, American Electric Power Company in Philadelphia, and Appalachian Power Company in Virginia.

With the increasing demand for electricity in the 1920s, AG&E constructed three large generating stations: the Twin Branch plant in northern Indiana, the Philo plant in southeastern Ohio, and the Stanton plant in northeastern Pennsylvania. Even during the Great Depression, the company persevered and maintained its financial integrity through the stock market crash in 1929.

AG&E constructed 36 new generating units at 14 locations in five states 1941–61 with a total generating capacity of 6 million kilowatts (kW). At that time, many AG&E plants occupied the top of the list of America's most efficient electricity generating stations. After that, it added 11 new generating units for 2 million kilowatts capacity. It also managed a 390-mi. (628 km.), 345,000-volt transmission system for the Ohio Valley Electric Cooperative (OVEC), which had been formed to supply electrical power to the federal government's uranium enrichment plant at Piketon, Ohio. In 1958, AG&E changed its name to American Electric Power (AEP). AEP continued to grow 1961–75, adding 21 new generating units to bring the total system's generating capacity to 17.6 million kW.

In 1967 AEP announced that it would build a nuclear generating station on the shores of Lake Michigan. The 1,020,000-kW Unit 1 of the Donald C. Cook Nuclear Plant went into commercial operation in 1975, and the 1,090,000-kW Unit 2 was completed in 1978.

New York City was AEP's headquarters for nearly three-quarters of a century, but it began moving its corporate offices to Columbus, Ohio, in 1980, and completed the move in 1983 with the completion of a new 31-story office facility at One Riverside Plaza. During 1996, AEP's sales of electricity to retail customers reached a record 100 billion kW hours. On December 22, 1997, AEP announced a definitive merger with Central and South West Corp. of Dallas, Texas. The merger was completed on June 15, 2000, and created a combined electricity sales amount of 200 million megawatt hours. As of 2007, AEP had more than 5 million U.S. customers and served parts of 11 states, including Arkansas, Indiana, Kentucky, Louisiana, Michigan, Ohio, Oklahoma, Tennessee, Texas, Virginia, and West Virginia. It was one of the largest investor-owned utilities in United States.

AEP has undergone successful expansion to date; however, with increasing concern for the environment, and greater international and governmental policing of energy corporations, AEP must consider the environment a corporate responsibility. Climate change, attributed to increasing atmospheric concentrations of greenhouse gases (GHG), is a growing concern for

AEP, because it is one of the largest consumers of coal in the United States. Therefore, reducing GHG emissions and supporting a reasonable approach to carbon controls is crucial to AEP.

AEP has been researching clean technologies. In August 2004, it announced plans to construct an Integrated Gasification Combined Cycle (IGCC) coal-fired power plant. IGCC technology is expected to reduce the atmospheric concentration of emissions, while providing additional electricity capacity to the customers served by AEP. IGCC is an innovative clean technology that turns coal into a gas, and then removes impurities from the coal gas before it is combusted. This results in lower emissions of sulfur dioxide, particulates, and mercury. It also results in improved efficiency compared to conventional pulverized coal.

IGCC technology is proven to work well with high-British thermal unit (Btu) coals such as the bituminous Appalachian coals readily available in AEP's eastern area. With this technology, AEP has concentrated research on developing technologies for carbon capture and storage. AEP became a founding member of the Chicago Climate Exchange (CCX), the first voluntary GHG credit trading system in the United States, and committed itself to reducing GHG emissions below baseline emission levels. The total cumulative CO_2 equivalent reduction requirement to meet the CCX commitment is approximately 46 million metric tons by 2010. AEP also committed to the recycling of its coal combustion products through the Coal Combustion Products Partnership in cooperation with the U.S. Environmental Protection Agency. Coal ash of the highest quality is dispensed to customers as products and unsuitable ash is identified and diverted for disposal. Examples of the utilization of coal ash include the construction of dams, plant roads, stacks, cooling towers, and buildings.

Approximately 73 percent of AEP's generating capacity is coal-fired plants, 16 percent natural gas, and 8 percent nuclear. The remaining 3 percent is wind, hydroelectric, and other sources. The company also operates its own inland barge line and owns major tracts of land throughout its service areas. In 2001, AEP acquired MEMCO Barge Line, Inc., and enhanced its coal transportation resources. As of 2007, AEP's transportation infrastructure consisted of approximately 7,500 rail cars, 1,800 barges, and 37 tugboats.

American Gas Association

THE AMERICAN GAS Association (AGA) is a national trade organization composed of natural gas-providing companies. This large group of companies, founded in 1918, was organized to better represent the interests of natural gas providers at the legislative level. The AGA is headquartered in Washington, D.C., on Capitol Hill. According to the AGA, nearly one-quarter of American energy is supplied by natural gas.

The AGA vision statement is "[T]o be the most effective and influential energy trade association in the United States while providing clear value to its membership." Membership includes 200 companies providing natural gas service to their local communities. The AGA and its members deliver 92 percent of the United States' natural gas supplies. Member companies represent suppliers from all 50 states. The companies are privately-owned, publicly-traded, or municipally-owned. Natural gas distribution companies in the United States are considered full members of the AGA. Additionally, brokers, distributors, gatherers, marketers, pipelines, and storage facilities can be Associate Members of the AGA if they are in North America; natural gas distribution companies in Mexico and Canada may also be associate members. Finally, international or international-affiliate memberships are extended to those companies beyond North America that support international communication between natural gas companies and governments.

Membership privileges include conferences and courses for company executive directors and other employees covering topics such as finances and investments, as well as compensations, legislation, and customer service. Members can also elect to receive newsletters. The five newsletters are the *Associate Update, Executive Bulletin, Financial Edge, International Bulletin*, and *Operations Bimonthly Review*.

The AGA also provides written documents related to the use of natural gas and current concerns about climate change and global warming. On February 19, 2007, the company released the "AGA Climate Change Principles," outlining how changes can be made that would result in natural gas being a safer, more environmentally responsible form of energy. Another document from the same day, the "AGA Climate Change Talking Points," outlines various significant facts about natural gas, focusing on the improved efficiency of modern appliances and industrial machines, low rate of emissions compared to coal and fuel oil; and arguing for construction of domestic natural gas plants, access to natural gas wells, and the construction of other plants and factories in the United States that would use natural gas power. The organization does not offer a solution to the problem of natural gas wells in protected areas. Nevertheless, due to limited availability of natural gas, AGA proposes research into alternate energy sources as a complement to natural gas; namely, solar and wind power, along with cleaner coal and oil fuel usage.

To further disseminate information about issues concerning natural gas, the AGA publishes a magazine approximately every two months, *American Gas Magazine*. Issues are focused by theme, including technology and partnerships, legislation, natural gas supply, and even climate change. The climate change issue (August/September 2007) provides information to its readership about carbon footprint reduction and how using natural gas directly for power, rather than using it to generate electricity, provides a cleaner energy source. Because of the relative environmental and economic benefits of natural gas, the AGA has adopted the slogan *Natural Gas: the Nation's Energy Advantage*.

A board of directors manages the AGA. A total of 45 of the full member companies have senior executives on the AGA board. The board is composed of a chair, a president and chief executive officer, officers, directors, and non-voting advisory directors. The Environmental Regulatory Action Committee (ERAC) is a sub-committee in AGA. Its members report to the Government Relations Policy Committee and the Operations Sections Managing Committee. ERAC acts on behalf of AGA to influence environmental legislation. The sub-committee writes documents defending its statements, testifies when needed, recommends pertinent legislation, and otherwise deals with matters concerning environmental legislation.

The AGA website offers information for members, policy makers, and the public. Summaries of congressional hearings and legislations are available, as well as information on the stance of the AGA on issues regarding natural gas, the environment, and energy. Information is also available on statistics such as trends in natural gas usage and prices. For example, the website states that the average annual residential gas cost rose from $597 per consumer in 1996 to $935 in 2005. Additionally, in 2005 the average gas price was three and one-half times higher in the second-most expensive state (Florida) than the least expensive state (Alaska). The most expensive state was Hawaii, with an average gas price that was another one and one-half times higher than that of Florida. When examined by region, New England pays more for gas than any other region, with the South Atlantic states close behind.

American Geophysical Union

THE AMERICAN GEOPHYSICAL Union (AGU) is a nonprofit organization of geophysicists with over 50,000 members from over 140 countries. The AGU's activities are focused on the collection and dissemination of scientific information in the interdisciplinary and international field of geophysics. The geophysical sciences include four fundamental areas: atmospheric and ocean sciences, solid-Earth sciences, hydrologic sciences, and space sciences. The AGU's mission is to promote the scientific study of Earth and its environment in space and to disseminate the results to the public; to encourage cooperation among scientific organizations involved in geophysics and related disciplines; to initiate and participate in geophysical research programs; and to advance the various geophysical disciplines through scientific discussion, publication, and dissemination of information. In December 2003, the AGU clearly stated its position on global warming, explicitly pointing to human activities as determining factors in changing the Earth's climate.

The AGU was established in 1919 by the National Research Council and for more than 50 years operated as an unincorporated affiliate of the National Academy of Sciences. In 1972 the union was incorporated in the District of Columbia and membership was opened to scientists and students worldwide. The AGU offers to its members a wide range of publications, meetings, and educational and other activities that support research in the Earth and space sciences. Many AGU members are involved in crucial research for the future of the planet on issues such as global warming, climate change, ozone depletion, natural hazards, water supply and quality, and other environmental factors. The AGU's membership includes many of the world's foremost geoscientists from industry, academia, and government.

The AGU is an individual membership society and membership has increased each year, doubling during the 1980s. About 20 percent of the members are students. Members and associates receive *Eos*, the AGU's weekly newspaper, and *Physics Today*, a magazine produced by the American Institute of Physics. All members may vote and hold office. The AGU's fellows are selected from the membership because of their acknowledged expertise in areas of the geophysical sciences.

The AGU organizes an annual meeting in San Francisco every December, known as the fall meeting. This is the largest annual scientific conference in the world. The AGU also holds a joint assembly cosponsored with other societies such as the Geochemical Society, the Mineralogical Society of America, the Canadian Geophysical Union, and the European Geosciences Union every spring in various locations around the world. Traditionally held in Baltimore, this spring meeting was moved to different locations, starting with Boston in 1998, due to declining interest. With the meeting in Nice, France, in 2003, the event was renamed the Joint Assembly. In addition to these meetings, which cover all areas of the geophysical sciences, the AGU also sponsors many specialized meetings that are intended to serve the needs of particular scientific disciplines or geographical areas, including the Ocean Sciences Meetings and Western Pacific Geophysical Meetings, which are held in even-numbered years. The Chapman Conferences are smaller, and highly-focused meetings.

The AGU Council runs the union, has full responsibility for all affairs of the AGU, and is its representative in its external relations. The Council consists of the AGU's president, the president-elect, the immediate past-president, the general secretary, the international secretary, the executive director, and the president and president-elect of each of the AGU's 11 scientific sections. The executive director serves as secretary to the Council. The Council usually meets twice a year, at the AGU's spring and fall meetings. The Executive Committee, composed of the president, the president-elect, the general secretary, the international secretary, and the executive director, conducts the affairs of the AGU between meetings of the Council according to the policy decisions of the Council.

Adopted in December 2003, "Human Impacts on Climate" is the AGU's official statement on global warming. They explicitly argue that human activities are increasingly altering the Earth's climate and the level of greenhouse gas concentrations in the atmosphere is already affecting the climate. The AGU strongly recommends enhancing national and international research and other efforts to support climate related policy decisions. They conclude that because science can serve as a useful tool to deal with natural hazards such as earthquakes, hurricanes, and drought, it can also provide an answer to human-caused global warming.

American Meteorological Society

THE AMERICAN METEOROLOGICAL Society (AMS) supports the growth and diffusion of information and education on the atmospheric and related oceanic and hydrologic sciences and the development of their professional applications. Founded in 1919, AMS has a membership of more than 11,000 professionals, professors, students, and weather enthusiasts. AMS publishes nine atmospheric and related oceanic and hydrologic journals, both in print and online and sponsors more than 12 conferences annually. It also offers numerous programs and services.

Charles Franklin Brooks of the Blue Hill Observatory in Milton, Massachusetts, founded the American Meteorological Society. Its initial membership was formed primarily by the U.S. Signal Corps and U.S. Weather Bureau and numbered less than 600. Its initial publication, the *Bulletin of the American Meteorological Society*, served as a supplement to the *Monthly Weather Review*, which, at the time, was published by the U.S. Weather Bureau. Many of the initial members were not professionals in the field, but after the dues increased from $1 to $2 in 1922, the amateur meteorologists began dropping out, and the AMS moved toward a membership primarily of practicing meteorologists. It has made important official statements on ozone depletion and climate change that recognize human activities as a cause of the phenomena.

The 1930s and 1940s were a period of significant progress in the atmospheric sciences, and the AMS contributed substantially to such progress through the publication of fundamental articles in the *Bulletin*, the production of books and monographs, and the organization of specialized meetings. World War II increased a new interest in meteorology. The conflict had shown the key role that the discipline played in support of military activities in ground and air operations. A large number of meteorologists were trained as part of the wartime effort and were employed in military research during the Cold War. After the war, the military and civilian sectors of society had a substantial number of meteorologists in their ranks. The AMS saw significant growth during this period, which corresponded to the birth of many departments of meteorology at universities. Because of new research and newly-trained meteorologists, the publications and meetings of the AMS increased. C.G. Rossby served as president of the AMS 1944–45, and developed the agenda for its first scientific journal, the *Journal of Meteorology*, which later divided into the two AMS journals: the *Journal of Applied Meteorology* and the *Journal of the Atmospheric Sciences*.

The AMS now publishes, in print and online, nine scientific journals and an abstract journal of high academic standard, in addition to the *Bulletin.* It also organizes over a dozen scientific conferences each year. It has published a series of monographs, as well as many other books and educational materials. The AMS administers two professional certification programs, the Radio and Television Seal of Approval and the Certified Consulting Meteorologist (CCM) programs. The Radio and Television Seal of Approval was established in 1957 as a way to recognize television and radio weather forecasters who present clear and scientifically-informed weather reports. The original seal of approval program will be discontinued at the end of 2008, and after that date, only the Certified Broadcast Meteorologist (CBM) seal will be offered. The CBM was introduced in January 2005, together with a 100-question multiple-choice closed-book examination as part of the evaluation process, covering many aspects of the science of meteorology and forecasting.

In the education sector, the AMS offers a variety of undergraduate scholarships and graduate fellowships to support students wishing to undertake a career in the atmospheric and related oceanic and hydrologic sciences. The AMS considers education as one of its strategic areas of intervention because, as its 2007 strategic goals brochure states, "the atmospheric and related sciences serve as a gateway to introduce both young people and adults to broad scientific issues."

The AMS has made several statements on climate change. It identifies climate change as one of the most important factors that will impact societies, and the environment as one of the fundamental elements that will influence the economies of developed and developing nations. The AMS's third strategic goal is "to promote science-based decision making" about climate and weather variability. Such variability can produce huge swings in national economies; thus, it is in the interest of nations to be able to cope with this phenomenon. Global warming causes rising sea levels and retreating glaciers. The most significant changes in U.S. climate have taken place in Alaska and in the west.

Although weather has always changed for natural reasons, the AMS concludes that, at least over the last 50 years, human activities have made a major contribution to climate change. The most apparent result of human activities on climate is the rising concentration of greenhouse gases that act as a blanket to reduce the outgoing infrared radiation emitted by Earth and its atmosphere. The AMS document closes with a plea to policymakers to take better care of the Earth.

Andorra

SITUATED IN THE Pyrenees Mountains along the French-Spanish border, Andorra is approximately 180 sq. mi. (470 sq. km.), or the size of New Orleans, Louisiana. The population (est. 80,000) inhabits a region with a cool, temperate climate, amid mountainous terrain. Its economic revenues come from tourism and regional agricultural specialization, both industries with links to climate change. With nearly 12 million visitors per year, tourism comprises over 80 percent of the country's Gross Domestic Product (GDP).

Roadways are limited and inadequate, making stagnant traffic commonplace. Pollution swells during the peak winter and summer tourist seasons, reducing air quality and concentrating greenhouse gases in the valleys. These conditions are exacerbated by high carbon dioxide emissions from low-grade coal-burning power plants in Andorra and northern Spain.

The stronghold of Andorran tourism is the ski industry. Like much of mountainous Europe, Andorra has seen snowfall amounts decline and winter seasons considerably shortened in recent decades. Global climate models indicate European locations below 4,921 ft. (1,500 m.) are most vulnerable to permanent snow loss. Unlike many Alpine locations, Andorran ski resorts are largely above this critical altitude. Snow reduction impacts include a decrease in tourism, investment in snowmaking machines, cancellation of winter events, and expansion of alpine grasslands. Diminished tourism revenue has prompted a recently-proposed corporate tax, a controversial initiative for a historically tax-free state.

Unlike most of the European community, Andorra is not active in global climate change policy and state-sponsored efforts are minimal. An official position regarding the Kyoto Protocol has not been entered according to the latest poll (2007) from the United Nations Framework on Climate Change (UNFCC). Despite close socioeconomic ties with France and Spain, Andorra has not followed the climate initiatives of its neighbors by ratifying the treaty. Instead, Andorra maintains neutrality and observer status in these proceedings, a similar position retained by Serbia and the Vatican City, the only other European states not to have ratified the protocol.

The Andorran Weather Service, established in 1980 as a joint effort with Meteo-France to homogenize data for the region, conducts climate monitoring. The service has three automated weather stations and seven manual ski resort stations. Continuous weather data monitoring began in 1934, with three stations (Ransol's Dam, Casa del Guàrdia d'Engolasters, and the Central) providing the primary historical climate record.

Angola

LOCATED IN THE southwest of Africa, the Republic of Angola gained its independence from the Portuguese in 1975, and the civil war that followed lasted until 1991. The country covers 481,354 sq. mi. (1,246,700 sq. km.), with a population of 15,941,000 (2005 est.) and a population density of 34 people per sq. mi. (13 people per sq. km.).

Because of current upwelling, one of the salient feature's of Angola's geography is the very cold surface water along its coast on the south Atlantic Ocean. The largest concentration of people in the country remains Luanda, the capital, which has nearly a quarter of the entire country's population. The soil in Angola has always been poor, with only 2 percent arable land, and no permanent cultivated crops. Some 23 percent of the land is used as meadows or pasture, with large cattle herds adding to the increasing desertification of the country.

The result is an economy heavily dependent on the sale of petroleum, which contributes about 40 percent of the nation's Gross Domestic Product. This reliance on oil contributes to the high use of fossil fuels for electricity production, with 40.3 percent of Angola's electricity coming from fossil fuels, and 59.6 percent from hydropower.

The major hydroelectric electricity generation takes place at the Cambambe (Capanda) Dam located on the Cuanza River, with further production at the Biopio and the Lomaum dams located along the Catumbela River. In addition, there are other hydroelectric power generation plants, such as that at Luachimo used by the diamond mining works. The war led to the damaging of places such as the Ruacaná Falls dam, which was out of action for a long period.

All these factors have helped reduce the carbon dioxide emissions from Angola, which is only 0.4 metric tons per capita, although it rose to 0.9 metric tons per person in 1995, and then fell to 0.57 metric tons per person. The government has also tried to further reduce the already relatively low level of emissions from sulfur dioxide, nitrogen oxide, and carbon monoxide.

The Angolan government of José Eduardo dos Santos took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and the government also accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on May 8, 2007—the 171st country to do so. The Angolan government has argued that dealing with climate change should accompany a global political framework for reducing world poverty.

Animals

WHILE GLOBAL WARMING and associated climatic change have profound geological impacts on animal habitats, they also impact the dynamic living processes of the ecosystems of animals. Though the two types of impacts are highly interconnected, it is paramount to distinguish between changes that express themselves mainly at a climatic and geological level, from changes that require an ecosystems perspective. Unfortunately, the mass media, governments, and transnational conservation agencies and organizations often conflate these two types of changes. This conflation represents a major impediment to public understanding of global warming and global climatic change.

While many of the geological and climatic consequences have become starkly visible to the non-scientific community, ecosystem effects often have either not yet manifested themselves, or are only noticeable through the application of some form of expert knowledge. This includes scientific knowledge, as well as the traditional knowledge of peoples with generations of experience in interacting with specific environments.

This problem is exacerbated by the fact that both public and scientific reporting on global warming and climate change are rarely impartial or value-neutral. Information is not equally accessible to all groups of people. Accordingly, people's views on the veracity of global warming tend to differ according to their social, cultural, economic, and political position, as do their views on the importance of introducing measures to halt global climatic change, and what these measures should be.

THE ICONIFICATION OF ANIMALS

This reality is especially evident in reporting the impact of climactic change on animals, as some animals are perceived as having higher conservation and aesthetic value than others. European and North American elites have claimed more appreciation of these values as a mark of distinction since the turn of the 19th century, according to Karl Jacoby. These values were institutionalized and exported to the rest of the world in the setting of a global conservation regime that emerged in the context of European empires and westward expansion in North America.

These values were popularized with the rise of car culture after World War II, as large numbers of North Americans began visiting wild places in their leisure time, as explained by Roderick Neumann. They also became enshrined by the Walt Disney-style nature films that became popular during this period, and by the dramatic international success of Bernard Grizmek's book *Serengeti Shall Not Die!* For the most part, middle-class and formally-educated people embraced these values.

Over time, the popularization of charismatic fauna in the media has literally increased the value of certain animals. Images of soaring eagles sell pickup trucks, wild mustangs sell cigarettes, and a cartoon tiger sells cereal. Popular tourist destinations are marketed by promises of seeing grizzly bears, jaguars, scarlet macaws, kangaroos, elephants, lions, and rhinos in distant and exotic locations. These same types of animals and exotic locales are also a major selling point for films, such as *Finding Nemo*, *Madagascar*, and *The Wild*. Finally, the association of certain animals with major conservation organizations has been a source of advantage in a highly-competitive funding environment. The World Wildlife Fund panda is one of the most successful logos in the world. The African Wildlife Foundation's ivory ban campaign was the most successful direct mail charity solicitation of all time. Ironically, it contributed to an international treaty that resulted in an explosion of elephant populations in Southern Africa, such that the animals began destroying their own habitat.

Some species have become icons for conservation, while others have been neglected, even though their species may be under threat of extinction. The iconic value of some species is rising, while the iconic value of others is falling. In the 1980s and 1990s, for instance, many environmental movements and non-governmental organizations used images of whales to promote their conservation campaigns. In the context of anti–global warming, however, polar bears and penguins have come to assume pole-position in the effort to sensitize the masses to the seriousness of environmental problems. This makes sense, as it is clearly easier for lay people to grasp the relationship between these animals and the dangers of global warming.

The anthropomorphization of Antarctic animals in *Happy Feet*, produced in Imax 3-D, along with images of Knut the baby polar bear being bottle-fed at the Berlin Zoo, has also contributed to increased identification with these animals. And both these species naturally display characteristics similar to those typical of human beings: they can walk on two feet, their body forms are in many ways similar to the human body, and they display highly complex forms of social behavior. These developments have not been entirely negative. Documentaries such as Al Gore's *An Inconvenient Truth*, which features an animated polar bear crying in the middle of the ocean and Luc Jacquet's *The March of The Penguins* have played a major role in raising public awareness of global warming.

As icons, however, these animals represent only the most visible consequences of global warming and climate change. They stand for the problems of global warming symbolically, but they cannot stand for all that is wrong. The iconification of global warming through images of these animals for the most part glosses over the complex dynamic living processes of ecosystems. Instead, they emphasize the geological impact of rising temperatures on the habitats of these animals, which are easily captured through images of polar bears struggling across melting ice fields and drowning in the process. Rising temperatures are also easily represented through images such as the melting ice cap on Mt. Kilimanjaro, and they are experienced directly by people during highly-publicized heat waves.

The iconification of global warming through images of certain animal species may keep the public from understanding the extent and complexity of these phenomena. While climate patterns have always oscillated between given thresholds, for example, maximum and minimum numbers of hurricanes per season, climatic oscillations now show a tendency to increasingly occur at upper-end thresholds. What is at issue is that the iconification of these changes through images of animals conceals their complexity.

It is important to note, however, that the exact causal mechanisms that link the two are so complex that they have not yet been completely understood and explained by scientists. While, on average, the global temperature of the planet has increased, the manifestation of its consequences in terms of climate-related phenomena varies greatly from region to region. In some regions, it is associated with higher incidence of tropical and subtropical storms; in others, extreme rainfall and flooding; and in yet others, the onset of extreme drought. It has entailed record-beating temperatures in Europe, and an increase in erratic and destructive weather patterns in North America.

The plight of polar bears and penguins may call public attention to the fact that the melting of glaciers that began at the end of the last glacial period has accelerated at an exponential rate in the past four decades. However, it does not highlight the broader ecosystem impacts of the melting of the Earth's ice reserves. Many ecosystems of the world that simultaneously depend on, and sustain, animal life may disappear under the ocean, as may entire nation-states in the Pacific.

Erosion is another geological problem that occurs as a consequence of global warming and the related increase in the number and strength of storms. This is a particularly acute problem in areas of the globe that have already been subjected to human-caused erosion or land destruction. An example of this problem can be found in the Bayou areas in the Mexican Gulf Coast of Louisiana in the United States. The construction of human-made water canals had slowly deprived Bayous of much needed sediments that the Mississippi previously deposited there during its yearly cycles, according to MacGillivray Freeman.

As a result, extensive marsh areas that formerly protected New Orleans from floods and ocean surges underwent a process of severe erosion. This erosion tends to accelerate when the Bayous are hit by storms. To a great extent, the incalculable damages New Orleans suffered in the aftermath of hurricane Katrina were caused by the absence of previously-existing protective marshes. Meanwhile, the continent of Africa is currently undergoing processes of desertification that surpass previously known rates. As deserts expand into previously non-desert ecosystems, the existence and survival of the plants and animals that were part of these ecosystems is seriously threatened. Consequently, the role of animals in the ecological processes of these systems is also compromised.

HUMAN-INDUCED MASS EXTINCTIONS

Ever since ecosystems have comprised the living component of the planet, there have been periods where mass animal extinctions took place because of catastrophic events, such as the impact of large meteors, or because of relatively sudden drastic climatic changes, such as the onset of glacier periods. These types of mass extinction appear to have been a regular and natural occurrence in long temporal spans of ecological cycles and ecological change. What is a recent and new phenomenon in the history of the planet is the rapid mass extinction of animal species due to human-induced ecosystem changes. The most notable of these include agricultural expansion, industrialization, urban sprawl, and the appropriation of ecosystems for commercial purposes, such as forestry, fishing, hunting, and ecotourism.

All of these are closely related to climatic changes that affect animal life on unprecedented spatial and temporal scales. Ironically, tourists climbing on airplanes to see charismatic species in exotic locales contribute directly to climate change through the burning

Whales have been icons for conservation since the 1980s, but their iconic value is in decline in relation to arctic species.

of jet fuel. This, along with the iconification of global warming through images of animals, may give people an increased sense of being closer to nature. However, it does not encourage people to think about how their consumptive activities are contributing to climatic change and perhaps, ultimately, to the demise of the very species they wish to protect and preserve. These types of simplified understandings of nature and animals also hinder public understanding of the ways in which climactic changes impact the dynamics that characterize the lives of ecosystems, as opposed to more obvious geological changes.

Ecosystems are living entities, and as such they respond actively to change and difference by adjusting their patterns of behavior. Assessing environmental change from the perspective of an ecosystem requires paying attention to how patterns of relationships among the different species that comprise that ecosystem are altered and/or disrupted. It also entails paying attention to if new patterns of relationship emerge between them and what consequences this produces. Moreover, because these patterns unfold in distinct temporal frames, noticing change frequently requires long-term observation and study.

BIRD REPRODUCTION AND GLOBAL WARMING

Two examples elucidate the complexity of understanding changes to inter-species patterns of relationship and, thus, comprehending the complexity of the changes that global warming introduces to ecosystems. One example comes from the United Kingdom and concerns relations between flower blooming, butterfly production of caterpillars, and bird reproduction. For 47 years, naturalist Richard Fitter wrote down notes about the flowering times of many plant species, the arrival and reproduction of birds, and the life cycles of butterflies that he observed around his house and garden. In 2001, his son Alistair Fitter, an ecologist, analyzed these detailed data in order to assess what they might reveal about the potential impact of global warming on patterns of relationships within ecological systems.

He also sought to determine the extent to which such an impact might bear significant consequences in regard to the sustainability of interdependent species. The results, published in *Science* in 2002, were astoundingly informative. They were subsequently confirmed by research conducted under the auspices of the Intergovernmental Panel on Climate Change that same year, and by other independent researchers around the world.

This research shows that as late as 1980, the hatching food-needs of birds matched the peak mass of the quantity of caterpillars that were available within that ecosystem. In other words, the patterns of reproduction for these two interdependent species were coupled in time. By 2002, however, these patterns had been decoupled as a result of global warming and the onset of a sequence of years marked by a two-week earlier arrival of spring.

By 2002, the birds had maintained their average date for laying eggs (April 23) and their date for hatching (May 15), which marked the beginning of a two-week period where birds were in the highest demand for the caterpillars to feed their offspring. The birds' peak demand for nutrition, which in 1980 had corresponded with peak availability in caterpillar mass, continued to be on May 28. By 2002, however, caterpillars displayed different hatching dates, most likely related to an earlier arrival of spring temperatures, as well as to the consequent early blooming of flowers. The peak mass of caterpillar availability in 2002 was May 15, almost two weeks earlier than in previous decades. It is for this reason that ecologists say that the two species are now decoupled.

This example points toward four dimensions of the complexity implicit in the challenge of understanding the effects of global warming and climate change on ecosystems. First, it indicates that responses to the temperature variations that come with global warming are relative and peculiar to each species within an ecosystem. Some species, such as flowers and butterflies, seem to have a lower threshold for sensing temperature variation and respond accordingly by blooming and reproducing earlier in the season. Species such as birds, by contrast, seem less sensitive to temperature variations and continue to produce offspring at the same time as before.

Second, this example shows that a comprehensive understanding of the impact of increased global warming can be neither based on a discussion of absolute values, nor on the effects that such variations might have for a single species in an ecosystem. The full appreciation of the effects that global warming has on ecosystems must be based on an analysis of the extent to which, and the ways in which, this phenomenon affects relationship patterns among species.

A third dimension that must be considered in assessing the effects of global warming is that there are complex interactions between different ecosystems. Ecosystems do not exist autonomously and the sustainability of one ecosystem often depends on interactions with other ecosystems. This is particularly true of ecosystems that are connected through migratory species, such as ecosystems spanning from Central America to Canada, which rely on monarch butterflies for pollination. In addition, ecosystems are frequently nested within wider ecosystems such that their resiliency depends on complex interactions across different spatial scales.

Finally, this example shows that understanding the effects of global warming on ecosystems requires a temporally-extended view of the patterns that connect these different species, which are crucial elements in their long-term sustainability. It was only by means of analyzing the data that Richard Fitter collected over a period of 47 years that the decoupling of reproducing patterns of flowers, butterflies, and birds became visible.

BALEEN WHALES AND CLIMATE CHANGE

A second example concerns the sustainability of baleen whales in relation to the availability of plankton and krill. Baleen whales constitute a particularly interesting example in that they simultaneously point to the importance of the ecological relationships among different species at different scales, as well as to the importance of considering the temporal complexity of these processes. Most species of whales are migratory, with complex migratory patterns across the oceans, sometimes spanning more than half the planet. These patterns are fairly well-known across a relatively long span of history, not only through the efforts of scientific research and data collected by nongovernmental organizations, but also through many detailed records of whales' movement of that were collected by the whaling industry during the 18th and 19th centuries.

The migratory movement of whales tends to be coupled with the availability of nutrition. The main source of nutrition for baleen whales is krill. Krill, in turn, depend on plankton as their main source of nutrition. If ocean waters become too warm, plankton populations tend to expand to the point where they are poisoned by their own metabolic processes. Without plankton, krill populations are not sustainable, and, consequently, baleen whales may find themselves deprived of their main source of nourishment. In recent years, it has been reported that warmer ocean waters have affected the level of krill available to whales.

This example sheds light on the complexities of scale and time that are inherent in patterns of interspecies relations in an ecosystem. While ecosystems may become toxic from the perspective of the scale of plankton, they may not be toxic from the perspective of the scale of larger species, such as baleen whales. However, baleen whales are still affected, because their survival relies on a food chain in which plankton play a crucial role.

This example also raises the issue of temporal complexity in ecosystems. Whales live for several decades, on average 70–80 years. Therefore, understanding the long-term effects of krill deprivation will require years of systematic investigation and data analysis. As there are other factors that affect the health state of whales, scientists will have to consider which of these other factors may accentuate or attenuate the effects of the lack of krill-based nutrition on whales.

BEYOND POLAR BEARS AND PENGUINS

Simplified presentations on polar bears and penguins that do not account for spatial and temporal processes can never engage the types of ecosystem complexities that these two ecosystem examples reveal. In other words, the iconification of globalization through images of single species precludes a deeper understanding of global warming from an ecological perspective. Moreover, the focus on specific species of animals deemed more worthy of protecting and saving from extinction reflects the dominant views of Western societies and cultures, at the expense of alternative cultural views about animals. Different cultures have distinct views of which animals they value most. These views are often related to the different political and economic priorities of various societies. In many cases, however, they are grounded in more direct and long-term interactions with specific ecosystems than the dominant Western view.

This phenomenon is not exclusive to discussions of global warming, and it has long been at the core of tensions around conservation efforts going back to European colonialism and westward expansion in North America. In Tanzania, for example, efforts to create nature parks meant to preserve wild animal life have often produced conflicts with local populations that are displaced as a result. These conflicts have been well documented by social scientists such as Jim Igoe and Dan Brockingon. These researchers have shown that nongovernmental organization conservation efforts in Africa often reflect the political and economic interests of North American and European countries, transnational conservation nongovernmental organizations, and African elites. These groups are interested in protecting animal life so that it can be preserved as legacy for future generations, and as an economic resource for profitable commercial activities such as ecotourism. The local peoples who are displaced, however, often have different cultural and economic priorities, such as securing the sustainability of the local resource management practices on which their livelihoods depend.

While these debates do not pertain directly to global warming and climatic change, they are indicative of the sort of conflicts that emerge in the context of efforts to preserve animal life. They reveal political, cultural, and economic priorities about which species should be protected, for whose benefit, and at whose expense. Such conflicts are likely to proliferate and intensify as the impact of global warming and global climatic change on animals becomes increasingly prominent. As such, it will be important to consider that debates about these issues will need to foster productive communication among views and interests that, although distinct, often reflect equally legitimate perspectives. Most importantly, temporally and spatially complex human understandings of specific ecosystems should not be displaced in the rush to preserve and iconify individual species.

Recent scientific developments allow for the artificial manipulation of the gene pools of animal life. Though it has not yet gained mainstream acceptance, it is now possible through gene technologies to bring back species that may become extinct as a result of global warming and climactic change. Without more complex understandings of the dynamics of living ecosystems, however, it is questionable what value the revival of previously extinct species will have for the future of the planet.

An Inconvenient Truth

ARGUABLY THE MOST famous documentary of the early 21st century about the issues of global warming and climate change, *An Inconvenient Truth* was directed by Davis Guggenheim, with former U.S. Vice President Albert A. Gore, Jr., as narrator and creator. Gore steals the show, and very few people remember the filmmaker's name. *An Inconvenient Truth* is in essence a filmed public lecture, one and a half hours long, delivered by a former politician, not a scientist, about the importance and dangers of global warming.

The main character, Al Gore, is progressively introduced in the first scenes of the film, just before the film's title appears on the screen. The opening images show only nature: a calm river. Then, Gore's voice is coupled with various images of individuals from the audience who listen carefully to his message. At this point, Gore is viewed only from behind. Reaction shots are taken from individuals in the audience: most people listen, applaud; in another shot, others have the chance to get nearer or to talk to him directly. A man who seems impressed takes a photograph of nearby Gore, another candidly films him with his mobile telephone, showing that this is an important person, and this rare meeting is to become a memorable moment for all those who had the chance to encounter him. In the background, soft, instrumental music plays in a New Age style.

Then, perhaps on another day, in another city, Gore is about to enter on stage; first his shadow, from feet to head, then his whole person is shown. Until that moment, his face is not visible; then the magnified Gore introduces himself in a general shot, declaring jokingly, but without a smile, to the audience in a serious tone: "I used to be the next president of the United States of America." This opening sequence lasts about four minutes, until the film's title appears; it constructs Gore's image and credibility for the forthcoming demonstration.

The first hour shows Gore explaining how the climate went out of control in just a few years. Graphs, photographs, data, short films, and anecdotes are shown. From the beginning, the film mentions a national disaster from 2005, Hurricane Katrina in New Orleans, as a patent case of a tragedy that was not considered very important by the U.S. Government. At some point in the argument, these terrible events in New Orleans are presented as the direct consequence of the global warming. It also explains that the administration in Washington, D.C., does not seem to be fully aware of the danger of global warming to U.S citizens.

Among many facts, mixed with some personal memories, Gore mentions his admiration for his former professor at Harvard, Roger Revelle (1909–91), who in 1957–58 was already doing research and teaching about climate change, with the help of his partner Charles David Keeling. Both men are seen as the pioneers in the research and measures related to global warming. Gore recalls he was in Revelle's class in the mid-1960s; later, in the mid-1970s, when sitting in Congress, Gore wanted to bring his former professor Roger Revelle in as an expert to explain his position, during a congressional hearing about the climate.

One famous scene is when Gore wants to show his audience the exceptionally high level of carbon dioxide concentration, but he is not tall enough to point out the curve on the board. He also shows two variables on another graph, which he analyses in his own terms: "When there is more carbon dioxide, the temperature gets warmer." He adds that the string of big hurricanes occurred the same year the United States had an all-time record for tornados. But at some point, Gore brings the debate into another field, far from science and data, arguing that "Ultimately this is really not a political issue so much as a moral issue. If we allow that to happen, it is deeply unethical."

After the first hour, the movie introduces stronger images: for instance, the floods and droughts in Asia, Darfur, and Niger; Lake Chad, which dried up; or permafrost thawing in the Arctic. Many countries face the consequences of climate change, and the two poles are changing as well: the problem is worldwide. However, Gore does not pretend to be a scientist; he keeps a distance between the academic world and himself, for instance, when he "translates" into lay terms the fact "that Earth's climate is a nonlinear system," Gore adds that this is "just a fancy way they have of saying that the changes are not all gradual."

Throughout the movie, Gore also brings up lessons from history, quoting other repeated warnings that were not widely heeded, such as those of Winston Churchill in the 1930s about the Nazi threat. He adds, "…there had been warnings that hurricanes would get stronger." There was alarm as well about the dangers of cigarette smoking in the 1960s, although some skeptics used to pretend there was no danger. This last example about tobacco is used again later in the film, and transposed to illustrate how opponents often try to transform the evidence made by clear facts into a useless debate, in this case about the real existence of global warming.

The film concludes with the explanation of its title, when Gore shows how many people who deny climate change, sometimes identified as the "so-called skeptics," often raise doubts with feeble arguments, sometimes because they are influenced by powerful lobbies, either oil companies or energy producers. Gore compares them to scientists who used to serve in totalitarian regimes or communist countries, who could not enjoy free speech in presenting scientific opinions. In other words, their scientific conclusions were in contradiction with the official discourse and dominant ideologies, and therefore, raised more questions than answers, and had to be silenced.

The final images carry a touch of hope, given past gains: in sum, many challenges in the past such as slavery, Apartheid, and even the hole that was found in the ozone layer above the North Pole have been resolved. Therefore, the narrator calls for citizen involvement and a stronger advocacy for environment. When the film's credits are rolling, positive messages of good will such as "Recycle," "Speak up in your community," "Call radio shows and write newspapers," "Try to buy a hybrid vehicle," and "Encourage everyone you know to watch this movie" appear. Although some U.S. presidents such as Ronald Reagan and George H.W. and George W. Bush are portrayed as not acknowledging the facts of climate change, the Clintons are not shown anywhere in the film (except for a few seconds, when George W. Bush becomes the new president in the presence of President Bill Clinton and other guests).

REPUTATION

More than two decades before its release, *An Inconvenient Truth*'s lesser-known precursor was *If You Love this Planet* (1982), a short film by Terri Nash about nuclear dangers. It was so impressive it was even labeled in the United States as "political propaganda." It was also a documentary based on a lecture similar to a slide show, given to a university audience by Dr. Helen Caldicott (at State University of New York at Plattsburgh), with stock-shot images showing the consequences of the nuclear bombings in Hiroshima in 1945. Similarly, *If You Love this Planet* was also the winner of the Academy Award for Best Documentary (in 1982).

Other films that have created or fed public debate about environmental hazards include Roland Emmerich's *The Day After Tomorrow* (2004), which depicted a catastrophic global warming scenario. A Canadian documentary titled *The Refugees of the Blue Planet* (co-directed by Hélène Choquette and Jean-Philippe Duval in 2006) focuses on people around the globe who have had to move because of climate change. However, none of these had a social impact like *An Inconvenient Truth*, which was even presented in universities and colleges, mainly for debates in social sciences courses.

An Inconvenient Truth received countless reviews and criticisms; it brought the issues of global warming and climate change to a wider audience, especially in high schools. In Canada, the film was offered for free in some video rental stores by owners who believed the film had to be seen by everyone; in this case, the environmental cause seemed more important than profits from rentals. It is one of the few DVDs sold on the Amazon.com website that got more than 1,000 reviews.

However, some critics were perplexed, especially by the use of the term *truth* in the movie, because the whole issue is part of an ongoing debate. For instance, in the Canadian newspaper the *National Post* on May 19, 2007, Kevin Libin explains that the "Al Gore movie is too one-sided to be taught as fact"—most students who watch the movie in class cannot find two sides of a debate in the film. In fact, Libin's article gathered most of the previous criticisms that were expressed about *An Inconvenient Truth*. Libin wrote that most scientists do not agree with Gore on the predictions related to climate change, and some terms such as *science, facts, truth*, and *global warming*, do not have a single definition. Furthermore, schoolchildren are seen as too "credulous" to challenge the film's message.

Some Canadian academics, such as Professor Tim Patterson (from Carleton University), would even label this movie as "propaganda." Thus, some opponents argue that the documentary *An Inconvenient Truth* should not be used as a tool for environmental education because it is not neutral. On the other hand, other critics argue that *An Inconvenient Truth* illustrates what has become "politically correct" in the debate surrounding global warming, or could provide "facts, arguments and bullets" for anti-American ideologies linked with environmental issues. But Gore had already addressed his potential critics in his film, when referring to the "so-called skeptics." Some Republican voters have identified the film with the Democrats.

Despite its critics, *An Inconvenient Truth* was seen by millions and won two Oscars in 2007: one for the Best Documentary Feature, and a second Academy Award for the Best Achievement in Music Written for Motion Pictures (Original Song) given to singer Melissa Etheridge for her theme song "I Need to Wake Up," which plays during the final credits. The film *An Inconvenient Truth* was subsequently translated (in subtitled or dubbed versions) in many languages. Its DVD version gave an even wider audience to what was seen in the beginning as "just a slide show." The international success of *An Inconvenient Truth* proves that whenever scientific debates are brought to a wider audience in the public sphere, science itself can become an issue linked with many other debates: social, ethical, economical, environmental, and political. On Friday, October 12, 2007, Al Gore and the Intergovernmental Panel on Climate Change were given the Nobel Peace Prize for 2007, from the Norwegian Nobel Committee, with a medal and award of $1.5 million.

Antarctic Circumpolar Current

THE ANTARCTIC CIRCUMPOLAR CURRENT (ACC), also known as the West Wind Drift, is the only current that flows completely around the globe, unimpeded by continents. Famous explorers have often referenced the ACC in their navigational logs, including Edmond Halley (the first to note the ACC in a 1699–1700 voyage), James Cook, James Clark Ross, Sir Francis Drake, James Weddell. The ACC is notably the roughest sea crossing for navigators, particularly the 497 mi. (800 km.) wide Drake Passage extending around Cape Horn and the Antarctic Peninsula. The role of the ACC as "mixer of the deep oceans" also has a significant impact on global climate.

The ACC, as the name implies, flows around the continent of Antarctica in an eastward direction driven by westerly winds through the Atlantic, Indian, and Pacific Oceans. The ACC is as deep as 6,562–13,123 ft. (2,000–4,000 m.) and as wide as 1,243 mi. (2,000 km.), accounting for the vast transport of waters despite its relatively slow eastward current. It is estimated that some of the seawater of the ACC travels the entire circumference of the globe (24,900 mi.) in a mere eight years. For comparison, the ACC carries 150 times more water around Antarctica than flows through all of the world's rivers combined.

While flow of the ACC is not blocked by any landmasses, it is severely constrained by them. The borders of the ACC are further defined by convergence fronts with significant temperature and salinity variability. The greatest temperature change is north of the ACC in the Subtropical Convergence (Front), where the average sea surface temperature decreases from 54 degrees F (12 degrees C) to 45–46 degrees F (7–8 degrees C) in the ACC and salinity decreases from 34.9 or greater to 34.6 or less.

The southern boundary of the ACC is defined by the westward flowing Antarctic Coastal Current with a surface temperature around 30 degrees F (minus 1 degree C). Mean ACC temperature ranges from 41–30 degrees F (5 to minus 1 degree C). Climate change and ocean warming will likely have a significant effect on the ACC, because of this typically narrow temperature range. Any otherwise small increases in sea surface temperatures may induce dramatic effects on the system.

EFFECT ON THE CLIMATE

The ocean water temperatures of the ACC and the southern oceans play a critical role in the climate of the rest of the planet. Scientists have found that the ACC controls the climate of Earth in three ways. First, the ACC connects the world's major oceans (Atlantic, Pacific, and Indian), resulting in the redistribution of temperature and salinity. Changes in sea surface water temperatures can have severe impacts on regional weather patterns. Second, the vertical circulation of the waters of the ACC renews the deep waters of the world's oceans. This occurs as the waters freeze during the Antarctic winter and warm during the summer. The cooling of the surface waters during freezing increases the density of the water, causing it to sink, and dragging life-sustaining physical (heat and nutrients) and chemical (gases) resources from the surface to the depths, up to 2.5–3 mi. (4 or 5 km.) below the surface).

And, third, due to the vast size of the ACC, it contributes significantly to gas exchange with the atmosphere. It is estimated that the oceans contain 50 times the levels of carbon as the atmosphere on average, and the oceans act as a carbon sink, drawing carbon dioxide (CO_2) out of the atmosphere. CO_2 is produced by the burning of fossil fuels and deforestation and has been identified as a greenhouse gas. The ocean removes approximately half of the 6–7 billion tons of carbon that are released annually into the atmosphere.

MIXER OF THE DEEP OCEANS

The ACC is referred to as the ocean's mixer. The center of the current is the Circumpolar Deep Water. This water is a mixture of deep water from all of the world's oceans. The upper areas of this water are oxygen poor, where deep waters have been brought toward the surface by vertical circulation. The deeper waters are typically very saline, with primary sources in the Mediterranean Ocean (via exchange with the Atlantic). In the ACC, these "extreme waters" mix with waters from all of the oceans, including waters that are more oxygen rich and less saline, concomitantly forming a more uniform composite. This mixture is then redistributed to all of the world's oceans by the ACC, driven by wind, replenishing the deep waters and increasing overall ocean productivity.

Regionally, shifts in the ACC relocating warmer and colder waters can cause severe weather changes in those areas. While few landmasses are directly impacted by ACC contributions to weather patterns, these currents are carried far north, directly affecting some of the world's most populated areas. Further, organisms within the ACC are dependent on the stability of currents and temperatures in the ACC surface waters. Included in this are microorganisms, algae, phytoplankton, zooplankton, fish, and migratory species, including whales.

Warming of sea surface temperatures beyond the narrow range of 30–41 degrees F (minus 1 to 5 degrees) C will affect primary productivity (phytoplankton growth rates) in addition to survival, growth, and reproduction of all food web species. Researchers are most interested in the interaction of the ACC with the ice system of Antarctica (drift ice and the Antarctic Ice Sheet) and the global atmosphere. Knowing more about the transport of temperature and salinity by these waters will provide greater insight into climate modeling and predicting future climate conditions on Earth.

Antarctic Ice Sheets

ICE COVERS MUCH of the polar regions of Earth, and is a critical component to the planet's climate. An ice sheet is defined as a mass of ice that is greater than 31,067 mi. (50,000 km.) in area, such as those of Antarctica and Greenland. Ice sheets should not be confused with ice caps, which are masses of ice covering less than 31,067 mi. (50,000 km.) in area. It is estimated that approximately 90 percent of the Earth's total ice mass, or 27 million cu. km., is located in the Antarctic Ice Sheet. Scientists are concerned that increasing temperatures of air and sea will cause significant melting of the world's ice, including the Antarctic Ice Sheets, causing sea level rise.

Ice sheets, glaciers, ice caps, permafrost, snow, and sea ice are all components of the Earth's cryosphere (portions of the Earth's surface that are frozen over land or water). In the Southern Hemisphere, the Antarctic Ice Sheet covers approximately 98 percent of the Antarctic continent and is the single largest mass of ice on the planet. Ice sheets form as snow and frost build up in an area, compressing the previously fallen snow into ice. The total area of ice sheets is changed regularly by melting, primarily where the ice comes into contact with water or warmer dry land at its base, and by calving, or the falling off of large pieces of the ice sheet, which become known as icebergs. The Antarctic ice sheet covers the major landmass of the continent in the eastern Antarctic and extends over the ocean in western Antarctica. In western Antarctica, the ice sheet is as deep as 8,202 ft. (2,500 m.) below sea level.

The Antarctic continent is cold year round, and is extremely dry (desert; little to no annual precipitation). Because of this, the Antarctic ice sheet has historically experienced very little melting from the surface. Typically, the summertime melt that is experienced by the ice sheet is focused around the northern Antarctic Peninsula and the northeasternmost regions of the ice sheet. Most ice from the Antarctic ice sheet is lost by calving of glaciers from the protruding ice shelves of the sheet.

With climate in a constant state of flux on Earth, scientists have begun to give considerable attention to the warming trends that appear to exceed normal climate oscillations. While gradual melting and refreezing of ice is common anywhere on Earth, sudden large-scale melting of the polar ice sheets may have significant implications for local and global ecosystems. It is believed that the interaction of warming ocean waters and increasing air temperatures is contributing to the thinning and breaking up of the ice sheets. This disturbance of the ice sheets, and glacier tongues (extension of glaciers projecting seaward, typically afloat), primarily in western Antarctica at the ocean interface, has increased floating ice (drift ice), changing the ecosystem structure of this sensitive region. Long term, such disturbances may have a significant impact on macro-fauna, such as seals and whales, which are dependent on the ice sheet–water interface for feeding.

The contribution of melting ice to seawater will have a multitude of effects on global climate. While natural fluctuations of sea level do occur from gradual melting and thermal expansion, mean sea level has been on the rise in recent years. Data show that 1870–2001, mean sea level rose by almost 7.87 im. (20 cm.), whereas 1993–2006 global sea level raised an average of .12 in. (3.1 mm.) per year, or 2.7 in. (4.3 cm.) in 13 years. Experts are concerned that melting of the Antarctic ice sheet across its entire surface, not just minimally at the base and edges as is normally seen, accompanied by an increase in calving, may contribute to sea level rise. The Antarctic ice sheet accounts for about 61 percent of all of Earth's freshwater, whereas, together, the polar ice sheets of Antarctica and Greenland account for 98–99 percent of the freshwater ice on Earth. If the Antarctic Ice Sheet were to melt, over the next thousands of years there would be a 183.7 ft. (56 m.) increase in sea level, causing catastrophic scenarios. If the Western Antarctic Ice Sheet (WAIS) alone were to melt, there would likely be a five to six m. increase in mean sea level.

Approximately 150 million people live within one meter of high tide, and 250 million live within five meters of high tide. Melting of glaciers and ice caps is second only to thermal expansion of the oceans as the primary contributors to sea level rise. The immediate effects of melting are submergence and increased flooding of coastal zones. Under current coastal protection scenarios, and with the predicted 40 cm. rise in sea level by 2080, more than 100 million people will be flooded annually.

Beyond sea level rise, experts are concerned that the influx of freshwater to the oceans with the melting of the Antarctic ice sheet will significantly alter the salinity and temperature of the oceans, causing unpredictable effects on the ecosystems in this region. Such changes are known to affect the evaporation of the oceans to the atmosphere, potentially altering the precipitation events that contribute to the build up and maintenance of the Antarctic ice sheet. However, this rise in sea level will also force more saline waters further inland than has been experienced in recent times, flooding mangroves and coastal flood lands with seawater.

The breakup and collapse of the Larson B ice shelf, in 2002, off of the northern Antarctic Peninsula drew worldwide attention to the thinning and melting of the polar ice sheets. Experts report from sediment core records that a breakup of the ice sheet of this magnitude was unprecedented since the last Ice Age. Over the last 100 years, nine ice shelves around the Antarctic Peninsula have broken up. Reports by the National Aeronautics and Space Administration (NASA) indicated in 2002 that the overall mass of the Antarctic Ice Sheets were on the increase. Since then, satellite data compiled at the University of Colorado at Boulder suggests that, to the contrary, the amount of ice in Antarctica is actually decreasing.

Antarctic Meteorology Research Center

THE ANTARCTIC METEOROLOGY Research Center (AMRC) is part of the Space Science and Engineering Center (SSEC) at the University of Wisconsin–Madison's Graduate School. The AMRC collects most of its data from automatic weather stations. The center is funded by the National Science Foundation to make available daily composite images from weather satellite data. AMRC also monitors icebergs and has tracked the large iceberg B-15 since it calved in March 2000.

The AMRC was established in the 1992–93 austral summer season and initially consisted of work stations able to organize and display Advanced Very High Resolution Radiometer data, based on the existing satellite imagery acquisition system. This was followed by the acquisition and integration of a system that provided data collection, data display and archiving, scientific applications, network communications, and remote user access. The AMRC runs the Automatic Weather Station Project, which places automatic weather station (AWS) units in remote areas of Antarctica in support of meteorological research and operations. The AWS data are recorded by the ARGOS Data Collection System (DCS) on board the National Oceanic and Atmospheric Administration (NOAA) series of polar-orbiting satellites.

Antarctica is the highest and coldest continent in the world. 97 percent of its territory is covered with ice with an average elevation of 2,300 meters and an average annual temperature of minus 31 degrees F (minus 35 degrees C). Since large portions of Antarctica are difficult to reach regularly by humans, the idea of an automated system appealed to many, and thus the AWS project was born. Maintaining staffed sites for collecting meteorological observations was considered too expensive. An automatic weather station would allow the gathering of important weather information without having to have a person on duty at each site.

DATA COLLECTION

These stations have proven to be an invaluable resource for researchers and forecasters, as well as the public for the retrieval of important meteorological information about the Antarctic. At the end of the 2003–04 field season, just under 60 stations were operational in the Antarctic. Three new sites, Wanderer, Vito, and Emilie were added during the 2003–04 field season. As of 2004, Amundsen-Scott Station at the south pole was the only year-round interior station in Antarctica with personnel. The remaining year-round stations are located on the Antarctic coast at sites that can be reached by ship.

Charles R. Stearns, the principal investigator and founder of the AMRC, was the man behind the AWS. A renowned polar researcher for over two decades, Stearns began the AWS project at the University of Wisconsin in 1980 by purchasing the first AWS designed at Stanford University. These stations were then modified for transfer on location in Antarctica. The purpose of the AWS's was to allow for the first meteorological data to be acquired for the continent. The data from the AWS systems are transferred back to the University of Wisconsin for processing and distribution to the public free of charge. The weather stations are 10 feet tall and are equipped to record temperature, humidity, air pressure, and wind speed and direction. The cost of each station is approximately $15,000.

The automatic stations were mounted onto the frozen water of an iceberg or ice sheet and also include a global positioning device to track their migration with the ice. In addition to the 50 stations which are part of the University of Wisconsin's network, there are others that are used for research programs at British, French, German and Japanese sites. The AMRC stresses that the project entails a great degree of international collaboration and cooperation. After processing the temperature readings and barometric levels collected by the stations, the AMRC passes them on to international weather labs and researchers. The Man-Computer Interactive Data Access System (McIDAS) is a versatile computer-based system developed by the University of Wisconsin that is the basis of AMRC. It allows the organizing, manipulating, and integrating of environmental data. It receives the flow of Antarctic meteorological information from polar-orbiting satellites, automatic weather stations, operational station synoptic observations, and research project data.

The real-time data used to forecast also can be used to develop accurate forecasting models for future climate change. Computer programmers integrate these data into equations and design programs to predict climate change phenomena, such as global warming. It was thanks to the data collected by the automatic weather stations that the center was able to conclude that El Niño, which contributes to the warming up of the tropics, also extends its effects to the Arctic region.

The position of the AMRC and its staff with regards to iceberg breakage and global warming has been to deny a clear connection between the two. In 2002, it became apparent that another massive iceberg had broken off from the Ross Ice Shelf, reducing the Antarctic formation to about the size it was in 1911 when explorer Robert Scott's team first mapped it. Yet, through Stearns and other researchers, the AMRC stated that the breakage is part of the normal iceberg formation or "calving" that comes as thick layers of ice gradually slide down from the high Antarctic plateau, and is not related to climate changes or global warming.

Stearns and his assistant Mathew Lazzara have repeatedly stressed that icebergs break due to natural phenomena, not because of global warming. Admitting that the iceberg detaching in 2002 was unusually large, Lazzara maintained that the phenomenon was entirely natural, although not one frequently witnessed. Lazzara explained that "as the ice shelf develops and gets influences from the ocean it starts to deteriorate where the ice meets the ocean waters. The ocean tides act upon it, causing it to crack and wearing it away. The ocean currents and the tides are responsible for getting it going and putting it into motion." Charles Stearns explicitly denied that global warming was a factor in the break off and concluded that the piece of iceberg might have been in motion for the past 30 years: "Climate change is not a factor in the break off, although people try to use the event to further their objectives. If the ice did not flow off Antarctica, all the water in the oceans would be deposited there. Be glad that all the water in the world does not collect on Antarctica."

Anthropogenic Forcing

ANTHROPOGENIC FORCING IS one of two parts of radiative forcing in the classification used to describe disturbances in the Earth's energy budget when humans are considered as a factor to the Earth's climate system. The radiative forcing (in units of watts per m. squared) is the net downward radiative flux at the surface or at some level in the atmosphere, usually at the top of the atmosphere or at the tropopause. In atmospheric and climate sciences, the radiative forcing is used to predict surface climate response and for comparative studies of different forcings. A synonym for anthropogenic forcing is human-induced forcing. The other part of radiative forcing is natural forcing, which is a disturbance of the Earth's energy budget without human direct or indirect influences. Examples of natural forcing are volcanic eruptions, solar variability, or changes in a space object's orbital parameters.

Anthropogenic forcing is a change in the Earth's energy balance due to human economical activities. Human economical activities cause changes in the amount of atmospheric radiatively active gases; in the amount of gaseous precursors of atmospheric aerosols and atmospheric ozone (O_3), and in the Earth's system's albedo. Radiatively active gases, such as carbon dioxide (CO_2), methane (CH_4), nitrous dioxide (N_2O), and chlorofluorocarbons (CFCs), are mixed well in the atmosphere, while O_3 and atmospheric aerosols have regional structures due to their shorter turnover (lifetime) in the atmosphere. Changes in the radiatively active gases' atmospheric concentrations are accounted for by changes in the their emissions. Changes in O_3 and atmospheric aerosols are defined by emissions of their gaseous precursors. Changes in Earth's system's albedo are related to changes in land-use practices, reflective aerosols emissions, and changes in cloud cover due to air pollution and climate change.

It is assumed that changes in radiatively active gases, aerosols, and the Earth's system's albedo due to natural causes are small in comparison to changes from human economical activities. The unique radiatively active gas is an atmospheric water vapor, which has both direct (via irrigation and land use) and indirect (via change in cloud cover) influences from human economical activities. The phrase *greenhouse gases* combines radiatively active gases, O_3, and water vapor in one class. For policy applications, the total of atmospheric radiatively active gases is represented by an equivalent amount of CO_2.

Regional and temporal anthropogenic forcing strength can be calculated using an approach that requires estimation of a few parameters: the radiative forcing per unit emitted quantity (usually in watts per square m. per mass), an emission factor (usually in mass per unit of human economical activities), and a quantity of a particular human economical activities per unit time. Rigorous anthropogenic forcing estimation is difficult, as it carries uncertainties from every step of its calculation. Each step is based on an accuracy of information provided by a particular science: social science in description of social infrastructure of a region or a country, economics for human economical activities quantification in terms of emissions and land use, and atmospheric and climate sciences for radiative forcing calculations and conversion of the emissions to the atmospheric concentrations.

Regional anthropogenic forcing estimation is complex. Human economical activities are classified in primary, secondary, and tertiary industries. Primary (agriculture, forestry, and mining) and secondary (construction and manufacturing) industries are the main direct emitters and controllers of land use. In tertiary industries, the transportation, electricity, and gas suppliers are the main air polluters. Population, wealth, leadership, and technology are factors that define specification of the human economical activities by region.

A desirable goal for constructing accurate anthropogenic forcing estimates and projecting them into the future is to define a set of main pathways from a particular human economical activities to anthropogenic forcing, which takes into account all direct (emissions—forcing) and indirect (emissions—climate system—forcing) influences and resolves feedback loops in the Earth's system on the time scale much smaller than the period chosen for anthropogenic forcing estimation. When only the global or hemispheric changes in radiative forcing from the pre-industrial time to present are taken into account, calculation of anthropogenic forcing is based on assumptions of how the radiative forcing depends on the historical evolution of each radiatively active gas or precursor concentration or their emissions. For example, because CFCs have low concentrations in the atmosphere, their radiative forcing increases linearly with concentration.

These assumptions are derived from the numerical models, which accurately calculate the atmospheric distribution of the radiative fluxes for small temporal and spatial variations in each radiatively active agent. For aerosols, as they stay in the atmosphere only for a short time and have a large spatial variability in concentrations and radiative properties, estimation of their radiative forcing is based on inverse modeling, when the radiative forcing is constrained from aerosols' hemispheric asymmetry and observed temperature record, and on aerosols models built from the first principles. It is assumed that the total radiative forcing is a simple sum of its parts.

According to radiative forcing calculations, anthropogenic radiatively active gases make the largest warming contribution to changes in anthropogenic forcing from pre-industrial times. The contribution from the anthropogenic aerosol and land use is very uncertain in magnitude and patterns. Except for black carbon, most of the aerosols have a cooling effect. The indirect effect of the aerosols is larger than its direct effect. The contribution from airplane contrails is small.

Anticyclones

ANTICYCLONE IS A term for a region of closed circulation of air in the troposphere (the lowest 6 mi. [10 km.] or so of Earth's atmosphere) with descending air from aloft and high atmospheric pressure at the surface. Anticyclonic circulation is usually accompanied by relatively high atmospheric pressure at the surface, and so the term *high* is often used interchangeably with *anticyclone.*

Anticyclones, as the name suggests, are the opposite of cyclones, which are regions of low pressure and typically associated with clouds, precipitation, and storms. On a surface weather map, meteorologists often denote anticyclones with a capital letter "H," and cyclones by a capital "L." Unlike cyclones, anticyclones are not usually associated with weather fronts. Anticyclones are sometimes referred to as ridges of high pressure. This is not quite accurate, as an anticyclone is a closed circulation and a ridge is not, but both are associated with regions of high surface pressure.

Anticyclones are typically characterized by descending air, high surface pressure, clear skies, and calm winds. In the mid-latitudes, anticyclones and cyclones are transient eddies steered by the westerly wind belt at the boundary between warm tropical and cold polar air masses. In subtropical and polar regions, anticyclones are semi-permanent features of the general circulation of the atmosphere, associated with some of the world's major arid regions.

The descending air associated with an anticyclone suppresses convection, and causes the air to become warmer and drier through the process of adiabatic heating. As a result, the weather associated with an anticyclone is generally fair skies and clear weather, with relatively high pressure at the surface. The circulation of surface winds around an anticyclone rotation is outward from the center of high pressure, and is deflected by the Earth's rotation. The result is a clockwise spiral outward from the center of high pressure in the Northern Hemisphere, and counterclockwise in the Southern Hemisphere. This difference is the result of the difference in the direction of motion deflection by the Coriolis effect in each hemisphere—to the left of motion in the Southern Hemisphere, and to the right in the Northern Hemisphere.

In the mid-latitudes of both hemispheres, cyclones and anticyclones are transient features that develop and dissipate as embedded eddies in the Rossby (or planetary) waves of the westerly wind belt, steered generally from west to east by the polar jet stream. Regions in which anticyclonic circulation is a primary, semi-permanent feature of climate (persistent and dominant), such as the subtropical highs, are associated with some of the world's great deserts such as the Sahara in Africa, the Atacama in Peru, and central Australia.

Historically, ocean regions at subtropical highs were described as the doldrums or horse latitudes, becalmed areas in which mariners might find themselves stranded at sea for extended periods. In extreme cases, mariners would be forced by food and water shortages to either eat or jettison the horses aboard, thus the horse latitudes. The polar regions are also areas in which persistent anticyclones, or highs, dominate general circulation. The Siberian High is an example of a semi-permanent, high-pressure region that significantly affects climate in the high northern latitudes of Europe.

Changes in climate resulting from anthropogenic emissions of greenhouse gases will likely affect patterns of global general circulation and influence the development of high and low pressure systems. The consequences of global climate change on anticyclones are challenging to predict in detail. Increased persistence and development of anticyclones would enhance warm, dry conditions, thereby increasing the risk of droughts, heat waves, and forests fires.

Antigua and Barbuda

ANTIGUA AND BARBUDA, located in the Caribbean, are part of the chain of islands known as the Leeward Islands. The two main islands of Antigua and Barbuda have, respectively, land areas of about 100 sq. mi. (281 sq. km.) and 57 sq. mi. (161 sq. km.), with a total population of 82,786 (2005 est.), the vast majority of whom live on the island of Antigua, with the island of Redonda, which is currently uninhabited, having dependency status. Antigua and Barbuda have a population density of 394 per sq. mi. (184 per sq. km.).

The main environmental problems facing Antigua and Barbuda are hurricanes and tropical storms from July through October, and irregular droughts. In terms of carbon dioxide per capita, Antigua and Barbuda rank 78th in the world, with 4.8 metric tons of carbon dioxide per capita in 1990, and the amount falling and rising slightly until 2003 when the country exceeded its 1990 figure, recording 5 metric tons per person. In recent years, there has been a steady bleaching of coral reefs near Antigua, with the rising temperature of the waters also affecting the diversity of fish in the coral reefs. It is also expected that with the rising sea level, parts of Antigua and Barbuda that are low-lying could be flooded.

Antigua's role in global warming is related to its tourist industry. This is both in terms of the flights to and from the country taken by tourists, often from distant locations, and also the heavy demand the tourists make on the infrastructure of the island in terms of power (most of which is produced through using liquid fuels) and water usage, as well as increasing the amount of imported food and produce on the island. To try to offset this, there have been proposals since the mid-1980s to try to harness wind energy.

To combat climate change and global warming, the government of Antigua is a party to the Kyoto Protocol to the United Nations Framework Convention on Climate Change, having signed it on March 16, 1998, and ratifying it on November 3, 1998. On June 4, 2007, W. Baldwin Spencer, the prime minister and foreign minister of Antigua and Barbuda, in his speech to the 37th Session of the Organization of American States Assembly in Panama City, urged that greater action should be taken in the world to confront climate change. Antiguan delegates have also taken part in raising the issue of climate change and global warming at other international forums. However, some have challenged Antigua's environmental status under the government of Vere Bird and his son Lester Bird because Antigua traditionally votes with Japan on the International Whaling Commission (against the protection of whales), and has done little to reduce the heavy reliance on tourists using air travel.

Applied Energy Services, Inc.

APPLIED ENERGY SERVICES, INC. (AES) is a global power company providing energy to five continents (all but Australia and Antarctica). Since its founding in 1981, AES has expanded globally with a purpose of bringing safe electric power to people, including those who have never before had access to it. To this end, the company uses the slogan *The Power of Being Global*. The first AES power plant was built in Texas in 1985; the AES power plant cadre subsequently increased to four U.S. plants by 1989. Three additional plants were constructed in California, Oklahoma, and Pennsylvania.

Within the next decade, AES had expanded its business into the global market, supplying power to Argentina, Brazil, China, Hungary, Pakistan, the United Kingdom, and other countries. AES was the first U.S. power company to provide service to China. Further expansions included Bulgaria, Cameroon, Oman, Qatar, Sri Lanka, West African, and Central American nations. In 1988, AES, in partnership with other companies, became a member of the only privatized power generator in India.

AES is researching cleaner forms of energy, such as wind and solar power, and other means of environmental protection. Two decades after building its first U.S. power plant, the first AES wind farm was built in Texas, in 2006. The European countries of Bulgaria, France, and the United Kingdom also boast new AES wind farms. AES may also expand into liquefied natural gas. AES is also a partner with United Kingdom–based AgCert in AES AgriVerde, a coalition dedicated to reducing greenhouse gas emissions by tens of millions of tons per year, by the year 2012. Additionally, through other environmentally conscious endeavors, including capturing methane released by power generation reactions, the company plans to further reduce emissions by equivalent values. The power plants that participate in the emissions reductions are selected plants from Africa (northern), Asia, and Europe.

In the late 1980s, AES spearheaded a 10-year campaign to plant 52 million trees in Guatemala. The company is also reforesting an area along Brazil's Tiête River with native plants. In addition, since 1999 AES has invested more than $150 million to reduce emissions in coal-fired New York power plants that. At AES Greenidge, located in Dresden, New York, researchers investigate cleaner methods for harnessing power from coal. In Africa, Europe, and Kazakhstan, AES manages 24 power plants, employing more than 14,000 people. A total of 13 generation plants employing nearly 700 people supply Asia and the Middle East. Central and South America combined have 48 AES generation plants, with 10,000 employees. Finally, North America houses 33 power plants that employ more than 3,000 people.

An executive office, led by a president and chief executive officer, manages AES. An executive vice president manages each of the four regions in which AES provides power. There are also officers leading the AES divisions of Alternative Energy; Business Excellence; Communications; Energy and Natural Resources; Finance; Forecasting, Strategy and Risk Management; and Legal. Additionally, AES has a board of directors, with four standing committees. Members of these committees work to guide the company in the areas of Compensation; Finance and Investment; Financial Audits; and Nominating, Governance, and Corporate Responsibility. In the AES company guidelines, corporate responsibility is a global responsibility to provide safe, reliable, and responsible energy to all its recipients.

Arakawa, Akio (1927–)

AKIO ARAKAWA HAS been a leader in the field of atmospheric general circulation model (AGCM) development from its beginning. AGCMs are essential tools for studies of global warming and projecting the consequences of anthropogenic climate change. Arakawa's inventiveness and extraordinary insight on atmospheric processes have resulted in fundamental contributions to the design of AGCMs in several areas, primarily: 1) numerical schemes suitable for the long model integrations required by climate studies; 2) modeling of cloud processes including cumulus parameterization; and 3) modeling of planetary boundary layer (PBL) processes. His work has influenced the design of practically all numerical weather and climate prediction models.

Arakawa obtained his B.Sc. in physics and D.Sc. in meteorology from the University of Tokyo in 1950 and 1961, respectively. From 1961 to 1963 he visited the University of California Los Angeles (UCLA) and worked with Yale Mintz on developing the Mintz-Arakawa AGCM, the first among several generations of what would be the UCLA AGCM. Versions in each generation (currently the VII) have been made available to other institutions for further development and application. In 1965, Arakawa joined the faculty at UCLA, where he is currently Professor Emeritus and Research Professor.

In AGCMs the governing equations of fluid motion are written in a format suitable for numerical integration with a high-speed computer. The format used is particularly important in long-term integrations, since inadequacies can result in distortion of the solutions and unrealistic amplifications of kinetic energy. Arakawa designed elegant numerical schemes in which such unrealistic amplifications cannot occur and distortions were reduced. The schemes guarantee that flow properties constrained to be either constant or bounded in the continuous equations remain so in the corresponding expressions numerically solved by the computer. In this way, he derived the Arakawa Jacobian in late 1961, which was followed over the years by the derivation of families of numerical schemes for AGCMs.

The most widely influential of Arakawa's works in the context of global warming and climate change has been the parameterization for AGCMs of the effect of clouds generated by convection. The parameterization problem consists of formulating the collective effect of processes not resolved by the model grid in terms of the resolvable-scale prognostic variables, and is a crucial part of general circulation modeling. Arakawa struggled with the cumulus parameterization problem for several years. The breakthrough came in collaboration with his graduate student Wayne Schubert during the early 1970s. The basic tenet in the Arakawa-Schubert parameterization is the approximate cancellation (quasi equilibrium) between destabilization of the atmosphere by large-scale processes and stabilization by convection. Arakawa and several of his students would later refine the original formulation. The parameterization is still used today in different versions, including the Relaxed and Simplified Arakawa-Schubert schemes (RAS and SAS, respectively).

Arakawa has also made major contributions to the parameterization of PBL processes. These determine the complex interactions between the atmosphere and Earth's surface and as such must be represented correctly in climate models. PBL processes, however, are dominated by turbulent transport and mixing, which AGCMs in general cannot explicitly resolve. Furthermore, the PBL can be topped by stratiform clouds, which are also difficult to explicitly resolve. Errors at the surface due to misrepresentations of PBL cloud effects can spuriously amplify due to feedbacks, particularly over the ocean.

For the parameterization of PBL processes, Arakawa adopted a unique framework based on including a variable depth PBL in the model, which becomes the lowest layer in the UCLA AGCM generation IV. The PBL depth is explicitly predicted using the mass budget relationship, in which mass at the top can be added through turbulence processes and removed by cumulus mass flux for given large-scale conditions above the PBL. The latter term can be provided by the Arakawa-Schubert cumulus convection parameterization. In this way, interactions between PBL and cumulus convection processes can be modeled.

The increased power of computers has challenged the unambiguous separation between resolvable processes, which can be highly transient, and parameterized unresolvable processes, which can only be near a statistical equilibrium. Arakawa is currently working on the unification of those formulations and the reduction of the artificial dependency of model physics on grid size.

Arctic Ocean

THE ARCTIC OCEAN is one of the Earth's environments that will be most affected by climate change. As the Earth continues to warm, the Arctic Ocean will evolve into an environment that is much different from what is recognized today. Most of the animals currently living there will not be able to survive if this region warms too much. In addition, warming Arctic waters could affect ocean circulation elsewhere in the world.

The Arctic Ocean is unique in its physical properties. It has both the narrowest and the widest shelves on Earth due to glacial erosion, marine abrasion, and progradational clastics. It is a tectonically active region in which the closed-off basin of today developed in the Cretaceous (90 million years ago). The seafloor forming at the mid-ocean ridge in the Arctic is the slowest ridge system of any on Earth today.

The Lomonosov Ridge divides the ocean in half, creating the younger and deeper Eurasian (Eastern) basin and the older and larger Amerasian (Western) basin. The Amerasian Basin is divided by the Alpha Ridge into the Makarov Basin to the north, and the Canadian Basin to the south. The Alpha Ridge connects to the Mendeleev Ridge to the north. The Arctic Ocean is approximately 50 percent continental shelf, resulting in much of the sea floor being only 1,640–6,562 ft. (500–2,000 m.) below sea level.

The Arctic Ocean is the most extreme region on Earth in terms of climate and seasonality because of light and ice cover. The ocean covers an area of approximately 14,056,000 km^2 and extends below the Arctic Circle in some locations. The average depth is just over 3,280 ft. (1,000 m.), with the deepest location in the Eurasian Basin at 17,881 ft. (5,450 m.) The Arctic Ocean is surrounded on all sides by land except for narrow connections to the Atlantic and Pacific Oceans. The Atlantic water flows through the Fram Strait (8,530 ft. [2,600 m.] deep), where the largest amount of water flows into the Arctic. The other is from the Pacific Ocean through the Bering Strait, a shallow connection (164 ft. [50 m.]) that has intermittently closed during glacial periods over the past few million years.

The Arctic water column is strongly stratified into three layers: the shallow, relatively fresh surface layer; the intermediate layer; and the deep salty layer. The shallow layer obtains its water predominantly from melting ice sheets, icebergs, and river runoff. Because of its low density, this layer, approximately 9.8 ft. (3 m.) deep, creates a relatively fresh water film that easily freezes. It is because of this film and the freezing temperatures that the center of the Arctic Ocean is frozen year-round. The intermediate layer receives its water from the salty waters of the North Atlantic. The deep water forms through convection and has a very slow exchange with a residence time of 450–500 years (about half that of the world ocean residence time of 1,000 years).

Large amounts of freshwater come from rivers, specifically from the Russian rivers Yenisei, Ob, and Lena, and the Canadian MacKenzie River. Together, these rivers contribute 2,000 $km.^3$ a year of water. This influx of freshwater into an environment that is so cold creates a film of water on the surface because of the density difference and hence freezes solid. During the winter, there is $14x10^6$ $km.^2$ of sea ice, and about half of that in the summer. This number has decreased over the past several years, causing detrimental effects on the climate and resident species. The ice is critical for the heat exchange budget in the Arctic, as well as for sustaining life, from viruses, to polar bears, and subsistence hunters.

Because ice forms and leaves behind salt, during glacial periods the water is more saline due to an increased volume of sea ice. As the ice melts during interglacial periods, the surface layer becomes increasingly fresh, creating a deeper film of fresh water that does not mix with the rest of the water column. During this warmer period, there is more productivity in the surface layer, which allows more food and nutrients to sink to the bottom. It is this relationship between the surface layers and the deep sea that is recorded in the fossil record. The dominant surface productivity is from the phytoplankton that thrive in the summers due to 24 hours of light, and struggle to survive during the winter when there is 24-hour darkness.

MARINE LIFE

The structure of the water column influences biological productivity in the Arctic, making it unique in its biological properties. It hosts animals such as walruses, whales (belugas, narwhals, and bowheads), and seals. Other marine animals include squid, flatfish, Greenland halibut, worms, snails, crabs, shellfish, and krill. Polychaetes, crustaceans, and bivalve mollusks dominate the benthic macrofauna.

Many microscopic animals such as zooplankton, diatoms, copepods, and foraminifera also live in the freezing waters of the Arctic water column (planktonic) and on the sea floor (benthic). The most important primary producers are phytoplankton. However, the growing season is restricted because of the short summer season, low light angles, and the snow and ice cover. The season is between April and September with a single peak, June to July. With the retreating ice on the shelves during these summer months, an algal bloom is possible near shore.

The Arctic deep sea has been widely ignored because of the thick sea ice. Initial studies show little diversity in this area, with a dominance of deposit feeders. Dominant animals include polychaetes, crustaceans, and bivalve mollusks. Occasional tunicates, sponges, cnidarians, ophiuroids, and several species of worms have also been found. Approximately 350–400 species have been found so far in the deep central Arctic Ocean. The long-believed hypothesis that species diversity decreases with higher latitudes is being reconsidered as more species are discovered in the central Arctic. As more research is conducted in this region, the known species diversity is increasing, discounting this outdated theory.

In the Arctic, as in all high latitudes, the food cascading to the bottom of the is the limiting factor for

Many small but important forms of life underneath the ice of the Arctic Ocean still have not been adequately studied.

the benthos, not temperature, as the benthos organisms in the Arctic are adapted to the freezing temperatures. However, they need food for survival and can only obtain it from organic matter produced in the surface waters. In the shallow shelf areas during the ice-free periods, particle transport is abundant. The benthos, therefore, play an important role in the system and production of the Arctic waters.

Although collection of the pelagic organisms has gone on for over a century, many of the taxa are understudied. Only the larger organisms, mostly near shore, are well understood because of their ease of collection. Smaller taxa, deep-water organisms, and the gelatinous forms have been missed by current sampling techniques, therefore, scientists know little about these organisms.

Macro- and megafauna have received the most attention in the Arctic waters, while the meiofauna and microbial communities have been persistently ignored. This is, more often than not, because of sampling techniques and the ease of capture in the ice-filled environment. However, in terms of the quantity of organisms, there are more microbial animals per square meter than there are megafauna. There are still many species of microscopic organisms that have not been identified and further study of the microbial world will enhance knowledge of the Arctic system.

Polar bears also venture into the frozen waters, using floating icebergs as islands on which to rest before venturing onward. With the warming of the Earth and Arctic climate change, these icebergs are not as prevalent as they once were, and the polar bears are having difficulty without these resting places. In addition to the deteriorating climate, there are still many mysteries about marine life, both macro- and microscopic, and how the interaction of these many species sustains an environment that allows life to flourish despite the harsh conditions.

SEA ICE

The Arctic sea ice contains its own unique biodiversity with many endemic species. Specialized sympagic (ice-associated) communities live in brine pockets on top of the ice and in the ice-water interface. Flagellated protists, diatoms, and ice algae account for most of the primary productivity in the ice community. Protozoan and metazoan organisms (in particular turbellarians, nematodes, crustaceans, and rotifers), make up a portion of the ice community. Larvae and juveniles of some benthic animals migrate seasonally into the ice to feed on the algae in shallow waters. All of the organisms that live on and around the ice play a vital role in feeding the benthos. The climate cycle of melting and freezing causes these organisms to fall to the sea floor, creating food for the organisms living on the bottom.

The sediment record left by the sea ice can be used to reconstruct glacial/interglacial cycles. When sea ice and icebergs melt, they drop the ice rafted debris (IRD) that was contained within the ice as it scraped across the land and into the ocean. Sediment with abundant foraminifera and large sediment clasts is deposited during interglacial (interstadial) periods. Sediment that is mostly fine-grained, with few to no foraminifera, is deposited during glacial (stadial) periods. However, the lack of foraminifera in a sediment sample can also be a result of low surface salinity, a decrease in nutrients, dissolution of tests, a high sedimentation rate, or a thick layer of sea ice, causing difficulty in reconstructing glacial cycles.

The perennial sea ice is increasingly thinning, and there is a seasonal hole in the ozone layer over the North Pole. The thinning sea ice is having an effect on global albedo (amount of sunlight absorbed versus reflected back out of the Earth's atmosphere). Ice reflects more sunlight than it absorbs, so it has a cooling effect on the Earth. Without this ice to reflect the sun's rays, more heat will be absorbed, causing the Earth to warm. This causes a positive feedback that will continue to warm the earth, melting more sea ice. This is a concern because the added fresh water to the global marine system could cause a shutdown of the thermohaline circulation through the connection between the Arctic and Atlantic Oceans.

PROBLEMS WITH THE ARCTIC RECORD

The Arctic contains many records of past environments that scientists have used to recreate past climates. Bottom water temperatures can be inferred from calcite pseudomorphs such as ikaite ($CaCO_3 6H_2O$), an organic-rich mineral that accumulates in the sediment. Biomarkers such as algae, dinoflagellates, diatoms, and foraminifera are used for their stable isotopes to infer temperature and salinity over the past several million years. The $^{18}O/^{16}O$ values in these inorganic carbonates reflect sea ice and ice sheet variations through time. These can, in turn, be used to model glacial/interglacial periods. $^{13}C/^{12}C$ values in planktonic organisms reflect variation in productivity or sediment carbon flux from the surrounding continents.

The unique isolation of the Arctic Ocean may be a factor in maximizing the amplitude of some environmental signals in the sediment record. The water column is more strongly stratified than in most other parts of the world. However, throughout history, as the passageways between the Arctic Ocean and the Pacific and Atlantic Oceans opened and closed, this record was modified. Deep ocean waves may have also modified the sedimentary record. As water currents flow around the ridges on the ocean floor they move the sediment and replace it with sediment from other parts of the sea floor. Bioturbation also plays a role in the modification of the sediment record.

Modification of the sediment in the Arctic Ocean creates even more difficulty in reconstructing the history of this basin. The Arctic has extremely low sedimentation rates, so any disruption in the record could potentially create huge problems with dating and isotope analysis. The sedimentation rate is low in the Arctic for several reasons: the major reason is due to the presence of sea ice. It prevents most, if not all, sediment from settling onto the sea floor anywhere that is covered in ice. This, however, is one way that scientists can reconstruct glacial/interglacial cycles. At the beginning of every interglacial cycle, more sediment accumulates because it is dropped from icebergs and sea ice through melting. This can also be seen in the additional sediment discharge from the Arctic rivers.

Collecting enough material for stable isotope and trace element analysis can also be difficult, especially because during glacial periods when sedimentation and productivity are extremely low, there may not be any biological material to collect. During interglacial periods, there is typically enough material; however, in the event of a melt-water pulse or extreme melting, the amount of sediment is much higher than the number of organisms. This makes picking out acceptable specimens difficult. Dissolution is another problem in the Arctic Ocean. In many locations, any calcite will have dissolved before reaching the sea floor without leaving a record to what was present at one time. This also makes comparison across the ocean difficult because dissolution takes places at different times in different areas, creating hiatuses that only appear in certain sediment cores. This is usually caught when material is dated, but the dating of some cores is impossible.

Yet another problem with the oceanic record in the Arctic is the difficulty in getting to it. The field season is short, typically from late July to early October, because of sea ice. Even during this time, an icebreaker is needed to clear a path for ships to pass through, making it expensive and dangerous. Even with an icebreaker, the ice in the central Arctic is too thick to break through, and, therefore, almost impossible to study. Political boundaries also play a role in the scientific study of the Arctic. Seafloor sampling and imaging, especially on the Russian shelves, may be unwanted by foreign governments. This is especially true in areas with natural resources and suspected or known illegal dumping.

As knowledge of this region expands, scientists will gain insight into the dynamics of the past and present world climates. This information can then be used to model future climate changes that will aid in the prediction of how life will need to respond to the changing global climate. However, despite the importance of this region, the Arctic Ocean is one of the least studied places on Earth. Due to the harsh environment and perennial sea ice, this location is difficult to access. The knowledge obtained from sampling is also biased toward effort spent on certain taxa, specific regions, and techniques used for the acquisition of this data. The shallow Arctic shelves are the most studied, especially during the summer months when the sea ice melts back. The Canadian Basin is the least studied because it is covered in ice year round. There is much more that needs to be studied in this complex system of ice, water, land, and life.

Argentina

THIS LARGE LATIN American country occupies the southeastern part of South America, covering 1,073,514 sq. mi. (2,766,890 sq. km.), with a population of 40,301,927 (2007 est.), of whom some 12 million live in Buenos Aires, the capital, giving the country a population density of 36 people per sq. mi. (13.7 people per sq. km.), although this varies from 14,651 people per sq. km. in Buenos Aires, to 1.4 people per sq. km. in Patagonia. Nine percent of the land is arable, and 52 percent is used as meadow and pasture, especially for cattle. Argentina has the highest per capita number of cattle, at 50,869 cattle per 1,000 people. The heavy reliance on the cattle industry has led to the desertification of some parts of the country, and has contributed to very high methane emissions.

It has been calculated that about 44 percent of the country's carbon dioxide emissions come from the cattle industry or other parts of the agricultural sector, with 70 percent of those from methane from the 55 million cattle. As a result, many of the attempts to reduce the greenhouse gas emissions of Argentina have centered on the cattle industry, with cows from Argentina producing larger emissions than their counterparts in Brazil and Uruguay. The first attempts have focused on trying to change the diet of the cattle on the basis that the simpler the diet, and the less problems in digesting the food, the lower the level of greenhouse gas emissions; this also improves in the reproductive cycle of the animals.

When implemented, these measures are expected to reduce greenhouse gas emissions in Argentina by 10–20 percent. The country is also one of the largest producers of soybeans, the production of which also contributes to the output of greenhouse gases. This is largely because the soybean, when growing, emits nitrous oxide, which is about 300 times stronger than carbon dioxide. The deforestation of some areas to increase soybean production has made the problem worse.

Methane from waste dumps around Argentina has also been identified as a problem, and these are estimated to contribute about 5 percent of Argentina's total greenhouse gas emissions. Businesses are trying to extract the methane for use, rather than simply burning off the gases. A substantial part of the population has a high standard of living, using significant amounts of electricity, and contributing to a high private automobile usage. The Argentine press regularly criticizes the wastage of natural gas, the continued reliance on fossil fuels, especially extensive use of gaseous fuels, and the minimal use of solar technology. Some 51.8 percent of the electricity generated in Argentina comes from fossil fuels, with 40.6 percent from hydroelectric power, 7.2 percent from nuclear power, and the remainder from other sources. Hydroelectricity comes from a number of dams located around the country.

While contributing to greenhouse gases, Argentina has also faced many problems from global warming. Since the heavy rains in Buenos Aires in May 2000, when more than four times the average monthly rainfall fell in less than a week, there have been very high rainfall figures, whereas, by contrast, rising temperatures have resulted in severe water shortages in La Pampa province, despite some flooding around the Argentine-Uruguayan border from August to October 2001. The most noticeable effects of global warming have been in southern Argentina. It has been estimated that the glaciers in Patagonia have receded, on average, by as much as a mile since the late 1990s, and the Upsala glacier, located in the Los Glaciares National Park, once the biggest in South America, is now losing 656 ft. (200 m.) per year. The warmer temperatures have also seen a large increase in plant life in the Argentine islands in the Antarctic region, such as Antarctic pearlwort and hairgrass.

The Argentine government of Carlos Menem took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and in October 1997, D.A. Blasco from Argentina addressed the Fifth World Bank Conference on Environmentally and Socially Sustainable Development in Washington, D.C. In November 1998, President Menem made Argentina the first developing country to adopt binding targets for reducing emissions from greenhouse gases, and was one of the first countries to set exact targets.

This followed meetings held at Buenos Aires earlier that month in a follow-up meeting to that held in Kyoto. The ministry of social development and the environment in Argentina has managed to implement a number of policies to combat climate change, and the government of President Nestor Kirchner has argued that work on climate change should include recognition of the environmental debt that has been generated by forcing new rules on developing countries.

Arizona

ARIZONA HAS AN area of 113,998 sq. mi. (295,252 sq. km.), with inland water comprising 364 sq. mi. (942.8 sq. km.). The state's average elevation is 4,100 ft. (1,250 m.) above sea level, with a range in elevation from 70 ft. (21 m.) above sea level on the Colorado River to 12,633 ft. (3,850 m.) on Humphrey's Peak. The state has a variety of elevation regions, with the high plateau in the northeast with elevations of 5,000–7,000 ft. (1,524–2,134 m.), a mountainous region running in a diagonal from the southeast to the northwest ranges from 9,000 to 12,000 ft. (2,743–3,656 m.), and in the southwest the land is primarily made up of desert interspersed with low mountains.

The climate is dependent on the elevation, with warm summers and mild winters, except in the high plateau, which has cool summers and cold winters. The air is generally dry and clear with a relatively low humidity (August humidity in Phoenix is 38 percent, Flagstaff 55 percent, Winslow 46 percent, and Yuma 33 percent) and much sun. Precipitation is governed by elevation and seasons.

Average annual precipitation on the high plateau is approximately 10 in. (.25 m.) Summer rain early July to mid-September comes from moisture-bearing wind from the southeast source in the Gulf of Mexico. Air masses from the Gulf of Mexico and Gulf of California, which release moisture while rising over the southeastern mountains.

Flood conditions are infrequent, mostly flash flooding from thunderstorms in July and August. Air currents from November through March are strongly from the Pacific in the high mountains; cold air masses come from Canada in the central and northern parts of state bringing heavy snow accumulations (sometimes reaching 100 in. or more). The highest temperature recorded in the state was 128 degrees F (53.3 degrees C), in Lake Havasu City on June 29, 1994, and the lowest temperature recorded in the state was minus 40 degrees F (minus 40 degrees C), in Hawley Lake on January 7, 1971. Annual lake evaporation is 80 in. in the southwest and 50 in. in the northeast corner.

The warm climate allows Arizona to produce vegetables for winter supply, and crops such as wheat and corn. Mining for copper, coal, sand, and gravel are important to the economy. A 1992 Colorado River Compact required 8.23 million acre ft. of water to be released every year to Nevada, California, and Mexico. In 2002, the crisis between farmers who own most of the water rights to the Colorado River and California cities downriver occurred.

The federal government ruled that California had to stick with the water allotment provided for in the compact and had to divide it equitably. The federal government further stipulated that water provided for in the compact was only excess water. Coal-powered steam, nuclear power, and some hydroelectric plants provide electricity. The Glen Canyon Dam generates hydroelectric power and created Lake Powell.

CLIMATE HARDSHIP

Arizona's climate has changed over the centuries. The ancient native peoples began farming the area in approximately 1500 B.C.E., and optimum rainfall increased arable farmland and drew a larger population. A Medieval climate anomaly in the southwest during the 8th and 12th centuries caused hardship.

While climate models vary on the amount of temperature increase possible with unmitigated global warming, Arizona's temperature could increase as much as 6.75 degrees F (3.75 degrees C) by the end of the century. The potential risks include: decreased water supplies from decreased snow pack in the mountains, thereby reducing summer flow in Arizona streams; increased risk for wildfires; changes in food production as temperatures rise beyond the tolerance level of crops; more extreme fluctuations in precipitation levels across the region (heavier rainfall and flooding events in winter, and summer drought conditions); change in rain pattern to downpours with the potential for flash flooding; and health risks of certain infectious diseases from water contamination; disease-carrying vectors such as mosquitoes, ticks, and rodents; and heat-related illnesses. The recent drought and intense wildfire seasons in Arizona are consistent with what climatologists expect will occur more frequently as global warming continues. A study by an Arizona and New Mexico team examined charcoal residues of ancient forest fires. During colder climate periods, smaller, less damaging fires occurred and during warmer climate periods, severe, stand-clearing fires occurred. Based on these data, global warming may cause more severe forest fires.

Based on energy consumption data from the U.S. Energy Information Association in 2007, Arizona's total CO_2 emissions from fossil fuel combustion in 2004 was 96.16 million metric tons of CO_2, made up of contributions from: commercial 2.04, industrial 4.62, residential 2.20, transportation 36.07, and electric power 51.22. Arizona committed to lowering its greenhouse gas emissions to 2000 levels by 2020, and 50 percent below 2000 levels by 2050. Arizona instituted a requirement that 1.1 percent of the state's energy come from renewable sources by the end of 2007.

In February 2005, Arizona established the Climate Change Advisory Group. Arizona holds member status with the Western Regional Climate Action Initiative, in which the partners will set an overall regional goal for reducing greenhouse gas emissions and design a market-based mechanism to help achieve that reduction goal.

Arizona joined the Climate Registry, a voluntary national initiative to track, verify, and report greenhouse gas emissions, with acceptance of data from state agencies, corporations, and educational institutions beginning in January 2008. The state's solar energy program issues a tax credit to individuals for installing a solar or wind energy device at an Arizona residence.

Arkansas

A GEOGRAPHICALLY DIVERSE state in the southern United States, Arkansas depends heavily upon lumber and wood products, agriculture, forestry, and tourism for its economic stability. All of these sectors are particularly vulnerable to the changes global warming can produce in the state's ecosystem. Arkansans have been slow to respond to threats to the state's environment, but, in recent years, both city and state governments have begun implementing strategies designed to address the problem. A 2001 report from the Intergovernmental Panel on Climate Change (IPCC) predicts that temperatures in Arkansas could increase from 1–5 degrees F (0.5–2.7 degrees C) by 2100.

Water for irrigation of crops and maintenance of eastern Arkansas's fish farms is vital to the state's economy. The recent decrease in groundwater levels, due to heavy demands and the compromising of freshwater aquifers by seepage of saline water from underlying rocks, have already driven farmers to drill deeper wells and consider the use of surface waters from the Arkansas and other rivers within the state. Such problems are likely to worsen with warmer temperatures, and agriculture is not the only concern. Already, dry tributaries of the Arkansas River threaten the summer flow upon which fishing, and boating depend.

Even small increases in temperature could cause 40–60 percent of the state's forests to be supplanted by grasslands, a change that could, in turn, mean loss of wildlife and habitat. The timber business would suffer as a result, as would a $1.2 billion tourism industry that consists largely of wildlife viewers, hunters, and fishermen. Fears about the loss of breeding ground for the state's birds, some of them already endangered species, is a pressing concern. It was in the Big Woods of east Arkansas in 2004 that a research team sighted the ivory-billed woodpecker, believed to be extinct for more than half a century. Water quality could also be affected by warmer summers, and low oxygen, combined with increases in nitrogen and phosphorus, could threaten wetlands.

Although Arkansas meets all federal air quality standards for criteria pollutants such as sulfur dioxide, hydrocarbons, and lead, and its CO_2 emissions place it 33rd among the 50 states; in 2004, Arkansas ranked 19th among the 50 states in per capita emissions. Like other states that have grown economically, Arkansas's percentage of CO_2 emissions has risen comparatively. Between 1990 and 2001, the economy grew 49 percent and carbon dioxide emissions rose 42 percent. Power companies and the transportation sector are the greatest offenders. Despite these statistics, Arkansas has a poor record of acting to implement solutions.

The state has enjoyed some success in recycling solid wastes and in implementing building codes that encourage energy efficiency. More recently, the state has encouraged the use of solar energy. In 2005, the Eastman Chemical Company near Batesville, Arkansas, became the first plant in the state to produce biodiesel from soybean oil. Researchers suggest Arkansas's most promising experiment with biofuels may be processing cellulosic ethanol, in conjunction with synthetic fuels from large lignite reserves. The state has also provided tax credits designed to encourage the use of biofuels.

In April 2007, Governor Mike Beebe established The Governor's Commission on Global Warming to study the potential impacts of climate change on the state's environment and econom,y and to recommend global warming pollutant reduction goals and strategies. However, Arkansas's most effective strategies to combat global warming have come at the local level. Mayors of three of the state's largest cities (Little Rock, Fayetteville, and North Little Rock) signed the Mayors' Climate Protection Agreement, a movement by mayors of U.S. cities to circumvent federal delays in addressing global warming. Participating cities commit to use projects at the local level, such as anti-sprawl policies and urban forest renewal, to meet or exceed the greenhouse gas emission reduction target suggested for the United States in the Kyoto Protocol. This includes a 7 percent reduction from 1990 levels by 2012, and to urge bipartisan support for legislation targeting the same goals at state and national levels. Fayetteville Mayor Dan Cody developed the first public-sector sustainability department in Arkansas, and, in 2007, built a biofuel station for fleet vehicles that provides 60,000 gallons of Arkansas biofuel a year.

Armenia

THE LANDSCAPE OF Armenia is mountainous and varied, with rivers, waterfalls, forests, hot springs, natural caves, cliffs, and lakes such as Lake Sevan, one of the largest high altitude lakes in the world surrounded by non-active volcanoes. It is said that Mount Ararat, once geographically a part of Armenia, is where the biblical Noah's Ark landed after the great flood. The peaks of Mount Ararat can be seen from Yerevan, the capital of Armenia. This landscape is threatened by global warming and by deforestation—an estimated 4,000 hectares of forests are cut for fuel and other purposes every year. At this rate, Armenia may be a barren desert by 2020. Armenia has the proper climate, topography, and geography to develop renewable energy from water, solar, and geothermal sources, which would benefit the country immensely.

Armenia is one of the world's oldest civilizations. Throughout the centuries, Persians, Arabs, Greeks, Romans, Turks and Russians have invaded Armenia, but Armenia has maintained a distinctive culture and language. A land-locked country surrounded by Iran, Turkey, Georgia, and Azerbaijan, Armenia's borders have changed because of frequent religious wars. Armenia was the first nation to adopt Christianity as a national religion, and has fought to preserve its religious and cultural heritage among the encircling Muslim nations.

From the 16th century through World War I, large parts of Armenia were under the control of the Ottoman Turks, who in April of 1915, during World War I, ordered the extermination of Armenian leaders, both intellectual and religious. Historians such as Dr. Richard Hovannisian state that approximately 1.5 million Armenians were murdered or died of starvation during the following three years. This is considered the first genocide of the 20th century. Turkey continues to deny that this genocide took place.

Armenia received its independence in 1991, after having been under Soviet rule since 1922. Economic hardship and environmental destruction came with Armenia's newfound freedom. Because of the high costs of fuel and a struggling economy, many looked to the forests as a means to provide heat, using approximately 70 percent of cut timber for that purpose. Besides illegal logging, the latest threat to the forests is the possible establishment of an open strip mine that would potentially clear-cut over 1,500 acres of forest in northern Armenia. Many nongovernmental organizations, such as the Armenia Tree Project and Armenian Forests, are involved in educating communities about the need to protect their forests. An estimated 60 percent of the total 8 million Armenians worldwide live outside of the country, but still manage to keep a vested interest in the country's environmental issues.

Arrhenius, Svante August (1859–1927)

SVANTE AUGUST ARRHENIUS is considered both a founder of physical chemistry for his work on ionic solutions and their electrolytic dissociation and the father of climate change science for his work on the contribution of carbon dioxide to global warming. Both theories were a great challenge to the scientific community of his time.

Svante August Arrhenius was born on February 19, 1859, in Wijk, near Uppsala, Sweden, as the son of

Svante Gustaf Arrhenius, a land surveyer at the University of Uppsala, and Carolina Christina Thunberg. His ancestors were farmers; his uncle became Professor of botany and rector of the Agricultural High School at Ultuna near Uppsala and later Secretary of the Swedish Academy of Agriculture. He originally went to Uppsala University to study chemistry. Finding their standards mediocre, he transferred to Stockholm in 1881, to do research under the physicist Erik Edlund, working initially on electrical polarization and then on the conductivity of solutions.

Arrhenius's doctoral dissertation (1884), titled *Recherches sur la conductibilité galvanique des électrolytes* [Investigations on the Galvanic Conductivity of Electrolytes] and presented in 1883, described his experimental work on the electrical conductivity of dilute solutions. It also contained a speculative section that set out an early form of his theory that molecules of acids, bases, and salts dissociate into ions when these substances are dissolved in water—in contrast to the notion of Michael Faraday and others that ions are produced only when the electrical current begins to flow.

Later, he proved that electrolytic dissociation influences osmotic pressure, the lowering of the freezing point and increase of the boiling point of solutions containing electrolytes. He also explored connections with biological problems, such as the relationship between toxins and antitoxins, serum therapy, and links to digestion and absorption as well as to the gastric and pancreatic juices. Although it has been modified over time, the importance of electrolytic dissociation theory is widely acknowledged today.

Arrhenius also applied physicochemical principles to the studies of meteorology, cosmology, and biochemistry. Interested in a debate about the cause of the ice ages he speculated that changes in the levels of carbon dioxide in the atmosphere lasting tens of millions of years were the trigger for a substantial change of the surface temperature of the earth. He took note of the Industrial Revolution, then underway, and realized that the amount of carbon dioxide being released into the atmosphere was increasing. Moreover, he believed carbon dioxide concentrations would continue to increase as the world's consumption of fossil fuels, particularly coal, increased ever more rapidly. He estimated that coal burning would drive a steady rise in CO_2 levels of about 50 percent in 3,000 years, leading to a much warmer climate, a prospect he found entirely rosy. He believed that a warmer world would be a positive change and that a warmer earth would be needed to feed the rapidly-increasing population.

ARRHENIUS'S GREENHOUSE LAW

In 1898, Arrhenius put forward a theory we now call the greenhouse effect. A simplified explanation is that shortwave solar radiation can pass through the clear atmosphere relatively unimpeded, but longwave infrared radiation emitted by the warm surface of the Earth is absorbed partially and then re-emitted by a number of trace gases—particularly water vapor and carbon dioxide—in the cooler atmosphere above. On average, the outgoing infrared radiation balances the incoming solar radiation, so both the atmosphere and the surface will be warmer than they would be without the greenhouse gases. Using Stefan's Law (better known as the Stefan Boltzmann Law), Arrhenius formulated his greenhouse law. In its original form, it reads as follows: "if the quantity of carbonic acid increases in geometric progression, the augmentation of the temperature will increase nearly in arithmetic progression." This is still valid in the 1998 simplified expression by G. Myhre:

$$\Delta F = \alpha \ln(C/C_0)$$

Arrhenius estimated that halving of CO_2 would decrease temperatures by 7–9 degrees F (4–5 degrees C) and a doubling of CO_2 would cause a temperature rise of 7–11 degrees F (5–6 degrees C). Although some of Arrhenius's calculations turned out to be wrong, current (2007) estimates from the Intergovernmental Panel on Climate Change (IPCC) say this value (the climate sensitivity) is likely to be between 3–8 degrees F (2–4.5 degrees C).

Nevertheless, over the decades after he developed this, Arrhenius's work was criticized, then reinforced, then criticized again. Many disregarded his conclusions, pointing to his simplification of the climate and how he failed to account for changes in cloud cover and humidity. The oceans would absorb any extra CO_2 pumped into the atmosphere, and any remainder would be absorbed by plant life, leading to a lusher landscape, skeptics argued.

Until about 1960, most scientists dismissed the hothouse/greenhouse effect as implausible for the cause of ice ages, as Milutin Milankovitch had presented a mechanism using orbital changes of the earth (Milankovitch cycles) that has proven to be a powerful predictor of most of the millions of past climate changes. Today, the accepted explanation is that orbital forcing sets the timing for ice ages, with CO_2 acting as an essential amplifying feedback.

Arrhenius was offered many opportunities to move to other European universities, and he delivered important lecture series at universities in the United States, but he always returned to Stockholm. He was elected as a foreign member of the Royal Society in 1911, was awarded the Society's Davy medal, and also the Faraday Medal of the Chemical Society (1914). Among the many tokens of distinction that he received were honorary degrees from the Universities of Birmingham, Cambridge, Edinburgh, Greifswald, Groningen, Heidelberg, Leipzig, and Oxford. In 1903, he received the Nobel Prize in chemistry, and in 1905, he was made director of the newly-created Nobel Institute for Physical Chemistry.

Nevertheless, Arrhenius was destined to have a bigger impact than he or anyone at that time could have imagined. Far beyond his mainstream work, he uncovered secrets of the Earth's atmosphere, inarguably becoming the father of climate change science. In doing so, he triggered research into what many see as the biggest threat to modern humans. Arrhenius was a contented man, happy in his work and family life. During World War I, he made successful efforts to release and repatriate German and Austrian scientists who had been prisoners of war. He was twice married—in 1894 to Sofia Rudbeck, by whom he had one son, and in 1905 to Maria Johansson, by whom he had one son and two daughters. He died at Stockholm on October 2, 1927.

Atlantic Ocean

THE ATLANTIC OCEAN is the second largest of the world's oceans, covering 31.7 million sq. mi. (82 million sq. km.) or a fifth of the Earth's surface. The Atlantic's role in global climate is well-studied, and although it is not entirely understood, it is profound. Understanding how the ocean both responds to, and affects, climate change is a challenge, given the Atlantic's expanse, mass, and both short and long term variability in its physical and chemical characteristics. Oceans, including the Atlantic, absorb most of the carbon dioxide emitted by human activity, and, thus, are extremely important for their role in mitigating the effects of increasing greenhouse gases in the atmosphere.

The immediate effects on the Atlantic of increased atmospheric greenhouse gases, most importantly carbon dioxide, include changes in the flux, or movement, of carbon dioxide within water and between the ocean surface and the atmosphere, acidification of the ocean, changes in surface temperature because of exposure to a warming atmosphere, and changes in the freshwater input to the ocean resulting from melting ice and anomalous precipitation both on continents and over the ocean. Longer-term effects include rising sea level, changes in weather patterns, and, potentially, changes in the climate of the ocean, neighboring continents, and the planet at large.

CARBON DIOXIDE FLUX

Presently, the net movement of carbon dioxide into the Atlantic and other oceans is from atmosphere to water. The oceans are an important sink, or storage reservoir, for carbon dioxide, holding as much as 60 times the amount of carbon dioxide as the atmosphere. More than three quarters of anthropogenic (human-sourced) carbon will eventually be stored in the oceans as carbon dioxide or as various carbon-containing ions and compounds. In the Northern Hemisphere, the North Atlantic is believed to be the largest reservoir for carbon. The effectiveness of the Atlantic Ocean as a carbon sink varies naturally over time.

Part of this variability is related to a phenomenon known as the North Atlantic Oscillation (NAO). The NAO refers to periodic movement of atmospheric mass and subsequent changes in the atmospheric pressure difference between two semi-permanent pressure systems that form over the Atlantic: the Icelandic Low and the Azores (or Bermuda) High. Changes in the NAO induce changes in sea surface temperature and mixing of layers of water. A strong NAO index (a relatively large difference in pressure between the two systems), tends to create warmer water and shallower winter mixing. Carbon dioxide is more soluble in water at cooler temperatures and under pressure. Thus, the carbon dioxide concentration of ocean water increases with depth. Deeper convection, or mixing of surface waters, increases the ocean's efficiency as a sink for carbon dioxide.

Mixing also affects the nutrients available for biological activity, which has a seasonal effect on the carbon flux in the oceans. Carbon dioxide is used at the ocean surface by photosynthesizing organisms, and it is incorporated into shells of organisms in the form of carbonate, most importantly, calcium carbonate. A small portion (but still a large mass) of these organisms sinks to the ocean bottom, where much of the planet's carbon is stored. At the surface, the amount of carbon dioxide is generally at equilibrium with that in the atmosphere. Thus, as atmospheric carbon dioxide increases, so does the concentration in the surface water of the ocean. Once the ocean absorbs carbon dioxide, it combines with water to form carbonic acid and a series of acid-base reaction products, thereby lowering pH. It has been calculated that ocean pH has decreased by 0.1 units since the Industrial Revolution. This decrease in pH is expected to continue as the concentration of atmospheric carbon dioxide rises.

The effect of decreasing pH on the ocean ecosystem is being investigated, and some researchers warn that it could be a serious problem. Increased carbon dioxide may favor certain organisms and harm others. Organisms that photosynthesize need carbon dioxide, but the acidification caused by added carbon dioxide can have deleterious effects. For example, corals take calcium carbonate from water to build skeletons, and many planktonic organisms, even ones that photosynthesize, use it to build shells. The solubility of calcium carbonate increases as pH decreases. Higher solubility of carbonates impedes the building of carbonate structures. This could affect the survival and population dynamics of these organisms. Depressed populations of these organisms could have an amplifying effect on global warming. Coccolithophores, for example, are abundant, shell-building planktonic photosynthesizers. Some of their carbon-containing shells end up in sediments. They also contribute to ocean lightening and cloud formation, both of which increase the amount of light reflected off the planet.

Ocean pH has decreased by 0.1 units since the Industrial Revolution, likely harming corals like this one in the Caribbean.

In addition to biological mediation of ocean carbon, the flux of carbon dioxide between the oceans and the atmosphere is affected by physical processes such as winds and circulation, and by complex chemical interactions. Layering, or stratification of oceans, affects the mixing and movements of water masses, including deep water, which differs substantially in chemistry from upper waters. For long-term storage, carbon dioxide mixed into surface water must be transported to deeper layers. Stratification in the Atlantic Ocean varies spatially by region and depth, and temporally, over short-term and long-term time scales. Near surface stratification is affected by salinity and temperature.

Stratification can be a significant barrier to mixing, and, thus, to the transport of chemicals and heat downward, and the resupply of nutrients upward. Decreases in these fluxes can negatively affect the ability of the ocean to take up carbon dioxide. Winds also influence the absorption and retention of carbon dioxide in the ocean via their effect on the ventilation of surface water. Winds, at least over some parts of the Atlantic, appear to be decreasing as a result of global warming. This lowers the rate at which carbon dioxide is taken out of the atmosphere by the oceans, thus raising the point at which atmospheric carbon dioxide will stabilize. In the southern oceans, however, winds have been speeding up, perhaps in response to warming or some other atmospheric change, such as ozone loss. The result is enhanced upwelling and ventilation of deeper, carbon-rich water.

The ability of ocean water to absorb carbon dioxide also depends upon its buffering capacity, which is determined by the carbonate and other ion concentrations in the water. The warm, tropical portion of the Atlantic, for example, has a very high buffering capacity, while cooler water is less efficient at absorbing carbon dioxide. Dissolution of carbon dioxide in water frees up hydrogen ions. These ions react with carbonate ions to form bicarbonate ions. This process serves as a buffer against change in pH; however, the buffering capacity decreases as carbonate ions are converted to bicarbonate. Thus, although the oceans will eventually take up some three quarters of human-produced atmospheric carbon, the efficiency of this process will decrease as carbon dioxide concentrations in the water increase. Further, the solubility of gases in water decreases as temperature increases.

SALINITY

The chemistry of the Atlantic Ocean is also changing in terms of its salinity, or salt content. A number of factors contribute to the salinity profile of the Atlantic Ocean. Evaporation, for example, is responsible for surface salinity being greater than the salinity of deeper water. When evaporation exceeds precipitation, salinity at the ocean surface increases. This has implications for movement of water and mixing of upper water with lower water. Melting of Arctic and Greenland ice because of warming sea and air temperatures, and increased precipitation over the ocean and neighboring continents, would be expected to have a freshening effect on the Atlantic, because these sources are low in salt. Changes in circulation, stronger winds, and changes in precipitation would be expected to increase salinity of surface waters near the tropics.

Measurements along the western basins of the Atlantic indicate significant freshening of high latitude water in both the Northern and Southern Hemispheres, and increased salinity in low latitudes during the latter half of the 20th century. The changing distribution of fresh and saline waters throughout the Atlantic and other oceans may be indicative of significant changes in the global hydrological cycle. The salinity of the Atlantic Ocean is also of particular interest because of its role in the thermohaline circulation (THC). The THC, along with prevailing winds produced by the Coriolis effect (circulation of large bodies of fluids such as air and water caused by the rotation of the planet), is the driving force behind the Atlantic meridional overturning circulation (AMOC).

THE ATLANTIC MERIDIONAL OVERTURNING CIRCULATION

The word *meridional* in AMOC indicates movement that is in a north-south direction. The AMOC is of immense importance to the global climate and is responsible for transferring heat from the tropics northward to the poles in the Atlantic. AMOC is the Atlantic component of the ocean conveyor belt. Evaporation of surface water at the tropics causes this water to be very salty, because only water is evaporated, leaving behind a high concentration of salt. At the same time, however, the density of the water is lowered through warming by the strong tropical sun. This is because water is maximally dense at 39 degrees F (4 degrees C); above or below this its density decreases. In the North Atlantic, water circulates clockwise because of the Coriolis effect. From the tropics, part of this conveyor belt takes water into the Caribbean basin and along the east of the West Indies.

These two flows unite to form the Gulf Stream, which passes along the east coast of North America. The Gulf Stream influences the climate of the east coast of North America. For example, it keeps the waters of southeast Florida considerably warmer than the rest of the North America in the winter, while in the summer it maintains warmer temperatures in Nantucket and Martha's Vineyard than are found slightly more inland, in Massachusetts Bay. Southeast of Newfoundland, Canada, the Gulf Stream turns easterly across the North Atlantic, where it breaks into numerous branches.

One branch of the warm, salty water moves northward along Great Britain and Scandinavia, shedding heat and warming that part of the world. As it cools, its density increases. It sinks and returns southward as deep water, mostly along the western side of the Atlantic. Eventually, it will recirculate to the tropics, where it will warm once again and rise to the surface. This process explains why it is termed an *overturning circulation*.

A warming climate is predicted to increase freshwater input in the northern reaches of the Atlantic via increased precipitation, continental run-off, and melting of Arctic Greenland ice. Pulses of freshwater and ice from the Arctic during the latter third of the 20th century appear to have diluted much of the upper waters in the high-latitude North Atlantic. Potentially, such freshening could weaken the circulation by decreasing the density of surface water and by pulling heat from the northern current. Uncovering a trend in the circulation has proven to be difficult because the strength of the circulation varies greatly by season and year and researchers are still learning the extent of this variation. There is presently a shortage of data to make any confident conclusions about changes in the overturning. Longer-term temperature and salinity data covering a greater range of latitudes are needed; more work along these lines is currently underway.

There is circumstantial evidence linking cooling and glacial events several thousand or tens of thousands of years ago to changes in the ocean heat conveyor. Some researchers believe that it is unlikely that a sufficient injection of freshwater is available to shut down the AMOC, or that a substantial slowing is centuries away from occurring; whereas others believe that this tipping point may be approaching. Of intense interest is the Greenland Ice Sheet, which has been losing mass in recent years. In some models, a rapid input of ice and water from Greenland could have a significant effect on the overturning circulation; other models show a melting Greenland Ice Sheet to be insufficient for such an occurrence.

TEMPERATURE AND SEA LEVEL RISE

The freshening of the high-latitude (generally from 45–60 degrees N) North Atlantic creates an exception to the overall trend of warming in the Atlantic, because water from the melting ice is cold. When examined over their entirety, the energy content in the form of heat in the world's oceans is increasing, at least since the mid-20th century. This increase in heat may be greater for the Atlantic than other oceans. Temperature increases have been measured at the surface and to depths of 9,843 ft. (3,000 m.). A warming atmosphere caused by anthropogenic greenhouse gases is widely considered to be the cause of increasing ocean temperatures.

Heat from the air at the surface of the ocean is transferred to the water, raising sea surface temperatures. Heat in the surface water is mixed downward in the summer. During winter, some heat moves by convection from deeper water to the surface and then is released to the atmosphere. Elevated sea surface temperature during winter weakens this convection, thereby trapping heat in the ocean. Factors other than greenhouse gases, such as changes in solar radiation or cosmic rays, have been proposed to explain the rising temperatures. Measured changes in these phenomena appear inadequate to explain the extent to which the heat content of the ocean and atmosphere has increased.

Both increasing ocean heat content and melting ice are contributing to sea-level rise in the Atlantic Ocean and elsewhere. Sea-level change is not uniform worldwide, with sea levels far exceeding the mean rise at some locations, and drops in levels at some others. The overall trend of rising sea levels, however, is apparent. Based largely on tidal gauge readings, this rise was from about 0.06–0.08 in. (1.5–2 mm.) per year in the 20th century. Part of this, about 0.02 in. (0.5 mm.), occurred through expansion of the water caused by heating (thermal expansion). The remainder is an actual change in the mass of the oceans caused by influx of water from melting glaciers, ice caps, and the Antarctic and Greenland ice sheets.

Scientists have determined that glaciers and ice caps around the world are melting and are responsible for most of the changes witnessed in oceans' mass. Ice caps are larger than glaciers, but larger still are the world's two ice sheets. These huge bodies of ice have the greatest potential to raise sea level, holding enough water to raise sea levels 230 ft. (70 m.). Fortunately, there is no indication that a complete melting will occur. The Greenland Ice Sheet is, however, losing mass, largely from its periphery, and there is concern that the rate of discharge of glaciers from the ice sheet into the surrounding ocean is accelerating.

THREATS TO COASTAL COMMUNITIES

Rising sea level poses a problem for people and development along the ocean. With over 60,000 mi. (100,000 km.) of coastline, rising water on the Atlantic Coast has the potential to be very costly in human and economic terms. It also poses an ecological problem by altering the hydrology of coastal land and the salinity of freshwater bodies and wetlands entering the ocean near the coast. Extreme high tides and storm surges could bring water to places that historically have only uncommonly or never flooded. Such unusual events increased along the Atlantic coast of United States in the 20th century.

Coastal flooding and erosion is not only a function of mean sea level, but is also affected by storminess and wave height. Trends in these parameters in the Atlantic Ocean are difficult to discern because of high yearly variability and naturally occurring cycles. There is some indication of slightly increased storminess and wave height in the northern Atlantic and declines elsewhere during the latter part of the 20th century. Changes in overlying atmospheric pressure appear to be the cause. These meteorological changes may be natural, however, and at this time there is insufficient evidence to directly link them to human activity.

HURRICANES

A related concern is the possible effect of climate change on hurricane activity. Hurricane records are being intensely scrutinized to identify trends. Like other weather phenomena, hurricanes seem to exhibit cyclical variation on multiple time scales, plus other naturally occurring variation. Some of this variation may occur on time scales longer than storm records have been kept.

The methods used to record storms and measure their intensity have also changed over time, adding difficulty to reaching firm conclusions. For example, intensity of storms that occurred prior to the use of satellite imagery may be under-reported. While some scientists have reported apparent effects of climate change on storm frequency, intensity, and number of strong storms, others have refuted or rejected such claims.

Because hurricanes get their energy from warm ocean water, it might be expected that increasing sea temperatures would elicit an increase in storm numbers or intensity. There are many complicating factors, however, in the formation of hurricanes. These include air movement where hurricanes form, height differences in wind speed (shear), and sea-level air pressure. The debate about the relationship between hurricanes and greenhouse gases is certain to continue.

Atmosphere, Climate and Environment Information Programme (UK)

IN RESPONSE TO rising concerns about climate change and global warming at the end of the 20th century, the government of the United Kingdom created the Atmosphere, Climate, and Environmental Information Programme (ACE) as the academic arm of the Atmospheric Research and Information Centre (ARIC). Operating under the auspices of the Department for Environment, Food, and Rural Affairs (DEFRA) and supported by the Department of the Environment, Transport, and Regions (DETR), ACE was established in part as a means of promoting DETR's "Are You Doing Your Bit?" campaign. Activities of the ACE were directed at educating the public about the ways in which human activities affect climate change and in promoting national legislation and international cooperation in mitigating those effects.

In 2005 DEFRA withdrew financial support for the Atmosphere, Climate, and Environmental Information Programme. However, much of the information distributed by ACE remains available in ACE pamphlets, papers, reports, and the internet. Through Manchester Metropolitan University, the ACE website continues to serve as a clearinghouse for information on topics such as the British government's efforts to curb air pollution, ways in which the public can mitigate the effects of air pollution on climate change, and statistics on emissions of pollutants in the United Kingdom 1970–2000. ACE data on governmental efforts to combat climate change, ozone depletion, and British participation in the Kyoto Protocol are also available. The ACE website continues to serve as a major resource of information on the environment for teachers and young students, offering basic facts, games, and puzzles.

The Atmosphere, Climate, and Environmental Information Programme's most lasting contribution may arguably be two comprehensive online encyclopedias. The award-winning *Encyclopedia of the Atmospheric Environment* offers some 400 essays on topics that include climate change, global warming, acid rain, and the weather. A number of articles offer supporting photos and statistics. Published in both English and French, this encyclopedia provides information to individuals from elementary school age to college and beyond who are concerned with global warming and climate change. The encyclopedia also serves as a valuable resource for government agencies, advocacy groups, industry, and nongovernmental organizations. The "References and Further Reading Section" of the encyclopedia directs interested parties to printed sources that explore global warming and climate change topics in greater depth.

More action-oriented than its sister encyclopedia, the *Encyclopedia of Sustainable Development* is available only in English. It provides access to approximately 100 articles that are designed to explain the intricacies of sustainable development to a general audience. In addition to the two online encyclopedias, between March 1998 and November 2004, ACE annually published six issues of *Atmospheric Issues*, a newsletter that gathered information from around the world on topics dealing with air pollution, air quality, climate change, ozone depletion, renewable energy, transport, and sustainable development.

SHIFT IN SUPPORT

After 2005, DEFRA shifted its support from ACE to the Digital Library for Earth System Education (DLESE), in which the government joined with educators, students, and scientists to generate knowledge about global warming and climate change. Funded in large part by the National Science Foundation, DLESE provides students of higher education with information on such topics as ecology, environmental science, forestry, hydrology, natural hazards, space science, atmospheric science, and biological oceanography. Information is generated from sources ranging from the GLOBE Program Collection, the New York Instructional Collection, and Realtime Atmospheric Data. Teachers are encouraged to use resources provided by DLESE, including lesson plans, maps, images, data sets, visualizations, and online courses.

As support for the ACE program declined, attention also focused on action-oriented programs designed to deal with the implications of climate change. In the early 21st century, the government established the Climate Change Programme, which set emission reduction targets throughout the economic sector, including the establishment of industry caps on pollution, promotion of the development of alternative fuels, legislative efforts to enact stricter building codes, support for more effective home energy savings, and the generation of public and business support for achieving government goals on mitigating the effects of climate change. In March 2006, the government announced that goals of the Climate Change Programme included a 23–25 percent reduction in base year levels of carbon dioxide emissions and a 15–18 percent reduction beyond 1990 levels by the year 2010.

Since the 1990s, the British government has served as a leader in promoting efforts to mitigate the effects of global warming. During that period, greenhouse gas emissions in Britain have continued to fall. In October 2006, the British government issued a controversial 700-page report written by economist Sir Nicholas Stern that sought to call worldwide attention to the economic aspects of global warming. Stern concluded that the potential effects of global warming and climate change could be more devastating than the world wars and the Great Depression combined. Some economists, most notably William D. Nordhaus of Yale University and Sir Partha Dasqupta of the University of Cambridge, questioned Stern's findings.

Then Prime Minister Tony Blair challenged nations around the world, particularly the United States and China, where efforts to reduce global warming have often run into political stumbling blocks, to join Britain in reducing the carbon emissions that are believed to be leading to warming temperatures around the globe. Despite a close political alliance between Britain and the United States, Blair urged President George W. Bush to rethink his position on global warming, which has allowed the industrially dominant United States to forego the restrictions on greenhouse gas emissions that have been instituted throughout much of the world as a result of the Kyoto Protocol of 1997. The provisions of that protocol are set to expire in 2012.

Atmospheric Absorption of Solar Radiation

SOLAR RADIATION IS radiant energy emitted by the Sun. The process begins at the Sun's core, where hydrogen atoms are fused to helium atoms via nuclear fusion. For each second of nuclear fusion, the Sun converts 700 million tons of hydrogen into 695 million tons of helium, with 5 million tons of electromagnetic energy radiating out into space.

Some of this energy travels the approximately 92.89 million mi. (149.5 million km.) across the solar system to Earth. The importance of the Sun to Earth is hard to overstate: quite simply, it makes life here possible. It provides us with heat and light, controlling everything from daily weather patterns to the placement of climate zones, while our trips around it provide us with our annual seasons.

Not all incoming solar radiation makes it to the Earth's surface; in fact, almost half of it is deflected back into space by the outer layers of our atmosphere. Inside the atmosphere, it scatters and interacts with gasses and particles in different ways, depending on the size and composition of its wavelengths. For example, gamma rays, ultraviolet light, and x-rays of 200 nanometers in wavelength are absorbed by ozone and nitrogen is converted into heat energy. Ultraviolet rays of 200–300 nanometers in wavelength are absorbed by ozone in the stratosphere, while infrared rays of 700 nanometers in wavelength are partially absorbed by ozone, carbon dioxide, and water vapor in the lower atmosphere.

In all, an estimated 6 percent of incoming solar radiation is reflected back into space by the atmosphere, 51 percent is absorbed at the Earth's surface (where 4 percent of it is reflected back), while 39 percent is either reflected or absorbed by clouds. Solar radiation that has passed beyond these forces of scattering or absorption and reaches the Earth's surface is called *diffused* solar radiation, while that which reaches the ground without stopping is *direct* solar radiation.

The Sun's intensity changes in a number of long and short cycles, and those who do not believe in anthropogenic (human-caused) global warming often point to the Sun as the true culprit. While there is no denying the Sun's influence on past cycles of heating and cooling, the majority of scientists believe that it is a combination of natural and human-caused processes that are driving observable climate changes today.

Changes in albedo are an important part of the global warming picture. Albedo, a word derived from the Latin word for white, is the surface reflectivity of solar radiation. A dark surface will absorb more solar radiation than a light surface. The overall albedo of the Earth is 30 percent, and it plays a crucial role in keeping the planet's temperature habitable.

Albedo varies depending on the color of the surface. Open water has an albedo of 8 percent, meaning it reflects only 8 percent of the solar radiation that strikes it, absorbing the remaining 92 percent as heat. Dry desert sands have an albedo of 35–45 percent, coniferous forests between 10–20 percent, and deciduous forest between 5–10 percent. It is the polar regions that do the most to reflect solar radiation, with fresh snow carrying an albedo of 95 percent, snow-covered sea ice about 70 percent, and melting snow about 50 percent.

The interplay of anthropogenic and solar impact is best illustrated by recent events in the Arctic, where each year has seen the shrinking of summer sea ice at the North Pole and in Greenland. Something—perhaps the burning of fossil fuels—has allowed more heat to become trapped in the atmosphere and has warmed the environment. This causes some snow and ice to melt, which drops the region's surface albedo, which in turn allows an increased amount of solar radiation to reach the surface. The radiation produces more heat, which causes more snow and ice to melt, and soon the process becomes unstoppable. The loss of the polar ice caps could have tremendous repercussions around the world, from destabilizing the world's weather patterns, to rising global sea levels from the melting of the Greenland ice sheet.

Atmospheric Boundary Layer

THE ATMOSPHERIC BOUNDARY LAYER (ABL) is the bottom layer of the atmosphere. Its defining characteristic is that it interacts with the Earth's surface on a time scale of a few hours or less. Therefore, all constituents emitted at or near the surface rapidly diffuse throughout the ABL. This rapid interaction is a direct result of turbulence, which is an essential feature of the ABL. Over land, its depth can vary from a few miles in the daytime to a few dekameters at night.

The atmosphere near the earth's surface is almost always turbulent; that is, the air is continually undergoing seemingly random motions, in addition to whatever wind may exist. The sources of turbulence are wind shear (the change in wind speed and direction with height) and convection (motions driven by air density differences resulting from surface heating or latent heating from water phase changes). Defining characteristics of turbulence are its chaotic fluctuations over a broad range of scales, and its diffusiveness. Therefore, trace constituents released into a turbulent fluid are rapidly diffused and the small-scale patterns of this diffusion cannot be predicted. Because of the randomness and the large range of scales of ABL turbulence, processes in the ABL are often described in terms of statistical averages of fluctuations. This means that most measurements of ABL structure need to be spatially or temporally averaged before they can be quantitatively interpreted.

The top of the ABL is characterized by an increase in temperature (such as a decrease in density) with height, which also caps the level to which turbulence extends. The ABL grows by entraining air from the overlying non-turbulent air by turbulent eddies. That is, the kinetic energy of the ABL turbulence is used to overcome the lower density of the overlying air as it diffuses into the ABL. The lowest few yards to dekameters of the ABL is known as the surface layer (SL). This region, roughly up to about 10 percent of the ABL, is characterized by nearly constant vertical turbulent transport and relatively large vertical gradients; in contrast to the rest of the ABL, where the transport can vary significantly, but the gradients are typically small. In this layer, wind shear caused by the interaction of the average wind with the surface, and with obstacles such as plants, buildings, hills, and ocean swell, is the dominant source of turbulence.

If turbulence generation by convection occurs in the ABL, it is known as an unstable or convective boundary layer (CBL); if the hydrodynamic stratification of the ABL acts to suppress or dissipate turbulence, it is known as a stable boundary layer (SBL). In the course of a typical diurnal cycle over land, the surface becomes warmer than the overlying air within a few hours after sunrise, and warms the lowest layer of air so that it is warmer and less dense than the air higher up. This relatively warm air rises and thereby converts its potential energy to kinetic energy in the form of turbulent fluctuations that deepen the boundary layer through the morning. By mid-afternoon, as solar heating begins to decrease, the boundary layer reaches a plateau of one to several miles in depth and turbulence decreases.

At night, infrared cooling of the surface suppresses turbulence, while wind shear near the surface can still generate it. As a result, the nocturnal SBL is much shallower—typically a few dekameters or less—and the temperature decreases less rapidly with height than the daytime CBL. The overlying air that was previously within the CBL, and therefore well mixed, is no longer turbulent. This residual layer may again become turbulent the following day when solar heating of the surface resumes.

This diurnal cycle is strongly dependent on the surface characteristics. A bare, dry surface, for example, will become warmer than a moist or vegetated surface. Therefore, the turbulence is likely to be stronger and the boundary layer deeper over a bare, dry surface. The moisture given off by vegetation will likely cause clouds to form at lower heights than over a bare, dry surface. If these differences occur over a large enough area, there may be significant differences in the mean temperature, humidity, and cloudiness. Horizontal variations in the surface can induce corresponding horizontal variability in the ABL. For example, on clear summer days, cumulus clouds are often observed to form preferentially over land, but a nearby lake may remain clear. Similarly, in mountainous terrain, clouds often preferentially form over ridges and elevated plateaus, rather than adjacent valleys.

Over the ocean, the diurnal cycle is quite different, and often scarcely noticeable. Because the ocean has a much larger effective heat capacity and heat conductivity than land, its surface temperature is hardly perturbed by the daily solar cycle. As a consequence, the ABL depth, typically about a kilometer, is much less variable. Furthermore, in daytime the boundary layer air is heated directly by the sun, which typically more than compensates for long-wave (infrared) radiational cooling. In this case, the boundary layer may be more stable (with less convection) in the daytime than at night.

When relative humidity reaches 100 percent within the ABL, clouds form, which can have dramatic effects on its subsequent evolution through generation of turbulence by release of the latent heat of condensation, shading of the Earth's surface, and precipitation. The resulting clouds may be confined to the ABL, or they may penetrate into the overlying atmosphere, depending on the change of temperature (density) with height across the ABL top; a large increase in temperature across the top suppresses cloud penetration and results in stratiform or layered clouds, while penetration leads to cumuliform or vertically-developed puffy clouds. Cumulus convection is an important mechanism for transporting ABL air, and, thus, trace constituents released at the surface, into the overlying atmosphere, thereby ventilating the ABL.

In the surface layer, which makes up about 10 percent of the ABL, turbluence is increased by surface features such as hills.

Atmospheric Component of Models

SCIENTISTS HAVE BEEN creating models of the climate and atmosphere on a systematic basis for more than a century. However, only with the development of powerful computational devices has a sophisticated simulation of the atmosphere started to become possible. The accurate modeling of turbulent liquids and gases, of which the atmosphere is of course composed, remains one of the most difficult tasks facing scientists studying the Earth. The problem is made more difficult by the lack of accurate and complete data dating back more than a few decades. Despite these difficulties, researchers have become able to create models that do represent the major features and changes of the atmosphere with a high degree of confidence.

The degree of sophistication inherent within the atmospheric component of climate models is revealed by the number of data points on the surface (the horizontal element) as well as the number of layers considered in the atmosphere (the vertical component). Currently, scientists are developing a third generation atmospheric circulation model that consists of 32 layers within the atmosphere. The coverage extends to 37 mi. (50 km.) from the surface of the Earth and the model also includes three layers of the Earth itself. Previously, a single soil layer was predicated across the surface of the Earth, but this is now supplemented by, when necessary, a snow layer and a layer of vegetative canopy.

Clearly, the rate of change of land cover across the surface of the Earth means that it would be impossible to create a model that is 100 percent accurate. However, models now represent the overall effect of the atmosphere to a satisfactory degree. For example, variables are included in the third generation models that include soil surface properties and heights, various types of surface albedo, and varying soil moisture conditions. Nevertheless, the central component of the model is the investigation of the heat exchange between the earth through the atmosphere and the ways in which this has an impact upon the climate. Understanding this has been a goal of scientists for more than a century, although it was not until the detailed observations first made in the middle of the 20th century that a real understanding of circulation became possible.

The discovery of the various wind systems and accurate mapping of them enabled a huge leap in understanding of the Earth's atmosphere as a whole. It revealed the need for more advanced understanding of the atmosphere than could be provided by a single equation, no matter how sophisticated that might be. The Norwegian meteorologist Vilhelm Bjerknes and the British physicist Lewis Fry Richardson were among the vanguard of scientists attempting to use a series of mathematical equations to represent weather changes over finite parts of the globe. This was to be achieved by dividing the surface of the earth into a grid of cells of such a scale that it was feasible to complete the equations with the tools then available. However, these attempts were unsuccessful and ultimately abandoned.

One particular problem was that it was necessary to compare results that had been calculated with real-world data and there were insufficient mechanisms to make those measurements. World War II was the impetus to measure climatic conditions (for inherently military purposes) that provided the amount of data necessary to refine and improve models. Contemporaneous improvements in computers made more rapid and wide-scale calculations possible, and a series of researchers, mostly based in the United States, were able to improve their models over the subsequent decades.

IMPROVEMENTS

Major improvements included the division of the surface of the earth into land and water, inclusion of topographical features and the integration of increasingly more layers in the atmosphere, which both improved the sophistication of the model and enhanced its scope to heights further from the surface of the earth. It took many years, nevertheless, for modeling to be completed faster than the weather elapsed in real time and the ability to make meaningful weather forecasts has only recently become possible. However, this is now possible and the geographical scope of the coverage has grown from regional to global in nature. Regional models may be more useful for state agencies to make forecasts across their territory, but the atmospheric system is global in scope and only models that include the whole globe can be really helpful in predicting the future.

Advanced modifications to the atmospheric component of climate models have included the dynamics of cloud and precipitation processes, radiation processes, and the impact of aerosols. Other areas of improvement have included the division of precipitation into frozen and liquid forms and the various forms of condensation involved with cloud formation processes. The modeling is not complete, but is advancing at a rapid rate.

Atmospheric Composition

ALL LIFE ON Earth exists within a thin film of air, water, and soil about 9.3 mi. (15 km.) deep. This spherical shell of life is known as the biosphere. The biosphere can be divided into three layers: the atmosphere (air), the hydrosphere (water), and the lithosphere (rock and soil). The unique attributes of the Earth's atmosphere create a habitable place for humans, animals, and plants. It reaches over 348 mi. (560 km.) from the surface of the Earth. The atmosphere is a mixture of gases and particles that surround the planet. When seen from space, the atmosphere appears as a thin seam of dark blue light on a curved horizon. It is made of layers that surround the Earth like rings. About 99 percent of the Earth's atmosphere occurs within 31 mi. (50 km.) above the surface. The remaining one percent extends outward for several hundred km., fading gradually into interplanetary space.

The atmosphere serves several purposes: it provides habitants with the air to breathe, its gases retain the heat that warms the Earth, and its protective layer of ozone shields habitants from harmful ultraviolet rays emitted by the sun. The atmosphere also acts as a reservoir, or storehouse, for natural substances as well as emissions derived from human activities. Within the storehouse, physical and chemical actions and reactions take place. Many of these can affect climate and weather systems. Four distinct layers of the atmosphere have been identified using thermal characteristics (temperature changes), chemical composition, movement, and density. These are the: troposphere, stratosphere, mesosphere, and thermosphere. Beyond these atmospheric layers lies the exosphere.

Approximately 81 percent of Earth's atmosphere occurs in the troposphere, which extends about 3.7–10.5 mi. (6–17 km.) above the Earth's surface and is thickest at the equator. Temperatures in the troposphere generally decrease as altitude increases. Temperature in this layer is highest nearest the earth, in part because gases in the troposphere are warmed by heat radiated from the earth. The stratosphere extends beyond the troposphere to about 31 mi. (50 km.) above the Earth. Gases in the stratosphere are heated mainly by incoming radiation from the sun; temperatures in the stratosphere gradually increase as altitude increases. As a consequence of temperature differences between the troposphere and stratosphere, and the resulting circulation patterns, exchange of air between the two layers is slow.

The stratosphere is also known as the ozone layer. The distribution of ozone is closely linked to the vertical structure of the atmosphere. Approximately 90 percent of all ozone molecules are found in a broad band within the stratosphere. This layer of ozone-rich air acts as an invisible filter to protect life forms from over-exposure to the sun's harmful ultraviolet rays. Human activities have led to a depletion of the ozone layer observed since the mid-1980s.

The mesosphere starts just above the stratosphere and extends to 53 mi. (85 km.) beyond the stratosphere. In this region of atmosphere, temperatures fall as low as minus 135 degrees F (minus 93 degrees C). The thermosphere starts just above the mesosphere and extends 372 mi. (600 km.) beyond mesosphere. The thermosphere has two parts: the ionosphere (the inner part), and the exosphere (the outer part) that gradually merges into space.

The composition of the atmosphere has changed over time. The original atmosphere primarily consisted of helium and hydrogen. Heat from the still-molten crust and the sun, and probably from enhanced solar wind as well, dissipated this atmosphere. The surface cooled about 4.4 billion years ago, but was still full of volcanoes that released steam, carbon dioxide, and ammonia. This led to the early second atmosphere, which was primarily composed of carbon dioxide and water vapors, with some nitrogen, but virtually no oxygen.

The second atmosphere had approximately 100 times more carbon dioxide than the third, or current, atmosphere. As the atmosphere cooled, much of the carbon dioxide either dissolved in the seas or precipitated as carbonates. Bacterial forms of life began approximately 3.3 billion years ago, and were probably were the first oxygen-producing phototropic organisms. They were responsible for converting the Earth's atmosphere from an anoxic to an oxic state during the period 2.7–2.2 billion years ago.

As life evolved on the planet and more plants appeared, the level of oxygen increased significantly, while levels of carbon dioxide dropped, eventually giving rise to the modern atmosphere, which is also known as the third atmosphere. This modern atmosphere has a composition enforced by oceanic blue-green algae, as well as geological processes. Thus, oxygen does not remain naturally free in atmosphere, but tends to be consumed by inorganic chemical reactions, animals, bacteria, and even plants at night. Carbon dioxide is produced by respiration and the decomposition of organic matter.

Dry air near the Earth's surface consists mainly of Nitrogen (78.1 percent by volume) and oxygen (20.9 percent) with a small amount of argon (about 0.9 percent) and carbon dioxide (about 0.035 percent). Air in the troposphere also contains water vapor and small amounts of "trace gases," such as methane, nitrous oxide, hydrogen, and ozone. Even though many of these gases are present in minute amounts, they cause the atmosphere to act like an insulating blanket around the planet. Without this atmospheric blanket, the Earth's surface would be too cold to sustain life. Naturally occurring atmospheric gases play a key role in determining the climate, and the increase in their concentration, attributed to natural and anthropogenic causes, results in more dramatic climate changes. In addition to these naturally occurring gases, there are other gases such as halocarbons (a result of industrialization) present in the troposphere. The chemical composition of the atmosphere is very important and influences the climate; the addition of gases changes the composition of the atmosphere, complicating climate-change processes.

Atmospheric Emission of Infrared Radiation

THE EARTH'S CLIMATE system is characterized by the energy balance of the Earth, the distribution of energy in space (or Earth's atmosphere), and temporal energy variation. The Earth's radiative energy balance is governed by the balance between the solar radiation and absorption by the Earth, and subsequent radiation from the Earth to outer space. The absorbed solar shortwave radiation by Earth is emitted back to outer space in thermal infrared or longwave radiation to maintain the Earth's heat energy balance. The imbalance (surplus) in the Earth's energy budget leads to global warming.

In the 20th century, according to global temperature records, the near surface of the Earth warmed by nearly 1.0 degree F (0.6 degrees C). This global warming is due to anthropogenic climate-forcing agents, such as greenhouse gases (GHG) including carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), ozone (O_3), water vapor, and other gases. These climate-forcing agents block, trap, or absorb the thermal infrared energy radiated from the Earth to space. These agents also have energy-scattering ability. The absorbed thermal infrared energy is later radiated back to the Earth making the Earth warmer (the greenhouse effect). These climate-forcing agents also absorb solar shortwave energy and radiate that to the Earth in a later stage, thus warming the Earth's surface.

According to climatologic research, water vapor (without clouds), CO_2, CH_4, and O_3 cause about 36–70 percent, 9–26 percent, 4–9 percent, and 3–7 percent of the greenhouse effect on the Earth, respectively. The higher ends of the ranges quoted here are for the gas alone and the lower ends are for overlapping. Water vapor is a profound contributor to the greenhouse effect. Unfortunately, based on evaporation feedback, the amount of water vapor in the atmosphere is increasing with passing years.

Climate forcing is an imposed, natural, or anthropogenic perturbation of the Earth's energy balance with space. Anthropogenic greenhouse gases such as CO_2, CH_4, O_3, N_2O, chlorofluorocarbons (CFCs), and black carbon particles cause the largest positive climate forcing, warming up the Earth. CO_2 is the greatest climate-forcing agent as its absorptive and radiative power of atmospheric infrared energy is more than any other greenhouse gases. Black carbon produced by forest burning, emissions from thermal power plants, and volcanic activities has the next highest climate-forcing effect. CH_4 and O_3 also contribute significantly to global warming.

Climate forcing agents' ability to absorb and emit back to earth thermal infrared or longwave is also measured in terms of global warming potential (GWP). GWP is a relative scale: GWP of a climate-forcing agent is compared to the same mass of CO_2. GWP is mostly based on the radiative properties of the gases and how they impact the climate system, especially the warming of the surface of the Earth. Of course, each greenhouse gas does not absorb the Earth's radiated heat with similar potential. It also depends upon the rate of decay of each gas relative to CO_2. GWP is the measure of relative radiative effect of a given gas compared to another (CO_2) over a particular time horizon, such as 50, 100, 500, or 1,000 years. Hydrofluorocarbons (HFCs) and Perfluorocarbons (PFCs) are the most heat-absorbent. Methane and N_2O are more than 21 times and 270 times more heat-absorbent than CO_2.

It is essential to reduce the amount of positive climate-forcing agents, or GHGs, from the atmosphere to at least slow down the global warming process. The proposed Kyoto Protocol is designed to slow emissions of several of these positive climate-forcing agents.

Atmospheric General Circulation Models

GENERAL CIRCULATION MODELS of the atmosphere are computer-driven mathematical models that aim to represent the numerous actions within the atmosphere of the entire world and its interactions with the surface of the Earth. Initially intended to improve understanding of the movements of the atmosphere, with a view to predicting weather phenomena and preparing for adverse weather, circulation models have since provided further understanding of the impact of atmospheric warming and its implications for all forms of life on the Earth.

The atmosphere is an extraordinarily complex system—or set of systems—and modeling its actions is far beyond the ability of any single human brain. Indeed, its complexity is such that it even defeats the intuitive nature of the brain because second, third, and higher-order effects are, if not unimaginable, then at least incalculable. However, appreciating that level of sophistication and complexity was not possible until the expanded observations of the atmosphere that resulted from World War II.

These new observations opened the eyes of scientists to global interactions. Previously, only partial models, based on geographical regions, had been attempted. They also helped to demonstrate that processes such as cloud formation and other forms of meteorological physics were much more complex than had previously been imagined. Indeed, understanding the turbulent behavior of gases and liquids remains one of the most complex problems in modern mundane physics. For example, the influence of tropical and trade wind systems had not been fully integrated into worldwide models, while the circulation of the oceans has still not been comprehensively audited at all depths.

Attempts to create a model by experimental means, through, for example, heating gases around a spherical object, were crude approximations at best because of the lack of subtlety in defining the specific characteristics of the earth compared to a simple, homogeneous sphere. More success has been reached by identifying a series of simpler, lower-level equations and the ways in which they interact with each other from the bottom up have been more successful than approaches from the top down.

IMPROVEMENTS

The level of complexity of these issues meant that it was not until the development of digital computers in the 1950s that any serious attempt could be made to model the atmosphere as a whole. Early attempts treated the atmosphere and, indeed, the Earth's surface, as homogeneous composites of all possible values of the variables employed. Hence, there was little or no differentiation between land and sea or among the various layers of the atmosphere. Clearly, no model based on these initial conditions would be able to represent the complexity of the overall model.

The development of computer power has, on a rapidly accelerating trajectory, improved the accuracy of existing models and enabled integrating new variables into the overall model. As the model grows in its ability to provide satisfactory answers—that is, to provide increasingly better predictive power in forecasting actual weather conditions—scientists are able to identify new variables that may be included. On some occasions, practical issues preclude direct observation of the desired variables and, hence, proxy variables must be included instead. At the same time, researchers are adjusting their models by employing different variable weightings, varying certain initial conditions, and making other slight changes to determine the sensitivity of the models and their ability to replicate accurate simulations on a consistent basis.

No individual model is likely to provide a definitive answer, or to be qualitatively better than any other or to have one set of weightings that is consistently superior to any other. Prudence suggests, therefore, that researchers will search for a broad consensus of results before making claims for improved performance. This is facilitated by the peer-reviewing process in the academic world, which measures research findings against existing knowledge and information. The process tends to enhance accuracy, but delays reporting of some findings and tends to make researchers act with more equivocation than they might be asked to show by journalists or politicians. As the issues of global atmospheric warming and attendant climate change have taken an increasingly central role in political agendas around the world, climate modelers have found their methods and results questioned more stringently than ever before and there have, as a result, been some cross-cultural collisions that have done little, if anything, to improve aggregate understanding.

One of the first scientists successfully to make the link between the emission of carbon dioxide into the atmosphere at unprecedented rates with future climate change, was Syukuro Manabe. Manabe integrated oceanic and atmospheric climate models and identified the flows between them of momentum, heat, and water. His conclusion was that general atmospheric temperatures would rise by several degrees if the amount of carbon dioxide in the atmosphere doubled. A great deal of subsequent work on circulation models has been involved with either verifying or falsifying this initial conclusion. The main effect has been to refine the result and it has become apparent that, despite many (often well-financed) attempts to find flaws in the fundamental assumptions of such models, there can be no meaningful doubt that increasing levels of carbon dioxide and other greenhouse gases are having a measurable impact on current weather conditions and will have a greater impact in the future. The issue has been complicated for political reasons as powerful incentives exist to inspire certain people and interests to cast doubt on the findings. Media ownership issues in countries such as the United States mean that proper treatment of science in public discourse sometimes has been overtaken by partisan, and often uninformed, opinion.

FUTURE DEVELOPMENTS

Much remains to be done to improve the accuracy and sophistication of existing models, as well as to expand the range of data observations. The urgency with which this work should be completed has increased as the impact of global climate change intensifies. There is an urgent need for properly reviewed research to inform policy decisions in governments around the world to a much greater extent than occurs at the moment. Although many governments have committed themselves to international undertakings such as the Kyoto Protocol, their actual performance nearly always features as the lower end of target brackets and, at the same time, it has become increasingly clear that the existing targets are insufficient to deal with already forecasted changes in the atmosphere. There is a clear need for improved public education concerning the scientific method and ways of separating fact from obfuscation.

In technical terms, in addition to the continuous improvement of the treatment of variables and their integration into existing models, there is an important need to extend the time scales over which predictions of future weather phenomena take place. This will improve understanding of future changes. Second, there is also a need to improve understanding of the interaction among the different components of climate models and current understanding of past events.

Evidence from past ice ages, for example, provides a sound basis for understanding those conditions. However, there have been disparities between observed and predicted conditions, in the case of other factors such as sea temperatures. Even apparently small differences in conditions can significantly affect final results of these models.

Atmospheric Research and Information Centre

THE ATMOSPHERIC RESEARCH and Information Centre (ARIC) is an institution that works to educate citizens of Great Britain about environmental and geographical sciences. Established in 1984, staff at the Centre perform research and provide consulting in the field of atmospheric sciences.

The ARIC also maintained the Atmosphere, Climate & Environment (ACE) Information Programme, to educate people in Great Britain about the environment, specifically addressing pollution and air quality. The purpose of this program was to provide objective information to the public. It was supported financially until 2005 by the Department for Environment, Food, and Rural Affairs of the United Kingdom.

The ARIC is based at Manchester Metropolitan University, Manchester, England. Manchester Metropolitan University (MMU) was founded in the first half of the 19th century with the merger of the Manchester Mechanics' Institution (established in 1824) and the Manchester School of Design (established in 1838). Today the institution is spread over seven campuses. Five of these campuses can be found in Manchester, with two satellites in Cheshire, at Alsager and Crewe.

The ARIC is part of MMU's Centre for Air Transport and the Environment (CATE). CATE focuses on the sustainability of aviation and its intricate relationship with environmental maintenance. Researchers at CATE focus on the environmental impact of aviation. As a multi-disciplinary research center, CATE consolidates information from and shares information with all sectors: academia, industry, government, and nongovernmental organizations (NGOs).

The five major research branches at CATE are Climate Change, Local Air Quality, Noise and Community Impacts, Omega, and Sustainable Development. Climate Change researchers examine the impact of aviation on the global climate. Scientists in the Local Air Quality branch assist local airlines with reaching emissions standards and keeping British airports within national and international criteria. The Noise and Community Impacts team looks at the attitudes of local communities around airports and how these attitudes affect airport growth. Additionally, researchers study the impact of airports and their noise on these communities. In the research branch of Sustainable Development, while at the end of the year 2007 there were no projects underway, several had been completed. These projects examined a range of variables. such as the "Eco-footprinting of airports" and "Sustainability indicators."

Atmospheric Vertical Structure

THE ATMOSPHERE COMPRISES the thin envelope of gases held by the Earth's gravitational force. Extending for several hundred miles above the Earth's surface with no clear boundary, the atmosphere is often subdivided into vertical layers according to a distinctive physical properties. These properties include thermal characteristics, chemical composition, electrical attributes, or density. The vertical structure of the atmosphere is defined by changes in these physical properties, with each change determining a new layer.

The density of the atmosphere refers to the mass of atoms and molecules per unit volume of air. As with all gases, air molecules are not in a fixed, rigid arrangement, and can move randomly through space. No upper threshold to the mass contained per unit volume exists, and, as such, air density can fluctuate. The average density of air at sea level at a temperature of 68 degrees F (or 20 degrees C) is 1.2 kg. per cu. m. (or approximately 1.2 oz. per cu. ft.), decreasing rapidly at lower heights and more gradually with increasing altitude.

This nonlinear relationship between air density and altitude results from another common property of gases, compressibility: the atmosphere expands (and contracts) with decreasing (or increasing) pressure. Atmospheric pressure results from the force exerted by the mass of air molecules subjected to gravitational acceleration over a surface; in other words, the weight of the air above.

The average sea-level pressure of the Earth is 1011 hectoPascals (hPa), but can have considerable local variability. Because the atmosphere is compressible, air molecules are more compact closer to the surface, thereby increasing the density and pressure of the air at lower altitudes. As with air density, pressure decreases at a decreasing rate with increasing height. Approximately one-half of the atmosphere lies below a height of 3.5 mi. (5.5 km.), corresponding to a pressure of 500 hPa. Nearly 90 percent of the atmosphere lies below 10 mi. (16 km.) and a pressure of 100 hPa.

In comparison to density and pressure, the structure of the atmosphere according to thermal characteristics is more complex. Interactions among various atmospheric gases and radiant energy from the Sun and Earth result in distinct variations in the vertical temperature profile. Based on these thermal changes, the atmosphere is commonly subdivided into four major layers known as the troposphere, stratosphere, mesosphere, and thermosphere.

The troposphere encompasses the lowest portion of the atmosphere, from the surface to an average height of 7.5 mi. (12 km.). The temperature of the troposphere is primarily influenced by the radiant energy exchanges from the underlying surface. The further the air molecules are away from the surface, the less the atmosphere will warm. Tropospheric temperature decreases with height at an average rate of 3.5 degrees F per 1,000 ft. (6.5 degrees C per km.), a measurement termed the *normal lapse rate*. The top of the troposphere, known as the tropopause, has an isothermal layer, a zero lapse-rate region, where temperature does not change with altitude. The tropopause occurs at heights ranging from 5.6–9.9 mi. (9–16 km.), depending on latitude and season.

Beyond the tropopause lies the stratosphere. In this region, the isothermal layer gives way to a temperature increase with height or temperature inversion. This temperature increase occurs because of a localized concentration of ozone molecules (O_3) found 9–19 mi. (15 to 30 km.) above the Earth's surface. These molecules absorb ultraviolet solar radiation that warms the stratosphere.

Stratospheric warming terminates around 30 mi. (50 km.) at the stratopause, which marks the transition zone between the stratosphere and the much colder mesosphere. In the mesosphere, temperatures decrease rapidly with height. This layer contains the lowest temperatures of the atmosphere, averaging minus 130 degrees F (minus 90 degrees C) at 50 mi. (80 km.) above the surface. These lows are reached at the mesopause, the boundary between the mesosphere and thermosphere.

The thermosphere represents the outer layer of the Earth's atmosphere. Temperatures in this layer increase substantially with height from the absorption of solar energy by relatively few oxygen molecules (O_2).

While temperatures can register to values more than 1,800 degrees F (1,000 degrees C), the thermosphere holds an insignificant amount of heat due to the extremely low density of atmospheric gases. The thermosphere (and the upper mesosphere) also contains a large concentration of ions and free electrons in a sub-layer known as the ionosphere. Between 50–250 mi. (80–400 km.), these ionized molecules interact with charged particles from the sun to produce brilliant light displays at high latitudes known as the *aurora borealis* (northern lights) or *aurora australis* (southern lights), in the Northern and Southern Hemispheres, respectively.

Attribution of Global Warming

ATTRIBUTION OF GLOBAL warming refers to the recent effort to scientifically prove the cause of the warming effect. Many factors can cause changes in the Earth's heat balance, and changes large enough to cause major episodes of warming and cooling have taken place many times in the Earth's past. One cause of change of great concern to scientists is the amount of heat-absorbing gas in the atmosphere. Carbon dioxide, water vapor, and several secondary gases absorb thermal infrared radiation released from the Earth's surface and the lower atmosphere.

Greenhouse effect is the phrase for when a planet's atmosphere and surface are warmed by the absorption and emission of infrared radiation of atmospheric gases. When absorption takes place, the gas molecules take on heat and air temperature rises. If the atmosphere is heavy with water vapor and carbon dioxide, then heat tends to be retained in roughly the same way as the glass of a greenhouse contains longwave infrared radiation and heat. Hence, greenhouse effect is commonly used to describe the role of carbon dioxide (CO_2) and H_2O vapor and various secondary gases in holding heat within the atmosphere.

To illustrate the importance of the greenhouse effect, scientists estimate that if it were eliminated, the Earth's equilibrium surface temperature would fall 59 degrees F to 0 degrees F (33 degrees C to minus 18 degrees C). Global warming is one of the specific examples of climate change, referring to recent warming, and implying a human influence. Global warming is the status quo of the increasing average temperature of the Earth's near-surface air and oceans. It also refers to its projected continuation.

HUMAN-INDUCED CLIMATE CHANGE

The dominant mechanisms to which recent global warming and climate change have been attributed all result from human activity, such as increasing atmospheric concentrations of greenhouse gases, or aerosols. These attributions are supported by observations from the Intergovernmental Panel on Climate Change (IPCC). The IPCC concluded that most of the observed increase in globally averaged temperatures since the mid-20th century is "very likely" due to the observed increase in anthropogenic greenhouse gas concentrations via the greenhouse effect. It also concluded that it is "extremely likely" that human activities have exerted a substantial net warming influence on climate since 1700. These conclusions have probabilities greater than 90 and 95 percent, respectively.

Since the 1700s, the CO_2 content of the atmosphere has been increasing as a result of air pollution emitted by human activities. Pollution has also caused a significant increase in secondary greenhouse gases, namely methane from animal digestion and bacteria, ozone and nitrogen oxides from urban air pollution, and chlorofluorocarbons from spray cans and fugitive refrigerants. The increase in CO_2 and the four secondary greenhouse gases is a global trend. Since 1760, the atmospheric concentrations of CO_2 and methane have increased by 32 percent and 151 percent, respectively, compared to the pre-industry period. Therefore, the biggest root cause is worldwide population growth.

According to the IPCC, the projected increase of global surface temperatures is likely to be 2.1–11.7 degrees F (1.2–6.5 degrees C) between 1995 and 2100, based on the different scenarios of future greenhouse gas emissions and climate sensitivity. These conclusions have been endorsed by at least 30 scientific societies and academies of science, including all of the national academies of science of the major industrialized countries.

The argument related to global warming focuses on how much the greenhouse effect will be increased with the growing atmospheric concentrations of some greenhouse gases by human activities. Naturally occurring greenhouse gases consist of about 36–70 percent water vapor (not including clouds), 9–26 percent CO_2, 4–9 percent methane (CH_4), and 3–7 percent ozone. Comparatively small fractions of the greenhouse effect are caused by naturally occurring gases such as nitrous oxide (N_2O). Concentrations of N_2O are increasing because of human activity such as agriculture. CO_2 is produced mainly by natural processes such as volcanoes and rock weathering, and is recycled through the atmosphere by the biological processes of respiration and photosynthesis.

Over geologic time, atmospheric CO_2 has varied appreciably, causing shifts in the Earth's heat balance. Over periods of thousands of years, however, the CO_2 cycle can keep a fairly stable balance, thereby helping maintain a relatively stable global temperature regime. CO_2 from human sources, however, represents a surcharge on the natural system.

Human sources of CO_2 fall into roughly two major classes: fossil fuel combustion and open fires. Use of fossil fuels by humans contributes to three-quarters of the increase in CO_2 over the past 25 years. The fossil fuel sources are industry, power plants, automobiles, and households; the developed countries are the principal contributors. The open-fire sources are associated with the clearing of tropical forests, forest fires in general, grassland fires, household cooking and heating, and wars. The rate of increase in atmospheric carbon dioxide approximates that of global economic growth, about 2 percent annually. Current carbon dioxide levels are about 30 percent above the 18th century (pre-industrial) level.

It is crucial to scientifically determine mechanisms responsible for the observed warming of the Earth, and many efforts have been made to prove changes observed during the last 50 years, when human activity has grown fastest and observations of the upper atmosphere have become available. There are measurable signs that warming is underway, because the global atmospheric temperature has increased at least 0.9 degrees F (0.5 degrees C) in the last 100 years. This rise corresponds to the measured increase in atmospheric CO_2. Even though short-term temperature trends on the order of 50 or 100 years generally have little meaning with respect to global-scale warming, it is curious to note that studies of global temperature records dating from the late 1800s indicate that the 1980s and 1990s were the warmest two decades on record.

The IPCC has played an important role in providing the attribution of global warming, however, there are still several uncertainties that have to be resolved, including the exact degree of global warming expected in the future, and how changes will vary from region to region around the globe. One reason for scientists' uncertainty about how much global warming will take place is related to the rate of removal of CO_2 from the atmosphere. CO_2 is removed from the atmosphere by two main absorbing agents, vegetation and the oceans.

Under natural circumstances, it can be assumed that the oceans annually extracted 90 billion tons of CO_2 from the atmosphere, an amount equal to the quantity they put into the atmosphere yearly. However, with the rise of global air pollution, the oceans appear to have increased their CO_2 intake and now absorb a large part of the 7 billion tons of excess CO_2 put into the atmosphere annually from human sources. The amount may be as great as three billion additional tons a year. Therefore, the net amount of CO_2 left to accumulate in the atmosphere is about 4 billion tons a year.

At this rate, coupled with allowances for population growth, atmospheric CO_2 is expected to double by 2050. Whether the oceans and land vegetation will increase or decrease their intake of CO_2 in the future is difficult to claim at this point. Recent researchers concluded that the estimate of 3 billion tons of annual ocean intake may be high. The oceans may actually be taking in closer to 2 billion tons a year, and some other agency is responsible for extracting the remaining 1 billion tons of CO_2. Perhaps the world's forests might be a good candidate to increase the rate of intake. Some studies suggest that air pollutants such as CO_2 and sulfur dioxide may actually increase forest growth and intake CO_2 in some regions. The annual rate of rainforest destruction, as much as 65,000 sq. mi. (168,349 sq. km.) a year, is a considerable loss, especially when forests have very high annual CO_2 intake capacities.

FEEDBACK PROCESSES

The second category of the attribution of the warming is the various feedback processes caused by the forcing agents on the climate. Evaporation of water might be the most evident feedback effect that contributes to global warming. The initial warming generated by CO_2 will cause more water to be evaporated into the atmosphere. Then, water vapor acts as a greenhouse gas and causes more global warming. As a result, the global warming causes still more water vapor to be evaporated until the concentration of water vapor has reached the dynamic equilibrium, with a much larger greenhouse effect than that due to CO_2 alone. This increases the amount of the absolute moisture in the air, but the relative humidity of the atmosphere rarely changes because the air is warmer.

Cloud feedback effects are an area of ongoing research. In the air, clouds emit infrared radiation from the ground back to the surface and enforce the warming effect. The same clouds reflect sunlight and emit infrared radiation from sun to space and enforce the cooling effect. Because the type, altitude, and other variables are important factors in deciding the net effect of clouds on cooling or warming, it is very difficult to represent in climate models. Nevertheless, cloud feedback is reported as the second largest positive feedback that contributes to the global warming models that were used in the IPCC Fourth Assessment Report.

Ice albedo feedback is another feedback process that contributes to global warming. As global temperatures increase, the melting process of the ice near the poles increases rapidly. The resulting land and open water are, on average, less reflective than ice, and, thus, absorb more solar radiation. This causes more warming, which in turn causes more melting, and this cycle continues. Positive feedback due to release of CO_2 and CH_4 from thawing permafrost is an additional mechanism contributing to warming. Possible positive feedback due to CH_4 release from melting seabed ice is a further mechanism to be considered.

A COUNTERARGUMENT

In contrast to the scientific consensus, there is a counterargument by a few individual scientists who cast doubt on the global warming forecast. Their claims are based on the blocking effect on solar radiation caused by aerosols. Aerosols are particles of solids and liquids suspended in the atmosphere that backscatter incoming solar radiation. Aerosols are produced from both natural sources such as volcanoes, and pollution sources such as forest fires and urban emissions. They occur in both primary and secondary forms, meaning that some enter as particles, whereas others develop into particles from gaseous pollutants. In addition, pollutants increase condensation and cloud formation, thereby increasing reflection of solar radiation. Because aerosols and clouds reduce solar radiation receipt in the lower atmosphere and at the Earth's surface, they also reduce solar heating and may cause temperatures to decline as a result.

The effect of aerosols on solar heating of the lower atmosphere was dramatically demonstrated in the hours immediately after 9/11. The U.S. government ordered grounding of all aircraft, and for a short time, skies over the United States and Canada were clear of condensation trails from high-flying jetliners. During that time, a distinct rise in surface temperature was recorded over broad areas.

With the resumption of flying, temperatures fell back to pre-9/11 levels. With the dramatic increase in global air pollution in this century, the atmosphere has grown dirtier and less transparent to solar radiation. Less solar energy reaches the Earth's surface, and if there were no counterbalancing factors, the lower atmosphere would probably be growing cooler. But there are counterfactors in the form of CO_2 and warming gases.

EFFECTS OF GLOBAL WARMING

If global warming proceeds, Earth's equilibrium surface temperature will rise 3–11 degrees F (2–6 degrees C) over the next 100 years. Earth's equilibrium surface temperature will reach 62–68 degrees F (17–20 degrees C). This means that more thermal energy will be available to drive atmospheric processes such as winds, air mass movement, and evaporation. How all of this will interrelate to shape the broad picture of global climate is difficult to forecast. Based on computer simulation models illustrating anticipated changes in atmospheric circulation, scientists forecast that warming will not be geographically uniform; in some regions it will be significantly greater than others, and the climatic changes will likely be different in different parts of the world.

Specific examples of the modeling approach for change of global temperature scenarios are simple climate models (SCMs). SCMs are the simplified models used by the Intergovernmental Panel on Climate Change (IPCC) to provide projections of the atmospheric concentrations of greenhouse gases, global mean temperature, and sea-level change response, using as input emissions scenarios describing the future developments in the emissions of greenhouse gases.

The increased heat content of the troposphere will strengthen certain air masses, increasing their moisture content, leading to greater storminess in some regions. It is already known that that storminess and precipitation on the Pacific coast of the Americas increases substantially with only 1.8–3.6 degrees F (1–2 degrees C) of atmospheric warming associated with El Niño, the periodic buildup of warm water in the east Pacific near the equator. Increased ocean temperatures may also lead to increased magnitude and frequency of hurricanes. Hurricanes are driven by the energy of water vapor, called latent heat. Warmer ocean waters supply more vapor, and thus more energy, to the atmosphere to fuel storms. Hurricanes are the most powerful storms on the planet, and the greater their fuel supply, the bigger and more destructive they are.

Although it is difficult to connect specific weather events to global warming, an increase in global temperatures may, in turn, cause other changes, including glacial retreat and worldwide sea-level rise. Changes in the amount and pattern of precipitation may result in flooding and drought.

There may also be changes in the frequency and intensity of extreme weather events. Other effects may include changes in agricultural yields, reduced summer stream flows, species extinctions, and increases in the range of disease vectors. Some effects on both the natural environment and human life are, at least in part, already being attributed to global warming.

The broad agreement among climate scientists that global temperatures will continue to increase has led nations, states, corporations, and individuals to implement actions to try to curtail global warming or adjust to it. Many environmental groups encourage action against global warming, often by the consumer, but also by community and regional organizations. There has also been business action on climate change, including efforts at increased energy efficiency, and moves to alternative fuels. One important innovation has been the development of greenhouse gas emissions trading through which companies, in conjunction with government, agree to cap their emissions or to purchase credits from those below their allowances.

THE KYOTO PROTOCOL

The world's primary international agreement on combating global warming is the Kyoto Protocol, an amendment to the United Nations Framework Convention on Climate Change (UNFCCC), negotiated in 1997. The protocol now covers more than 160 countries and over 55 percent of global greenhouse gas emissions. As of 2007, the United States (historically the world's largest greenhouse gas emitter), Australia, and Kazakhstan had not ratified the treaty. China and India have ratified the treaty, but as developing countries, are exempt from its provisions. This treaty expires in 2012, and international talks began in May 2007 on a treaty to succeed the current one. Increased awareness of the scientific findings surrounding global warming has resulted in political and economic debate. Poor regions, particularly in Africa, appear at greatest risk from the suggested effects of global warming, while their actual emissions have been negligible compared to the developed world.

At the same time, developing country exemptions from provisions of the Kyoto Protocol have been criticized by the United States and Australia, and have been used as part of their rationale for continued non-ratification. China's CO_2 emissions, mainly from automobiles and coal power plants, are expected to exceed those of the United States within the next few years. China has contended that it has less obligation to reduce emissions, since its emissions per capita are about one-fifth those of the United States. The United States contends that if they must bear the costs of reducing emissions, so should China. India will also soon be one of the biggest sources of industrial emissions, and has made assertions similar to China's on this issue.

The world's primary body for crafting a response is the Intergovernmental Panel on Climate Change (IPCC), a UN-sponsored activity that holds periodic meetings between national delegations on the problems of global warming, and issues working papers and assessments on the current status of the science of climate change, impacts, and mitigation.

Aurora

AN AURORA IS a colored display of light usually seen at night. They are natural, and occur more commonly in the polar regions than in temperate southern regions in the Northern Hemisphere or more temperate northern regions in the Southern Hemisphere. Auroras occur most frequently in the Northern Hemisphere around the time of the autumn equinox in September and October and at the spring equinox in March and April. Auroras are sometimes called polar auroras (*aurorae polaris*), or in the Northern Hemisphere, *aurora borealis*. A popular name in the Northern Hemisphere is the *northern lights;* in the Southern Hemisphere they are the *southern lights* or the *aurora australis* (Latin for southern is *australis*).

The *aurora borealis* begins with a magnetic storm on the sun. If the sun emits an extra mass of particles in a solar wind to the Earth, this can then produce a magnetic storm on earth. If the conditions are right, the *aurora borealis* can be seen not only at the poles, but far to the south in the Northern Hemisphere or far to the north in the Southern Hemisphere.

The light displays of auroras are caused by charged ion particles reaching the upper atmosphere of the Earth in solar wind. If the particles arrive as a cloud, they are called solar plasma. If the particles collide with one another when they are in an excited atomic state, light is emitted. This means that there may be more electrons surrounding an atom than normal. The excess energy can be emitted from the particle as visible light. Usually, the light is in wavelengths of 22 in. (557.7 mm.), which is in the visible light range of green. Some may be at lower or higher wavelengths and, thus, seen as red or other colors. The particles follow the Earth's magnetic field and may appear to glow as wavering sheets or curtains. Other forms of aurora activity occur as arcs of light, which can also be in folds that appear to have striations. Contributing to the shape of the *aurora borealis*

Aurora activity has been associated with sunspots since 1852; links to climate patterns are still being investigated.

are the rotation of the Sun and the rotation of the Earth. As the solar stream hits the Earth, it meets the Earth's rotation. The two combine to make a spiral shape.

Contributing to the frequency of the aurora is the sun's 11-year cycle. Sunspots and the emission of solar particles occur in a cycle that rises and falls in activity. Auroras are associated with a high number of sunspots. This relationship has been known since 1852, when Edward Sabine first identified it using sunspot and aurora spotting data that went back 100 years. This relationship seems to also correlate with climate patterns.

There is speculation that fluctuations in climate are closely related to the presence of aurora activity in Earth's atmosphere. The *Maunder minimum* is the term that was first used to identify the period 1645–1715. This was a time in which aurora activity was rarely seen, and sunspots were not observed with any frequency. In 1976, it was demonstrated that the Maunder minimum was associated with abnormal amounts of C_{14} in tree rings. When the Edda Period, a period of high sunspot activity in the 12th and 13th centuries was examined, numerous references to aurora activity were also found.

Some researchers have theorized that global warming may be associated with sunspot activity, or global cooling with its absence. Research is being conducted into the possibility that global warming is caused by solar emissions, rather than by the increasing presence of higher levels of carbon dioxide in the atmosphere due to pollution emissions since the Industrial Revolution.

Australia

AUSTRALIA IS A developed country in the Southern Hemisphere. With a landmass of 2,941,299 mi. (7,617,930 sq. km.), it is the sixth largest country in the world, but is sparsely inhabited, with a population of approximately 21 million. Prior to federation in 1901, the continent of Australia was comprised of separate colonies and territories. The Commonwealth of Australia is now divided politically into six states and two major territories. Australia is also responsible for a number of minor territories, including Christmas Island, the Cocos Islands, and Norfolk Island.

Most of Australia's population is concentrated in the southeast of the country, although there has been rapid population growth in the northeast (Queensland) and in the southwest (Western Australia). The national capital is Canberra. The largest cities are Sydney and Melbourne (each with about 4 million residents); and Brisbane, Perth, and Adelaide, each with 1–2 million residents in 2006. Most of the population lives close to the coast. There are inland agricultural and mining towns, but the interior of the country is semi-arid or arid with little human settlement.

Indigenous people have inhabited the continent for at least 40,000 years. European and Asian exploration and trade occurred for hundreds of years before the arrival of the English. Dutch explorers, particularly those associated with the

Dutch East Indies Company, are known to have landed on Australia beginning at least early in the 17th century. They gave the land the name *Terra Australis Incognita* ("unknown southern land"). Captain James Cook claimed the land for England in 1770, and English settlement began in 1788, in what is now Sydney. The colonies developed at different rates, boosted by gold rushes in New South Wales and Victoria in the 1850s, and in Western Australia in the late 1880s and 1890s. Mining booms have been significant, particularly coal mining in New South Wales and Queensland, and iron-ore mining in the northwest of Western Australia.

Climate change is an important issue for Australia, due to its position on the global political scene, its generation of greenhouse gases, and the potential impact of climate change for Australia. With regard to political positioning, in December 1992, Australia became the eighth country to ratify the United Nations Framework Convention on Climate Change, which had been signed by 155 countries in Rio de Janeiro. The most significant of the Conferences of the Parties (COP) held to develop and implement the framework was COP3 in Kyoto, Japan. At COP3 in 1997, the Annex One (developed) countries agreed to an average reduction of 5.2 percent of greenhouse gas emissions from a base year of 1990 by the period 2008–12.

Australia signed up to an 8 percent increase in emissions over the same time period, but also managed to insert a clause into Article 3.7 of the Kyoto Protocol to allow the emissions from land clearing to be included in the total emissions by Australia in 1990. Land clearing had decreased between 1990 and 1997. The baseline inflation gave room for Australia to expand other sources of greenhouse gas emissions and potentially remain within the 108 percent target.

Australia and the United States refused to ratify the Kyoto Protocol, citing the exclusion of countries such as China, India, and Brazil, plus Australia's unique economic structure (a large coal exporter and a very high greenhouse gas emitter per capita) and its national interest, as other reasons not to ratify the protocol. In February 2002, the U.S.-Australia Climate Action Partnership was established to work outside of the Kyoto Protocol framework. This concept was expanded in January 2006 into a new Asia-Pacific Partnership on Clean Development and Climate Change, comprised of Australia, China, India, Japan, the Republic of Korea, and the United States.

Australia is working outside of the Kyoto Protocol because of the political stance of the government, Australia's economic structure, its emissions generation, and because of the likely impacts of climate change for Australia. Australia produces approximately 2.3 percent of the world's greenhouse gas emissions, which is a very high rate per capita. Australia is also connected through the coal chain to global greenhouse gas emissions. At a global level, Australia is a rare example of a country that exports most of the coal it mines. Australia is the world's largest coal exporter, with markets mainly in Japan, South Korea, Taiwan, and other European and Asian destinations. The Port of Newcastle is the largest exporter of coal by tonnage in the world.

Stationary energy/power stations (68 percent), agriculture (19.5 percent), and transport (14.2 percent) generated most of Australia's greenhouse gas emissions in 2001. Industrial processes contributed only 4.6 percent of the total emissions. These aggregate figures do not account for the end use of the energy. The figures also highlight Australia's reliance upon fossil fuels. Australia's transport energy is predominantly petroleum; 84 percent of electricity in Australia is generated from coal.

The impacts of climate change will vary. Australia is vulnerable to drought, the ecosystems and biodiversity are prone to climate change in the long term, there are concerns that fires and insect outbreaks may be increased, and that coastal settlements are susceptible to flooding and erosion caused by sea-level rise. Inland temperatures are anticipated to increase more than temperatures in coastal locations, thereby making Australia very vulnerable to water shortages and threatening the health of rivers. By 2050, cities in northern Australia, such as Cairns, are likely to experience more intense tropical cyclones, with wind speeds likely to increase by 10 to 15 percent, the associated rainfall likely to increase by 20 to 30 percent; the area that is inundated by storm surges is likely to double.

There are innovative programs at federal, state, and local government levels in Australia that address the issue of climate change. These include Cities for Climate

Protection, which is coordinated and supported by the Australian Greenhouse Office and the International Council for Local Environmental Initiatives. There are also business initiatives and environmental groups campaigning about climate change. Unfortunately, Australia's greenhouse gas emissions have been rising steadily since the 1990s, and as of 2004 were reported at 25 percent above 1990 levels.

Austria

LOCATED IN CENTRAL Europe, Austria covers 32,383 sq. mi. (83,872 sq. km.) and has a population of 8,316,487 (2007 est.), with a population density of 257 people per sq. mi. (99 per sq. km.). Some 17 percent of the land in the country is arable, with a further 23 percent used for meadows and pasture. In addition, 41–47 percent of the country is forested, making it the most extensively wooded country in Europe.

As a wealthy country, Austria's population uses electricity and private cars extensively. However, use of bicycles has increased in recent years, and there is an extensive train service covering much of the country, in part duplicated by bus service.

The prosperity of the country has resulted in a relatively high rate of carbon dioxide emissions per capita: 7.5 metric tons in 1990, rising to 8.6 metric tons by 2003, significantly lower than that of the Czech Republic and Germany, but higher than its other neighbors. As for electricity generation in Austria, only 28.4 percent of it comes from fossil fuels, with 68.6 percent from hydropower. As a result, the country produces extremely low rates of emissions of sulfur dioxide, nitrogen oxide, and carbon monoxide.

The effects of global warming in recent years in Austria include the melting of some of the Alpine glaciers. The melting glaciers in the Ötztal Alps led to the November 1991 discovery of the preserved body of a frozen Stone Age person, nicknamed Ötzi, indicating that the glacial ice is smaller than at any period in the last 5,000 years. One study has shown that alpine plants in the Austrian Alps are now growing higher and higher on mountain slopes, in response to the rise in average annual temperatures. These changes, as well as an increase in development, have led to the endangering of the *Kaiseradler*, or Imperial Eagle.

A United Nations environmental report in 2003 claims that if global warming continues to raise the temperature in Austria, many ski runs, and even entire ski resorts, will have no snow by 2030. The expected rise of between 2.5–10-4 degrees F (1.4–5.8 degrees C) by 2100 would result in the snow line moving from 3,937–5,905 ft. (1,200 m. to 1,800 m.), which would mean that many resorts, such as Kitzbühel, might not have any snow. This also poses a threat to the fauna such as the chamois, the mountain goat, and the ibex.

The Austrian government of Fred Sinowatz took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and the Global Warming International Conference & Expo (GW7) was held in Vienna on April 1–3, 1996. The government of Viktor Klima signed the Kyoto Protocol to the UN Framework Convention on Climate Change on April 29, 1998. It was ratified on May 31, 2002, and took effect on February 16, 2005. Focusing on a reduction on greenhouse gas emissions, the UN Framework Convention on Climate Change held a round of climate change talks in Vienna on August 31, 2007. During this period, there was a reduction in air and soil pollution from industrial chemicals, including the banning of leaded gasoline. Later government policies have encouraged wind power and solar power, with tax concessions given to people who install solar panels.

Automobiles

TEN BILLION METRIC tons of carbon dioxide and other greenhouse gases are spewed into the atmosphere each year by the fossil fuel-hungry transportation sector. Over the typical 124,000-mile lifespan of an automobile, the Toyota Prius will emit 32 tons of carbon dioxide from its tailpipe versus a Ford Excursion spewing 134 tons.

The type of transportation employed has a major impact on the amount of carbon dioxide and pollutants produced. People can choose their mode of transportation and whether or not to be a part of a growing community that wants to reduce the effects of global warming by cutting back on tailpipe emissions. The internal combustion engine (ICE) is a poor choice of power source. It dissipates 80 percent of its energy as heat, even before it reaches the vehicle's rear axle. Two major approaches to reduce the threat of global warming have emerged in the automobile industry. The first approach encompasses both conservation and new technology. A proven idea is increasing vehicle efficiency at a greater rate than has been done to date. The automobile industry can also develop new vehicle technology beyond the gas-electric hybrids. Introduction of Pluggable Hybrid Electric Vehicles (PHEVs) that double the range of current hybrids and further reduce greenhouse gas tail emissions is on the horizon. Utility operators already know that they can handle the additional demand expected of the power grid, since most PHEV owners would plug in their cars at night to be recharged, when demand for 120-volt supplies is low. All that is needed is improved battery technology and the will of automakers.

A second strategy is to develop alternative fuel supplies to power vehicles. Ethanol-blended gasoline, such as E85, is appearing on the market. New American cars work with this fuel which is 85 percent gasoline and 15 percent ethanol. Vehicles manufacturer-certified to burn E85 produce less carbon dioxide is produced combusting this fuel than burning regular gasoline, in spite of the CO_2 needed to produce the ethanol in the first place. Engine performance is boosted with E85, too, with some vehicles realizing a horsepower gain of up to 5 percent. One major advantage is lowered tailpipe emissions. Other mixtures are being developed, including the use of liquid hydrogen as an alternate source.

While many of these actions are voluntary, regulatory action is often required to raise mileage standards. In the United States, more stringent Corporate Average Fuel Standards (CAFE) spurs development of energy-efficient components and solutions for personal mobility. To achieve new goals for greater miles per gallon, and, hence, lower greenhouse gas emissions, more fuel-efficient engines and transmissions are needed for conventional gasoline-powered or diesel-powered vehicles.

BMW automobiles, a company that does not have a gas-electric hybrid on the market, is also contributing to better fuel efficiency. It developed a brake energy regeneration system as a result of an internal project to provide intelligent alternator control. Every car on the market uses an alternator to continuously generate power, regardless of the engine load. Known as "alternator drag," the alternator consumes energy even when the car is cruising or accelerating, a process referred to as freewheeling. If the alternator only generates power during the braking cycle, the amount of fuel consumed overall is reduced. BMW expects its brake energy regeneration system to cut energy consumption by 3 percent on every car that adopts the technology. The conventional energy cycle can be deconstructed,

A gas-electric hybrid, for example, a Toyota Prius, will emit only 32 tons of carbon dioxide from its tailpipe over a typical 124,000-mile automobile lifespan, while a Ford Excursion will discharge over 100 tons more.

analyzed, and subsequent innovations can deliver better miles per gallon for the driving public.

HYBRID AND ELECTRIC VEHICLES

Hybrid vehicles are available today and continue to gain market acceptance. Toyota's Prius has been the overwhelming favorite of the car-buying public interested in gas-electric hybrids. The first 100,000 Prius gas-electric hybrids were sold by September 2004, after the introduction of the car in Japan in 1997. While it took almost seven years to reach the first 100,000 sales, a five-fold increase was achieved in about 18 months. By April 2006, Toyota's worldwide sales passed 500,000 units. Momentum continued to build, and after another year had passed, Toyota exceeded the one million mark in sales. The Prius is a market hit, and the gas-electric hybrid technology for fuel efficiency and reduced greenhouse gas emissions has gained consumer acceptance. Electric vehicles that were popular at the turn of the 20th century are making a comeback in the 21st century. Two entrants come from Tesla Motors, the Roadster, a high-end sport car for the elite buyer, and Think, with their City car, a working everyday run-about. Think is working to fulfill a vision of producing a carbon-neutral vehicle. The Think City has a range of 112 mi. (180 km.) on a single charge, regulated at a maximum speed of 62 mi. (100 km.) per hour. It is ideal for local driving, easily exceeding the typical 50 mi. (80 km.) a day that most people drive.

Associated with an aspect of sustainability is the vehicle's battery, the major expense in any electric vehicle. It is expected that battery-leasing companies will appear to make vehicles like the Think City affordable to a wider audience. Utility operators can use batteries no longer suitable for transportation, but still retaining a useful charge, in their power facilities to store excess energy produced by renewable sources such as solar and wind. Many governments are offering some form of rebate incentive to go green and help improve local air quality, regardless of the type of gas-electric hybrid or electric vehicle driven. For example, the Canadian province of Manitoba initiated a $2,000 rebate program to offset the higher cost of gas-electric hybrid vehicles versus comparable “dirtier” vehicles. The objective was to increase the number of hybrid vehicles from a paltry .01 percent of vehicles operating, to some greater percentage that would help reduce greenhouse gas emissions.

A July 2007 joint study by the Electric Power Research Institute (EPRI) and the Natural Resources Defense Council (NRDC) reports that even with marginal reductions made to existing power plant emissions and acceptance of gas-electric hybrids on the order of 20 percent of the driving public by 2050, 163 million tons of greenhouse gas emissions would be cut. This worst-case scenario is great news for hybrid advocates, especially those pushing for PHEVs. In a better case scenario, where more aggressive pollution-control measures are invoked on utilities and where hybrids garner over a 60 percent share of the market, 468 million tons of greenhouse gases can be spared from the atmosphere. This translates into removing more than 80 million cars from the highways.

In early 2007, it was reported that a standard Prius converted to PHEV doubled its gas mileage range. One 51 mi. (82 km.) trip netted an efficiency of 124 mi. (300 km.) per gallon at a cost of a penny in electricity per mile. The conversion to PHEV delivered a huge reduction in gas consumption of just over 60 percent, while emitting about two-thirds less greenhouse gases. Total cost was $1.76 in gas and $0.51 electricity versus the $3.17 in gas it normally cost. PHEVs contribute lower CO_2 emissions, because they do not burn fossil fuels directly, but take electricity from a mix of sources produced by the utility. In a more typical comparison with conventional ICE vehicles, a standard Prius will release one-third less carbon dioxide than a large sedan into the atmosphere.

HYDROGEN-POWERED VEHICLES

In terms of reducing automobile pollution, each generation of new pollution control technology, since the days of the catalytic converter, has been pioneered by California. A recent plan for a California Zero Emissions Vehicle (ZEV) is spurring the development of new technologies, including hydrogen-powered automobiles. To run these, hydrogen fuel can be derived from fossil fuels (which defeats their purpose somewhat), biomass, or electrolysis of water. The most popular feedstock for producing hydrogen is natural gas. Using renewable alternatives, such as photovoltaics or wind to produce hydrogen, runs at three times the cost of other techniques. If the electricity for electrolysis comes from coal-fired plants, the CO_2 emissions are even greater than those from natural gas, unless the carbon can be sequestered. All things being equal, hydrogen produced from the electrical grid would produce a net increase in global warming for the next 20 years. Coal gasification can also be used to produce hydrogen.

Given that the economics to produce hydrogen dictate the selection of a fossil fuel feedstock, it makes a big difference how the carbon dioxide is produced. An internal combustion engine produces 248 kg. of carbon dioxide for each 600 mi. (966 km.) driven. Table 1 reflects the reduction in kilograms possible by using alternate forms of transportation:

Table 1

Propulsion type	CO_2 emissions	Reduced kg CO_2/600 mi.
ICE (internal combustion engine)	248	0
PHEV (coal-fired electricity)	237	11
FCV (onboard gas reformer)	193	55
FCV (onboard methanol reformer)	162	86
FCV (natural gas-derived hydrogen from a fuel station)	80	168
FCV (refinery-supplied hydrogen)	70	178

Hydrogen is used in fuel-cell vehicles (FCVs), which are a potential replacement for ICEs. Hydrogen is converted to electricity, without high temperature reactions and is done so very efficiently. Only water vapor is produced, a byproduct that is less harmful to warming global temperatures than carbon dioxide, methane, or chlorofluorocarbons (CFCs). Every major car manufacturer has a FCV prototype, and many have FCVs on the roads in places like California, Washington D.C., Japan, and parts of Europe.

It is expected that FCVs will appear when the following issues are resolved: high cost of fuel cells, overcoming poor fuel cell durability, improving onboard fuel storage to ensure comparable or better driving range, meeting and exceeding safety standards and demonstrating such, and ensuring there is an infrastructure to produce and distribute the hydrogen to large numbers of the driving public.

BMW's Hydrogen 7 or H-7 is a bifuel vehicle using an internal combustion engine that is propelled by either gasoline or hydrogen. It is a transitional vehicle that could be introduced to bridge the gap between the scarcity of hydrogen fueling stations today and their expected abundance by 2030.

INVESTMENT AND CHOICES

Chemical battery breakthroughs are needed to improve energy storage capacity and length of storage times, which are critical for hybrid vehicles to make the transition to PHEVs. Superior battery performance is also needed as electric vehicles begin to reappear after a more than 100-year absence. Continued investment in a hydrogen infrastructure that weans humanity from fossil fuel sources is a worthy long-term goal that can pay big dividends for the patient investor.

Furthermore, simply increasing fuel economy on existing vehicles can save millions of gallons of oil each year in the short term. This can be done without future hydrogen vehicles or all-electric vehicles making any contribution. Market pressure is making these types of investments happen faster than government regulations.

General Motors lost its position of market dominance by ignoring customer demands for gas-electric hybrids or evolving its early generation electric vehicle. No government bailouts are expected for American automakers, and there is little hope that continued lobbying for lenient mileage standards would be successful.

Aviation

AVIATION IS ONE of the most significant drivers of global warming and climate change. The rapid development of economies around the world has increased the desire to travel by air, thus creating greater levels of pollution, both in the air and on the ground. However, aviation plays an important part within the global economy and, as a result, governments, aircraft manufacturers, airlines, and airports are working hard to reduce their global impact. The growth of air transportation has been frenetic due to technical advancements and economic development. The jet engine and wide-bodied jet aircraft, such as the Boeing 747, revolutionized the number of people who could be carried over greater distances at far lower unit cost. The result was cheaper and more frequent holiday and business trips.

The economic development of countries and higher standards of living have also allowed passengers to travel more frequently. Linked to these advances has been the desire of governments across the world to deregulate the aviation industry, thus helping to create additional competition. The introduction of new carriers, particularly low-cost airlines, such as Southwest Airlines of the United States and Ryanair of Europe, has helped increase mobility by air for groups of consumers who would have previously found it difficult to travel by air. Commercial aviation carries some 4.5 billion passengers per year. With continued growth by low-cost carriers and the traditional airlines, it is estimated by the Airports Council International that this figure will reach an estimated 7.4 billion by 2020.

Economically, aviation is of great importance, creating both wealth and employment worldwide. The International Air Transport Association (IATA) has highlighted that commercial aviation accounts for 8 percent of GDP globally. Aviation has helped drive globalization and allows greater communication between industries and friends and families. Added to this are the millions of jobs created in the aviation sector ranging from aircraft manufacturing, airline carriers, airport operators, and employment within the regulatory authorities.

ENVIRONMENTAL IMPACT

The impact of aviation on the environment is multifaceted. Aircraft expel numerous gases during flight, including carbon dioxide, nitrogen oxide, water vapor, and a variety of particulates. According to the Intergovernmental Panel on Climate Change, commercial aviation contributes 3 percent of all CO_2 emissions. This is still low compared to energy providers who account for 25 percent of all carbon emissions. However, the percentage contribution to CO_2 emissions from aviation continues to grow, while energy providers have been able to reduce their contribution. The Aviation Environmental Federation estimates that commercial aviation produces 700 million tons of CO_2 per year. A flight from New York to London, for example, is estimated to create two tons of CO_2 per passenger.

The production of nitrogen oxides by jet engines results in further environmental impact associated with global warming. Nitrogen oxides have resulted in an increase in ozone, which has led to an increase in temperature. The emission of water vapor (most noticeable by the condensation trails that often follow aircraft) may seem harmless, but contributes to warming the atmosphere and, therefore, trapping heat at the Earth's surface. The release of particulates by jet aircraft can also cause the formation of clouds, which contribute to global warming. Other chemicals that are released during flight include: sulfur dioxide, hydrocarbons, and carbon monoxide, all of which have been linked to global warming.

A growing concern within the scientific community is the evidence that aviation not only emits chemicals that are linked to global warming, but that it does so directly into the most sensitive parts of the atmosphere. Commercial airliners tend to fly between 30,000 and 42,000 ft. (9,144–12,801 m.) Here, the atmosphere is extremely sensitive to chemicals such as carbon dioxide and nitrogen oxide. Scientists believe that the actual damage caused by aircraft may be greater than estimates predict. This is, however, disputed by the IATA, which points to the fact that the carbon footprint for airliners in 2005 was slightly reduced with the introduction of efficiency improvements.

INCREASED AIR TRAVEL

The popularity of flying causes greater levels of greenhouse gases to be emitted, as congestion grows around the world's busiest airports and air routes. It is not uncommon for aircraft to have to wait in long lines with engines running before they can take off from airports in cities such at Los Angeles and New York. When airborne, aircraft suffer from congested airways, it results in flights operating at less than efficient altitudes, which, in turn leads to less than efficient operations. The airway navigation systems found in most countries also tend to be outdated, stopping aircraft from taking the most direct route to their destination. Furthermore, airports such as London Heathrow are operating at levels well beyond their original runway capacity, which results in aircraft having to circle the airport before they are cleared to land. When on the ground, it is common for aircraft arriving at London Heathrow to have to wait for air bridges to become available, as the lack of infrastructure extends to the terminal facilities.

Airports are subject to a variety of environmental considerations. One of the main problems surrounds the lack of public transportation to reach terminal facilities. For example, Washington Dulles Airport has no direct Metro connection, which results in passengers needing to either use car transportation or change from rail to bus transportation. Aircraft require a vast array of support vehicles to help turn them around for the next duty. These vehicles are powered by gas or diesel engines, which in turn leave a carbon footprint.

NEW TECHNOLOGY

Although international aviation was excluded from the 1997 Kyoto Protocol, the International Civil Aviation Organization (ICAO) arranged a summit in 2007 to look at how manufacturers, airlines, airports, and governments can work together to reduce aviation's carbon footprint. Boeing has created the next generation of aircraft from composite materials that weigh far less than their predecessors. The Boeing 787 Dreamliner is one such new development, with 50 percent of its structure made up of composite materials. Boeing estimates that the 787 will create 20 percent less carbon than the current aircraft operating on medium/long range routes. Airbus has promoted the development of aircraft that place greater emphasis on reducing their carbon footprint. The Airbus A380 Super Jumbo, while bigger than the jumbo jet, has a low fuel burn (12 percent lower than the jumbo jet) and is able to take more passengers, helping to reduce the number of aircraft required to fly on certain routes. The Airbus A380 is the first jet airliner to meet International Environmental Standard ISO 14001.

Airlines have also encouraged manufacturers to look at new methods of powering their aircraft. Virgin Atlantic's Chair Sir Richard Branson has highlighted his interest in powering his fleet of aircraft via biofuel or clean-fuel technologies. There are, however, a number of issues that need to be addressed before such initiatives could become reality. First, biofuels such as ethanol tend to freeze at high altitudes, and therefore chemicals would be needed to reduce this risk.

Second, large areas of land and water are required for producing such energy. The land needed would require further deforestation, which in turn would have major implications for climate change. The use of hydrogen has also been suggested as a means of powering airliners of the future. However, such fuels would require greater storage space and would still leave contour trails, that warm the atmosphere.

REDUCING IMPACTS

Airlines have looked at addressing concerns of global warming by educating passengers as to the consequences of their actions and allowing them to offset their carbon footprint. In the United Kingdom, flybe.com has produced an energy consumption chart that allows customers to compare their carbon footprint with other aircraft within their fleet. British Airways and easyJet have introduced sections on their websites where customers can pay to offset their carbon emissions for a specific journey by planting trees in the developing world. Airlines are further tackling the problems of climate change by producing annual environmental audits that look at reducing their impact on the environment, both in the air and on the ground.

Fully addressing aviation's impact on the environment require unanimous worldwide governmental consensus on what measures to take. Aviation fuel remains untaxed (apart from domestic air services within the United States), which, in turn, has allowed airlines to offer cheap travel options. The industry has lobbied successfully to stop such taxation being applied unilaterally by governments, as it is thought that such measures could have a detrimental impact on those country's airlines. Within Europe, the European Union has developed an Emissions Trading Scheme.

This initiative looks at companies trading credits based on the amount of CO_2 they create. Companies are given an initial allowance, and are then free to trade by selling unused credits or purchasing credits for emissions that are produced above their initial allowance. Airlines, including British Airways and Scandinavian Airlines (SAS), and the IATA have all agreed that this control would be preferable to taxation on aviation fuel.

The development of low-cost carriers has been seen as one of the main reasons for the continued growth in popularity of cheap flights. Many commentators have seen the development of airlines such as Jet Blue, easyJet, and AirTran as a major hurdle to the possible reduction in air travel. The low-cost carriers have, however, started to market their green credentials by highlighting that their aircraft fleets tend to be the youngest and most fuel efficient within the industry.

Furthermore, low-cost airlines point to the higher load factors that they are able to achieve onboard their aircraft, which, in turn, leads to a lower carbon footprint per passenger. The use of less congested airports by these carriers has also reduced significantly the need for aircraft to queue for take-off and landing slots. Low-cost operators have further reduced the weight of their aircraft by introducing extra costs for passengers wishing to place baggage into the aircraft hold. Such policies have helped minimize the fuel burned, while at the same time allowing aircraft to be turned around quicker, and requiring fewer support vehicles.

While aviation continues to grow at a furious pace, the industry is aware of its effects on the environment. The air transport industry is investing heavily in new technologies as the key to reducing its current carbon footprint. However, with the continued growth of cheap air travel, it may require global governmental action through taxation or emission-trading schemes to make passengers pay a more realistic price for their flights.

Azerbaijan

AZERBAIJAN IS SITUATED on the western coast of the Caspian Sea and has boundaries with Iran, Armenia, Georgia, and Russia. The area of Azerbaijan is 53,813 sq. mi. (139,375 sq. km.), with a variety of geographic regions including mountains, steppe, desert, and subtropical rainforest. Pastureland, broad leaf forests, farms, and orchards lie in the fertile lower slopes. The range of climate zones include: dry subtropical regions with mild winters and hot dry summers; forest zones with more precipitation and a moderate climate, with cold winters and warm summers; and the city of Baku, with desert conditions, short, cold winters, long, sweltering summers, and little rainfall.

Natural resources include oil, natural gas, grain, cotton, rice, tobacco, fruit, vegetables, grapes, and livestock. Agriculture in arid and semi-arid regions requiring irrigation accounts for approximately 80 percent of production. Exploitation of Azeri oil, dumping of toxic industrial waste, and agricultural practices including overuse of artificial fertilizer and chemical pesticides have resulted in soil damage and contamination of water sources. The impact of global warming is already seen with the rising level of the Caspian Sea. Though the sea level fell due to hydroelectric dam construction on the Volga River and diversion of water for irrigation, since 1978, the water level has risen 6.6 ft. (2 m.) at a rate of 5.9–9.8 in. (15–25 cm.) per year.

Caused by a combination of climate change, increased runoff from deforested land, and tectonic movement, the impact has resulted in coastal erosion with damage to roads and buildings, salinization leading to desertification of forests and farmland, and contamination because of flooding of oilfields and industrial areas. In September 2000, Azerbaijan ratified the Kyoto Protocol, an international and legally binding agreement to reduce greenhouse gas emissions worldwide, which took effect on February 16, 2005.

Countries that are parties to the United Nations Framework Convention on Climate Change (UNFCCC) are required to undertake "national communication" that can include assessment of the potential impact of climate change. To meet this challenge, the Initial National Communication of the Azerbaijan Republic was developed and submitted to the UNFCCC Secretariat. Proposed projects aimed at reducing greenhouse gas emissions include increased use of hydropower, solar energy, and wind energy; switching to compact fluorescent light bulbs; improved efficiency in oil production; introducing new technology for biogas production and methane collection; and the protection of agricultural fields with the planting of forests to mitigate the effect of frequent droughts and hot dry winds that cause crop failures. A reduction of demand for water by 10–15 percent and an increase of lines of productivity by 15–30 percent are expected as a result of project implementation.

Bahamas

LOCATED IN THE Caribbean, the Bahamas consists of an archipelago of more than 700 islands that cover about 100,000 sq. mi. (160,934 sq. km.) of ocean, and a land area of only 5,378 sq. mi. (13,878 sq. km.). It has a population of 323,000 (2003 est.), with a population density of 60 people per sq. mi. (23.27 per sq. km.), although on the island of New Providence in the capital of Nassau, there are 4,402 people per sq. mi. (1,693 per sq. km.). Much of the economy of the nation comes from tourism, with only one percent of the land arable, and 32 percent of the land covered in forest, mainly on the island of Andros.

Traditionally, the Bahamas have had problems with hurricanes and tropical storms. However, the major environmental problems facing the Bahamas through global warming and climate change are from the rising temperature of the seas around the Bahamas, and the possibility of flooding with rising water levels. Some 80 percent of the land area of the Bahamas is within 5 ft. (1.5 m.) of the mean sea level. This is especially true of Andros Island, which makes up nearly half the land area of the country, much of which is already swamp at high tide. Not only would flooding have an effect on housing, but it could also lead to the contamination of fresh water reservoirs, with a possible rise in malaria and dengue fever.

In terms of its contribution to climate change, the Bahamas ranks 63rd in the world for carbon dioxide emissions per capita, with emissions at 7.7 metric tons of carbon dioxide per person in 1990, falling steadily to 5.9 metric tons per person in 2001. However, this number rose to 6.7 metric tons per person in 2002, but has started falling again. Part of this comes through the tourism industry in the Bahamas, which caters to many tourists flying to the islands; the Bahamas has a total of 64 airports, although most tourists use the main one in Nassau.

Rising temperatures have already started to have an effect on the coral reefs in the Bahamas, which include the third-longest coral reef in the world. Accounts of their size vary, but there are between 900–2,700 sq. mi. (2,331–6,993 sq. km.) of reefs in the Bahamas. They serve as a focus for many types of fish and other marine life, which are endangered by the rising water temperatures.

To try to reduce global warming and climate change, the government of the Bahamas took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. The Bahamian government was also the eighth country to accept the Kyoto Protocol to the UN Framework Convention on

Climate Change on April 9, 1999, which took effect on February 16, 2005.

Bahrain

LOCATED IN THE Persian Gulf, the kingdom of Bahrain extends over three islands in the gulf, covers 253 sq. mi. (665 sq. km.), and has a population of 698,585 (2005 est.), with a population density of 2,556 people per sq. mi. (987 per sq. km.). About one percent of the land is arable, with 6 percent used for pasture. The largest agricultural products are fruits and vegetables. The soil has been heavily affected by salinity and the country has suffered from extensive soil erosion.

As with the other Gulf States, Bahrain has a wealthy population, largely dependent on the petroleum industry, a high Gross Domestic Product per capita, and heavy use of automobiles and air conditioning. With all of the electricity in Bahrain generated from using fossil fuels, gaseous fuels in particular, it had a per capita emission of carbon dioxide of 23.8 metric tons in 1990, rising 60 percent by 1998, and then continuing to rise gradually to 31 metric tons by 2003. This means that Bahrain has the fourth largest per capita emission level of carbon dioxide, with only Qatar, the United Arab Emirates, and Kuwait having higher per capita levels. In addition, Bahrain has significant carbon monoxide emissions.

The effects of climate change and global warming are reflected in even higher temperatures in Bahrain. A recent study has shown that these temperatures reflect an 11-year cycle owing to the effect of sunspots, although some variations are explained by the high level of carbon dioxide emissions in the region, as well as the extensive use of cooling gases for air-conditioning in Bahrain and its neighbors. Because of the country's small size, Bahrain has managed to maintain a good bus system to alleviate street congestion and link the towns and main residential areas.

Bahrain's government took part in the Vienna Convention of 1900, and also the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. Bahrain accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on January 31, 2006. It took effect on May 1, 2006.

Bangladesh

BANGLADESH IS SITUATED in the northeastern portion of the Indian subcontinent on the Bay of Bengal. It borders India on the west, north, and south and Myanmar on the southeast. The area of Bangladesh is 56,977 sq. mi. (147,579 sq. km.). It is a low-lying country, with numerous rivers situated principally on the large delta formed by the Ganges and Brahmaputra Rivers, and scattered hills on the northern and eastern borders.

Approximately 10 percent of Bangladesh is still forested with teak, banyan, and kapok, and forests in the tidal zone along the coast include mangroves and sometimes hardwood. Mangroves blunted the destructive power of a cyclone and tidal wave that hit Bangladesh in 1991. Mangroves are able to grow in salt water, but depend on nutrients from silt from inland rivers, and have the ability to adapt to changing conditions (including salinity and rough waves). The extended roots stabilize coasts, preventing erosion.

The climate of Bangladesh is humid and tropical, with warm temperatures throughout the year. The average annual temperature is about 77 degrees F (25 degrees C). Rainfall is heavy, ranging from 55 in. (140 cm.) around the central eastern border to more than 200 in. (508 cm.) in the northeast annually. The majority of annual precipitation falls during the monsoon season, accompanied by flooding from June to October, and by cyclones with accompanying storm surge waves from April to May and September to November.

Bangladesh supports more than 143 million people, and the population is expected to double by 2050. The staple food and chief crop is rice. Other important crops include jute, tea, sugarcane, and cotton.

The principal energy resource, natural gas, is found in several small fields in the northeast. There is a coalfield in the northwest, and large peat beds underlie most of the delta. Electricity is generated in thermal plants burning fossil fuels (coal, natural gas, or petroleum) and hydroelectric facilities.

Bangladesh already faces complex environmental problems, including air, water, and soil pollution, and the overuse of natural resources, which causes deforestation, desertification, and energy and water shortages. Three percent of households lack access to improved water supply and 52 percent lack improved sanitation. The impacts of global warming could exacerbate already stressed conditions in some areas as the increasing population and scarcity of land drive occupation of marginal forest lands and temporary river islands. Agricultural practices including overuse of farmland and chemical pesticides have resulted in soil damage and contamination of water sources.

SEA LEVEL RISE AND CLIMATE CHANGE

Bangladesh is one of the countries most vulnerable to a rise in sea level. Estimates for future sea level rise vary from 3.2–43.3 in. (8–110 cm.) by the end of the century. A rise of 9.8 in. (25 cm.) or more in relative sea level would displace many residents of the delta region of the Ganges from their homes and livelihoods, while a 39 in. (1 m.) sea-level rise could inundate 11.5 percent of the land of Bangladesh. Extreme predictions of a 1 m. rise in the Bay of Bengal are that the Ganges Delta would lose 12–18 percent of its land. Loss of land (especially agricultural land) could be devastating, along with the displacement of coastal villages and people by severe flooding.

Seasonal flooding could increase and last longer, with higher sea levels decreasing the rate of drainage and increase the salinity of ground water. Also, as sea surface temperature rises, the ocean area capable of spawning tropical cyclones is expected to increase. Tidal waves during cyclones are likely to become more severe, as well. Climate change could translate into migration to urban areas or inland from the lowlands of the delta area. With transient populations, stress on sewage and waste systems could increase the spread of communicable diseases.

Warmer temperatures would increase the incidence of heat-related illnesses and lead to higher concentrations of ground-level ozone pollution causing respiratory illnesses and increasing risk of contracting certain infectious diseases from water contamination or disease-carrying vectors, especially for the malnourished. Flooding and storm surges associated with sea-level rise could increase the incidence of water-borne diseases, putting stress on limited health services.

In October 2001, Bangladesh ratified the Kyoto Protocol, an international and legally binding agreement to reduce greenhouse gas emissions worldwide that took effect on February 16, 2005. Strategies implemented to improve environmental conditions and human-induced climate change include assessment of the potential impact of climate change. Bangladesh began a National Conservation Strategy Implementation Project, assessed implementation of Agenda 21, established the Bangladesh Wetlands Network, conducted the case study "Sanitary and Phyto-Sanitary (SPS) Barriers to Trade and Its Impact on the Environment of Shrimp Farming in Bangladesh," established the International Dialogue on Water and Climate, completed the project design for "Integrating Economic Values into Protected Area Management in South Asia—Bangladesh Country Component" in collaboration with the Ecosystems and Livelihood Group (ELG), and executed another regional project titled "Sustainable Livelihood, Environmental Security and Conflict Management."

Barbados

LOCATED IN THE Caribbean, Barbados has a land area of 167 sq. mi. (431 sq. km.), and a population of 331,000 (2006 est.), with a population density of 1,663 people per sq. mi. (647 people per sq. km.). More than a third of the population lives in Bridgetown, the capital. Thirty-seven percent of the land on Barbados is arable, with an additional 5 percent used for meadows and pasture. About 12 percent of the country is forested. Historically, Barbados has been reliant on the sugar industry, but now also relies on tourism. Because of this, Barbados has been at the forefront of the Caribbean Tourism Organization's role in discussing the adverse effects of climate change. Barbados is regularly threatened by hurricanes, and is facing real problems from global warming and climate change. Much of the country is low-lying, and rising water temperatures caused by global warming endanger the coastal fringe of coral reefs.

In terms of its carbon dioxide emissions per capita, Barbados ranks 83rd, with 4.2 metric tons of carbon dioxide per person in 1990, falling to 2.9 metric tons per capita in 1994, and then rising to 4.6 metric tons in 2001–02, before falling slightly. Because of its isolated location, most of the people traveling to Barbados, including over 500,000 tourists each year, come by air. To reduce carbon emissions, the Barbadian government has attempted to reduce power use on the island. It has maintained a well-run system of public transport, with buses covering most of the country.

Furthermore, the Barbadian government of Erskine Sandiford took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. Barbados then hosted the Global Conference on the Sustainable Development of Small Island Developing States (SIDS), known as the Barbados Conference, in April–May 1994 when SIDS discussed the problems of global climate change and the impending rise in sea levels. The government of Owen Arthur accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on July 8, 2000. It took effect on February 16, 2005. Soon afterward, Barbados launched its own national energy strategy. On September 24, 2007, Owen Arthur pleaded at the UN in New York that wealthier countries introduce policies to help reverse the effects of global warming and climate change, pointing out the responsibility of developed countries that have historically contributed heavily to the problem.

Belarus

ONE OF THE former constituent states of the Soviet Union, the Republic of Belarus gained its independence in 1991. It has a land area of 80,155 sq. mi. (207,600 sq. km.), a population of 9,724,723 (2007 est.), and a population density of 127 people per sq. mi. (49 people per sq. km.). Although 29 percent of the land is arable, and a further 15 percent has been used for meadow or pasture, the nearby Chernobyl nuclear power plant in the Ukraine has contaminated some of the agricultural land in Belarus.

Suffering heavily from pollution during the Communist period, including the 1986 Chernobyl nuclear accident, Belarus has managed, since independence, to significantly reduce its per capita carbon dioxide emissions from 92 metric tons per person in 1992 to 7.6 metric tons in the following year, and then to 6.8 metric tons in 1994. Emissions have been between 5.8 and 6.4 metric tons per person since then. Belarus has a lower level of emissions per person than its neighbors, Russia and the Ukraine, largely because of the underdeveloped nature of the Belarus economy. However, there have been significant emissions of sulfur dioxide, nitrogen oxide, and carbon monoxide.

To reduce its effect on climate change, Belarus has embarked on an ambitious project of electrifying its train network, and investing more in public transport. However, it relies heavily on fossil fuels for the generation of electricity, which provides 99.5 percent of the power for the country, while only 0.08 percent comes from hydropower. With about a third of the country forested, Belarus lessens its effect on global warming, although there is the threat of deforestation with many cities becoming larger, and increasing demand for timber. The Belarus government of Vyachaslau Kebich took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and the government of Syarhey Sidorski accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on May 26, 2005. It took effect on November 24, 2005.

Belgium

LOCATED IN WESTERN Europe, the kingdom of Belgium has a land area of 11,787 sq. mi. (30,528 sq. km.), with a population of 10,511,382 (2006 est.), and a population density of 892 people per sq. mi. (344.32 per sq. km.). Twenty-four percent of Belgium's land is allocated for arable use, with another 20 percent used for meadows and pasture, and 20 percent still forested.

One of the earliest countries in the world to become involved in the Industrial Revolution during the 19th century, in recent years Belgium has focused heavily on the nuclear industry, which is now responsible for 57.6 percent of the country's electricity production, with fossil fuels accounting for 40.3 percent of the electricity, and only 0.5 percent generated from hydropower. Belgium ranks 46th in the world in carbon dioxide emissions per capita, with 10.1 metric tons per person in 1990. Most of these carbon dioxide emissions come from liquid fuel (36 percent), solid fuel (32 percent), and gaseous fuel (28 percent). Although emissions have risen slightly since 1990, there have been many government measures introduced since 2000 to reduce Belgium's impact on climate change and global warming.

The government has long had an extensive railway network, and in recent years has extended the public transportation network with an integrated transport system operating throughout much of the country, including tramway services in many of the major cities. There are also two prominent Green movements in the country, the AGALEV and the ECOLO, both of which have been involved in regional and national governments. They did very well in the 1999 national elections, but most of their gains were reversed in 2003.

Since 1999, the country has cleaned up some pollution, but as late as 2003, a UN report on water quality listed Belgium as the last of 122 countries in terms of its waste treatment, pollution control, and drinking water quality. The Belgian government of Jean-Luc Dehaene, during his first few months in power, took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and in his last year in office, Dehaene's government signed the Kyoto Protocol to the UN Framework Convention on Climate Change. It was ratified on May 31, 2002, and took effect on February 16, 2005.

Geelong Grammar School, Australia

Belize

BELIZE IS A small country in Central America south of Mexico's Yucatán Peninsula and east of Guatemala. Its eastern coast faces the Caribbean Sea. Belize is known as a small island developing state because of its low-lying seashore, coastal communities, and open and vulnerable economy. Small island developing states are considered extremely susceptible to the effects of climate change, including rising sea levels.

The small, open economy of Belize has historically been dependent on a narrow range of agricultural exports. Furthermore, it depends on foreign imports for most basic goods, and it relies heavily on a growing tourism sector for foreign exchange earnings to meet its import demand. These economic factors, along with its physio-geographic features, tropical environment, and coastal population centers increase the vulnerability of Belize to the impact of climate change.

Belize is a former British colony (known as British Honduras for most of the 20th century), and became an independent nation in 1973. Given its location, population, and cultural history, Belize is regarded as both a Central American and a Caribbean nation. Belize is a member of the Caribbean Community (CARICOM) and is the site of the Caribbean Community Climate Change Centre, which coordinates climate change research and regional responses for the nations of the Caribbean.

The coastline of Belize can be described as low-lying marshland and swampy plains. Tropical hardwood and pine forests in the western interior gradually rise to the forested Maya Mountains in southern Belize. The coral reefs and islands along the Caribbean coastline (known as *cayes*) form the Belize Barrier Reef. At approximately 200 mi. long, it is the longest reef in the western hemisphere. Tropical cyclones (hurricanes) and flooding regularly threaten human settlements during the rainy season, particularly in coastal areas. With a population of less than 300,000, Belize contributes very little to global greenhouse gas emissions, so its capacity to mitigate the effects of climate change is negligible. In a 2005 survey of residents' attitudes about climate change, nearly half responded that Belize is extremely vulnerable to the impacts of climate change, and 95 percent felt that Belize is not prepared to handle the impacts due to financial constraints.

Climate change poses five types of risk for Belize. First, a loss of coastal land may result from rising sea levels through erosion and increased flooding. Second, rising sea surface temperatures may increase the frequency and intensity of tropical cyclones, which pose risks to infrastructure and personal property. Third, warmer sea water and ocean acidification are expected to contribute to coral reef bleaching, and an increase in the extent and severity of coral mortality would threaten both the fishing and tourism sectors. Fourth, changes in temperature, rainfall, and sea level may increase the distribution and range of vector-borne diseases such as malaria and dengue fever, which already threaten public health. Finally, rising temperatures, increased salinity, and a shorter growing period may negatively impact the citrus, banana, and sugar cane industries, which already comprise more than half of major exports.

Benguela Current

THE BENGUELA CURRENT is located in the southern part of the Atlantic Ocean and moves northward from the western coast of South Africa, Namibia, and

Angola, merging into the Southern Equatorial Current. It takes its name from the Angolan port of Benguela, which was founded by the Portuguese in 1617. The current was quickly noticed by European seafarers, who initially had trouble navigating the region.

While the Benguela Current is cold, generated by water from the very deepest parts of the ocean moving in line with the rotation of the Earth, the Southern Equatorial Current is warm. The effect of the two merging is the subject of much research, starting with the English geographer James Rennell (1742–1830), whose book *Currents of the Atlantic Ocean* was published posthumously in 1832. From work by subsequent geographers, it has been found that the Benguela Current also includes subtropical water from the Indian Ocean. About 124–186 mi. (200–300 km.) wide in coastal regions, it becomes much wider as it reaches the tropics, and the cold current is responsible for some of the trade winds in the South Atlantic because there is a certain level of displacement of some of the waters on the surface of the ocean.

The problem facing the Benguela Current from global warming and climate change comes from a rise in the temperature of the water in the oceans, which has led to a rise in the temperature of the waters of the Benguela Current. A Benguela El Niño effect has already been detected. Not only has there been a rise in water temperature as far south as 25 degrees S, but the water has also become increasingly saline. This change may be generated by anomalous atmospheric conditions that have been seen in the western part of the tropical Atlantic Ocean.

Although each year some warm water from Angola has impacted the northern part of the Benguela Current, El Niño has caused this to happen further south. Although this may have occurred throughout history, there are accurate records of it taking place in 1934, in 1963, and in 1984. In 1963 the resultant temperatures off the Namibian coast were some 2–4 degrees higher than normal. The water pressure was also higher. Research by L.V. Shannon suggests that the problem is less frequent, and also has a lower intensity than the similar phenomenon in the Pacific Ocean.

The result of these changes from the Benguela El Niño is expected to have a serious effect on some of the lands in southern Africa, with a dramatic effect on marine life, on the southwest coast of Africa, and also on the trade winds, which are likely to affect marine life and shipping in the southern Atlantic.

Although the impact of the Benguela El Niño is not, at this moment, noticeable south of the Namibian port of Lüderitz, if the trend continues, it would have a major effect in the region off the Cape of Good Hope where the south-flowing Agulhas Current meets the Benguela Current. Throughout history, this has resulted in turbulence and storms on the surface of the sea off the southwest coast of South Africa, and the creation of a very rich marine ecosystem underwater. Off the coast of southwestern Africa, there has already been a fall in the catch of the fishing industry, including jack mackerel, sardines, and, off the coast of Angola, anchovies. Whether this is a result of over-fishing in the last two centuries or of less fish spawning because of the rising temperature has not been firmly established, although both are likely to be major contributory causes.

Although the marine ecosystem is likely to be affected, the most noticeable early impact of the Benguela El Niño will be changes in the trade winds. Although these changes will have a dramatic effect on journeys by yachts, it will have a much less important effect on container ships and tankers using the route than would have been the case during the 20th century. However, there will be an impact on the southern coast of Angola and much of the coastline of Namibia.

Over centuries, the current has led to the desertification of the coastline of southern Angola and Namibia, making the coastline extremely inhospitable. Some of the bushmen call it "The Land God Made in Anger." Because of the whaling industry, and the many shipwrecks there, it became known in Europe and North America as the Skeleton Coast. Although there is little flora or fauna along the coast, a number of plant and insect species have managed to adapt, making use of the dense sea fogs. Some desert birds also manage to survive. The small human populations that lived there many centuries ago seem to have survived heavily on seafood, with middens from the shells of white mussels still evident.

Benin

THE REPUBLIC OF Benin covers 43,483 sq. mi. (112,620 sq. km.) on the West African coast, equivalent to the size of Pennsylvania. Benin has a population of 7,460,025 people (2005 est.), with nearly three million inhabitants living in the coastal stretch that links Cotonou, the economic capital, with Porto-Novo, the political capital. Benin's economy is dominated by agriculture, including the commercial production and export of cotton and palm oil. Most of the rural population earns its livelihood through subsistence farming of corn, beans, cassava, peanuts, and yams. The per capita Gross Domestic Product is $1,200 (2004 est.) and 33 percent of the population lives in poverty.

A coastal belt of lagoons, rolling hills in the central part of the country, rocky plateaus in the northwest, and savanna plains in the northeast characterize Benin. The climate is tropical Soudano-Guinean, with six months of rain and six dry months. Along the coast, it is hot and humid, while the inland climate is semi-arid.

Four environmental issues facing the country are: inadequate supplies of drinking water, poaching of wildlife, deforestation, and desertification. Benin is a party to the following international environmental agreements: biodiversity, climate change, the Kyoto Protocol, desertification, endangered species, environmental modification, hazardous wastes, law of the sea, ozone layer protection, ship pollution, and wetlands.

Climate change awareness among the general population in Benin is significant, as scientists have documented disturbing changes in rainfall patterns beginning in 1971. Farmers are also aware of climatic changes, such as shorter rainy seasons and longer dry spells. The contributions that Benin makes to human-induced climate change are minimal compared to the rest of Sub-Saharan Africa and the rest of the world. Per capita CO_2 emissions in 1998 were only 100 metric tons, as compared to an average of 800 tons for the subcontinent, and the global average of 4,100 metric tons. The burning of liquid fuels (petroleum products) represented 65 percent of the country's CO_2 emissions, while the remaining 35 percent was from cement manufacturing, according to the World Resources Institute. Other non-CO_2 air pollution in Benin is low compared to the rest of the continent and the world.

Possible impacts of climate change could have significant consequences for Benin's people and environment. With nearly half of the country's population living along the coast, a rise in sea level would threaten their livelihoods and well-being, since this zone would become subject to more frequent erosion and flooding. Climatic changes and drier conditions could accelerate deforestation in the central part of the country and desertification in the north. Also, changes in rainfall patterns are likely to have serious effects on soil erosion, while also leading to changes in cropping patterns and, ultimately, changes in the livelihood patterns of farmers and herders.

Berlin Mandate

THE BERLIN MANDATE was a ruling reached at the first Conference of the Parties (COP 1) to the United

Nations Framework Convention on Climate Change (UNFCCC) in March 1995. It established a process for dealing with matters of climate change. The UNFCCC was adopted in 1992 at the UN Conference on Environment and Development (UNCED) held in Rio de Janeiro. Informally, the conference was known as the Earth Summit. It adopted an international treaty binding countries together in a common effort to meet the challenge of global warming by reducing its effects, or at least by preparing for higher temperatures. The treaty specifically aimed to stabilize greenhouse gas emissions to prevent anthropogenic interference with the climate system.

The UNFCCC was opened for signing on May 9, 1992. By March 21, 1994, enough countries had signed that it became a part of international law. The treaty as it was originally written did not set limits on greenhouse emissions by individual countries, lacked an enforcement provision, and was not legally binding. However, it did contain provisions that stated that updates, which were called protocols in the treaty, were to be issued that would set mandatory emission limits. The principal update was to be set at a new conference in Kyoto, Japan. The Kyoto Protocol was to become much better known than the UNFCCC. After each signatory nation conducted a greenhouse gas inventory, it was responsible for developing a plan for removing or reducing greenhouse gases to acceptable levels. The UNFCCC also named a secretariat that would be charged with supporting the work of implementing the treaty.

The COP 1 met in Berlin for its first session between March 28 and April 7, 1995. The participants concluded that the goals previously reached by those participating in the UNFCCC treaty were not sufficient to meet the challenge of global warming. Originally, the UNFCCC had a goal of returning greenhouse gas emissions to 1990 levels by 2000. It was decided that a process should be established for countries to take appropriate action well beyond 2000. COP 1 also called for legally binding standards and emissions limits to be set by international law. Participants in Berlin also created a separate body called the Ad Hoc Group on the Berlin Mandate (AGBM).

A second meeting of the Conference Parties took place at Geneva between July 8 and July 19, 1996. The meeting was styled COP 2. The meeting was a midpoint in the negotiations on greenhouse gas emissions that had begun with the Berlin Mandate. COP 2 acted in response to the IPCC Second Assessment Report issued December 1995 that stated that greenhouse gas concentrations had continued to increase, that the climate had changed since 1900, and that there was evidence that the change was anthropogenic. It also predicted that global temperatures would rise by 3.6 degrees F (2 degrees C) by 2100 and that the climate was expected to change in the future, adding that there were scientific uncertainties.

These Berlin Mandate negotiating sessions were held as follows: AGBM 1 (August 1995), AGBM 2 (October/November 1995), AGBM 3 (March 1996), AGBM 4 (July 1996), AGBM 5 (December 1996), AGBM 6 (March 1997), AGBM 7 (July/August 1997), and AGBM 8 (October/November 1997). The Berlin Mandate negotiations were concluded at COP 3 in Kyoto with the adoption of the Kyoto Protocol.

Bhutan

LOCATED IN THE Himalayan Mountains and bordering India and China, the kingdom of Bhutan covers a land area of 18,147 sq. mi. (47,000 sq. km.), with a population of 672,400 (2005 est.), giving it a population density of 117 people per sq. mi. (45 per sq. km.). Gaining its independence in 1947, Bhutan has embarked on a program of modernization, trying

Bhutan's forests, such as this one, cover three-quarters of the country, and it has one of the lowest rates of carbon dioxide emissions per person in the world. In spite of this, it is imperiled by rising regional temperatures, which are melting nearby glaciers.

to foster greater harmony between various ethnic groups. Being landlocked, the main effects of global warming on Bhutan will be from melting of nearby glaciers. With average temperatures in the Himalayas having risen by about one degree C since the mid-1970s, there has been a glacial retreat in Bhutan estimated at 100–130 ft. (30–40 m.) annually, with the real possibility of serious flooding from swollen glacial lakes. Over time, this is expected to dramatically change the flora and fauna in the country, posing risks for some endangered animals such as takins (similar to gnus), wild elephants, and snow leopards.

Within the country, there is relatively low car use, with a somewhat overburdened public transport network that still effectively covers the entire country. This network includes the government Bhutan Post Express, the private Leksol Bus Service, and other companies. Although tourist flights into the country have contributed to global warming and climate change, the number of tourists is strictly limited. Also, 75 percent of the country is still forested, only two percent of the land is arable, and another six percent is used for meadows and pasture. Accordingly, the per capita emission of carbon dioxide by the people of Bhutan is one of the lowest in the world, with 0.1 metric tons per person in 1990, rising to 0.19 metric tons per person in 2003. A total of 99.9 percent of the electricity in Bhutan is generated by hydropower, resulting in one of the lowest rates of fossil fuel use of any country in the world. The country also has extremely low levels of emissions of sulfur dioxide, nitrogen oxide, and carbon monoxide.

The Bhutan government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and 10 years later, on August 26, 2002, it accepted the Kyoto Protocol to the UN Framework Convention on Climate Change, which took effect on February 16, 2005.

Biogeochemical Feedbacks

FEEDBACKS ARE PROCESSES in a system that can either amplify or dampen the system's response to external influences. When the concentration of a certain variable in a subsystem affects the behavior of the entire system, then changes in inputs or concentrations of that variable can result in multiple, coupled responses. It is possible that some of the responses enhance, while others mitigate, the initial response of the system to the external forcing.

In the case of the Earth's system, if a change in the environment leads to additional and enhanced changes in that system, it is said to have resulted in a positive feedback. When a large external forcing results in an even larger response from the affected system, the phenomenon is commonly referred to as a vicious cycle of positive feedback loops. In contrast, if a change in the environment leads to a process that mitigates the change, and results in smaller response from the affected system, it is said to be a negative feedback. Some systems have the ability to regulate their environment and maintain a stable condition by using multiple, interrelated dynamic mechanisms, known as homeostasis. Feedback processes regulate the response of the Earth's system to natural or anthropogenic forcings.

Biogeochemical feedbacks operate in the coupled biosphere-pedosphere-hydrosphere-atmosphere system. Biogeochemical feedbacks include changes in biological activity; atmospheric, water, or soil chemistry; and terrestrial and oceanic uptake of greenhouse gases that affect, or are affected by, changes in atmospheric dynamics. Some of the most important biogeochemical feedbacks include: changes in rates of plant productivity and carbon sequestration by soils due to altered patterns of air temperature and precipitation; changes in temperature that lead to faster decomposition of organic matter stored in peat lands; and changes in atmospheric conditions that may lead to altered patterns of oceanic temperature and circulation that ultimately lead to changes in ocean carbon storage. By modifying the fluxes of greenhouse gases to/from the atmosphere, biosphere, pedosphere, and hydrosphere, feedback processes in the climate system affect the residence time of the gases in the different spheres.

A study released by the National Academy of Sciences in 2001 estimates that half of the anticipated increase in air temperature over the next few years to decades will be attributable to internal feedbacks within the climate system, and the other half to the direct response of external factors that force change in the climate system.

An example of a positive feedback loop that results in amplification of the response of a system to an external influence is one in which increases in atmospheric concentration of carbon dioxide (CO_2) lead to increases in air temperature. This, in turn, results in higher rates of organic matter decomposition (respiration) that releases CO_2 to the atmosphere—further increasing the concentration of CO_2 in the atmosphere. In this case, a negative feedback loop would result in a chain of events leading to decreased concentrations of CO_2 in the atmosphere. For example, an increase in CO_2 in the atmosphere leads to increases in air temperature, which results in additional plant growth, which takes CO_2 from the atmosphere (acts as a sink for atmospheric CO_2), reducing atmospheric concentration of CO_2.

Another important biogeochemical feedback to climate change is the changes in production of dimethyl sulfide gas (DMS, a common atmospheric aerosol around oceans) by phytoplankton in the upper layers of the ocean. Increased plankton activity during warm atmospheric conditions leads to greater release of DMS from the oceans to the atmosphere. Consequent increase in density and concentration of aerosols in the atmosphere reduces the size of cloud droplets, resulting in increased albedo (reflection of solar radiation by an object) that leads to increases in air temperature—a negative feedback loop.

Biogeochemical feedbacks can be manifested at different spatial and temporal scales and may have significant control of short- and long-term changes in weather and climate at the level of leaves, stands, biomes, or ecosystems. Moreover, biogeochemical feedbacks can be direct or indirect. Direct effects are those processes that influence chemical composition and dynamics of the atmosphere or oceans, and normal functioning of the biosphere. Some of the most prominent direct feedbacks are increased plant productivity due to increasing concentration of CO_2 in the atmosphere, a phenomenon known as the CO_2 fertilization effect. Indirect feedbacks are those mediated by ecosystem responses to climate changes that result because of increasing concentration of greenhouse gases. Some examples of this include the change in ocean circulation patterns on phytoplankton productivity, which, in turn, affect the amount of CO_2 that biological processes in the ocean can sequester.

Biology

BIOLOGY, THE STUDY of life, has grown in complexity and comprehensiveness from its origins in antiquity. By the 20th century, biology was not a single science, but a group of subfields. Among the subfields was conservation biology, the discipline that sought to verify the reality of climate change and to stop it before it causes a mass extinction of species. In a number of ways, conservation is unique among the biological sciences. It is the science that is most conscious of global warming and of the need to arrest it.

Biology had its first stirrings among the ancient Greeks; Aristotle was the pioneer. The founder of anatomical studies, Aristotle likely performed the first dissections. His study of anatomy presaged the work of French comparative anatomist Georges Cuvier. Aristotle also appears to have been the first taxonomist. His classification of marine invertebrates anticipated the work of Swedish taxonomist Carl Linneaus.

As the founder of developmental biology, Aristotle sought to explain why, for example, an acorn always develops into an oak tree, and a frog's egg always turns into a frog. This line of research would lead to the 20th-century science of genetics. Aristotle sparked an interest in biology among his pupils, one of whom, Theophrastus, established the science of botany.

From this impressive beginning, the study of biology languished in the early Middle Ages, a period of theological, rather than scientific, study. In the 12th century, several universities in Italy revived the study of anatomy. Their focus was on human anatomy as a method of training physicians. The dissection of cadavers brought reproaches from the Catholic Church; but this work continued and, in 1543, Flemish physician Andreas Vesalius published his landmark study of human anatomy, *The Fabric of the Human Body*.

To an agnostic, the dissection of human cadavers implied that a person was nothing more than the sum of his or her parts: organs, muscles, bones, and the like. French philosopher and mathematician Rene Descartes wrote that purely mechanical forces animated the lower organisms. Humans alone had an immaterial soul. The idea that humans had a soul did not persuade everyone, and many biologists in the 20th century quietly banished the soul to the realm of superstition. Swiss alchemist Paracelsus had a more promising insight in supposing that chemical processes animated life. From this insight would emerge the science of biochemistry.

The 18th century was the age of taxonomy, one of Aristotle's lines of research. Among the systems of classification, Linneaus's work continues to influence the science of taxonomy. It was Linneaus, for example, who named humans *Homo sapiens*. Linneaus assumed that humans were special and deserved a genus apart from all other organisms. Natural theology, the study of nature for theological ends, agreed that humans were special among all other forms of life. The science of evolutionary biology, emerging in the 19th century, eroded the belief that humans were somehow special. Like all other organisms, humans were the result of natural selection, the product of nearly 4 million years of evolution.

Evolutionary biology requires that natural selection operate on a diversity of traits. Not all organisms of a species are identical; they vary in their particulars. Humans, for example, differ in height, eye and hair color, shape and length of the nose, and myriad other traits. The source of this variation puzzled British naturalist Charles Darwin, who was unaware of Austrian monk Gregor Mendel's work. Mendel was the first to understand that genes code for traits and that organisms differ because they have different assortments of genes. Mendel founded the science of genetics, which grew in scope during the 20th century.

CONSERVATION BIOLOGY

In the 20th century, biology multiplied into several subfields, among them conservation biology, a discipline that traces its origin to Eastern philosophies. The ancient Chinese, Japanese, and Indians posited a link between humans, plants, and animals. Given this link, harm could not come to the animal world without also harming humanity. Eastern philosophies believed pristine lands to be essential for people who desired a spiritual experience. In the Gospels, both John the Baptist and Jesus went to the wilderness for spiritual cleansing.

In the West, the dominant ideology favored exploitation, rather than conservation, of nature. To the Western mind, nature had no spiritual qualities. In the 19th century, the Transcendentalists, notably Ralph Waldo Emerson and Henry David Thoreau, challenged the belief that nature was nothing more than a commodity to be used for economic gain. Emerson and Thoreau affirmed that nature held a spiritual value and that humans could not degrade nature without degrading themselves. By his actions, Thoreau demonstrated that a person could live simply and in harmony with nature. Going beyond the musings of Emerson and Thoreau, conservationist John Muir recognized the value of political activism and formed an alliance with Theodore Roosevelt, who was also sympathetic to the aims of conservation.

As a science, conservation biology coalesced during the 1970s in the aftermath of the oil embargo by the Organization of Petroleum Exporting Countries, an event that underscored the fragility of an economy based on the burning of fossil fuels. The economies of the developed world relied on cheap fossil fuels and a quiescent public. Conservation biologists were anything but quiescent. In 1978, they held the First International Conference on Conservation Biology at the San Diego Zoo, a location that highlighted conservation biologists' commitment to protect Earth's biodiversity. In 1985, a trio of scientists formed the Society for Conservation Biology, and two years later, its members founded *Conservation Biology*, the society's scholarly journal.

Conservation biology concerned itself with, among other things, the relationship among climate, human activity, and the fate of Earth's biota. Conservation biology tracks changes in climate and the harm they cause organisms and ecosystems. In some cases, the changes in climate have brought organisms to extinction. Conservation biologists, aware that climate change imperils species, called attention to the greenhouse effect and deforestation. The greenhouse effect traps heat in the atmosphere. Human activity has increased the amount of carbon dioxide, a greenhouse gas, in the atmosphere, which has caused global temperatures to rise.

Plants absorb carbon dioxide during photosynthesis and so are natural checks against the accumulation of carbon dioxide. Deforestation, however, reduces the number of trees and plants and so weakens the capacity of plants to absorb carbon dioxide. The greenhouse effect and deforestation are, therefore, a mutually reinforcing feedback loop that intensifies global warming. Conservation biologists point to ranchers as contributors to the greenhouse effect. By overgrazing the land, cattle further reduce the number of plants and weaken their capacity to absorb carbon dioxide.

Conservation biology tracks changes in the chemistry of rain. Rainfall is an important aspect of climate because it determines the distribution and density of plants and, when rainfall is scant, the distribution and size of deserts. Conservation biologists noted with alarm that rainfall in the eastern United States and parts of Europe is acidic. Factories and power plants discharge sulfur dioxide, which combines with water vapor in the atmosphere to form acids. These acids fall to earth as acid rain, accumulating in streams and lakes.

Half the lakes in the Adirondack Mountains in New York have no fish because they were unable to reproduce in the acidic waters. Conservation biologists have devised a temporary solution to the problem of acidic lakes by adding large amounts of calcium carbonate to them to reduce their acidity. While effective, this solution is costly and only temporary. Acid rain returns lakes to acidic conditions three to six years after treatment with calcium carbonate. The long-term solution to the problem of acid rain requires humans to use renewable sources of energy rather than continue to burn fossil fuels.

Conservation biologists worried that the thinning of the ozone layer would change the climate. The ozone layer makes life possible by blocking out large quantities of ultraviolet light, which is lethal in high doses. As the ozone layer thins, due to the release of chlorofluorocarbons into the atmosphere, it screens less ultraviolet radiation. Increases in ultraviolet light kill photosynthetic algae in the ocean. Because algae absorb carbon dioxide during photosynthesis, their reduction in numbers weakens their capacity to absorb carbon dioxide, contributing to the greenhouse effect. The thinning of the ozone layer thereby contributes to global warming. This thinning, itself a manifestation of climate change, harms Earth's biota. The ultraviolet light that penetrates the ozone layer also damages amphibian DNA, causing fewer amphibians to survive. Consequently, the number of frogs and toads has declined in the western United States.

Conservation biologists warn that the climate is not only changing, but changing rapidly. The speed with which the climate is changing may mark some species for extinction. Some tree species, for example, take 20–30 years to reproduce. By then, the climate may have changed to such a degree that the tree species may die before reaching sexual maturity and will become extinct. Conservation biologists assert that climate change is causing a mass extinction greater than any since the mass extinction at the end of the Cretaceous Era in which the dinosaurs perished.

THE TRAGEDY OF CLIMATE CHANGE

According to one line of reasoning, the tragedy of climate change is that it imperils humanity. The number of people on Earth has surpassed 6 billion. As the number of people increases, so must the food supply. Climate change, in targeting species of fish for extinction, robs people of a valuable source of protein. Overgrazing of rangeland does more than alter the climate by reducing the number of plants. It reduces the capacity of the land to feed a burgeoning population. In the 1930s, decades of overgrazing and wheat monoculture caused soil erosion on a vast scale. Drought brought matters to a crisis, as huge dust clouds assailed the western United States. As humans heat Earth with greenhouse gases, cause acid rain to accumulate in lakes, and overgraze the land, they may find food in short supply, causing a Malthusian crisis.

According to another line of reasoning, the tragedy of climate change is that it imperils Earth's rich biodiversity. Plants and animals do not have value because they can feed humans. They have value simply by their uniqueness. Beyond that, they have an aesthetic value apart from any economic considerations. They have as much right to the Earth as do humans. This view accords well with the recognition that all life, including humanity, is a product of evolution. No species may claim superiority. All happen by chance to occupy Earth at the same time.

Conservation biology may be unique among the subfields of biology in advocating policy. As a rule, geneticists and molecular biologists, for example, do not advocate policy. Often, they pursue research without the expectation that it will influence policymakers. By contrast, conservation biologists go a step beyond these sciences in urging government, for example, to curb the emission of sulfur dioxide, carbon dioxide, and chlorofluorocarbons. Conservation biologists are not only scientists, important as the profession of science is; they are advocates. They work with legislators to fashion policy that protects plants and animals. Because of their role in advocating policy, conservation biologists court public opinion. In this sense, conservation biology is a public science.

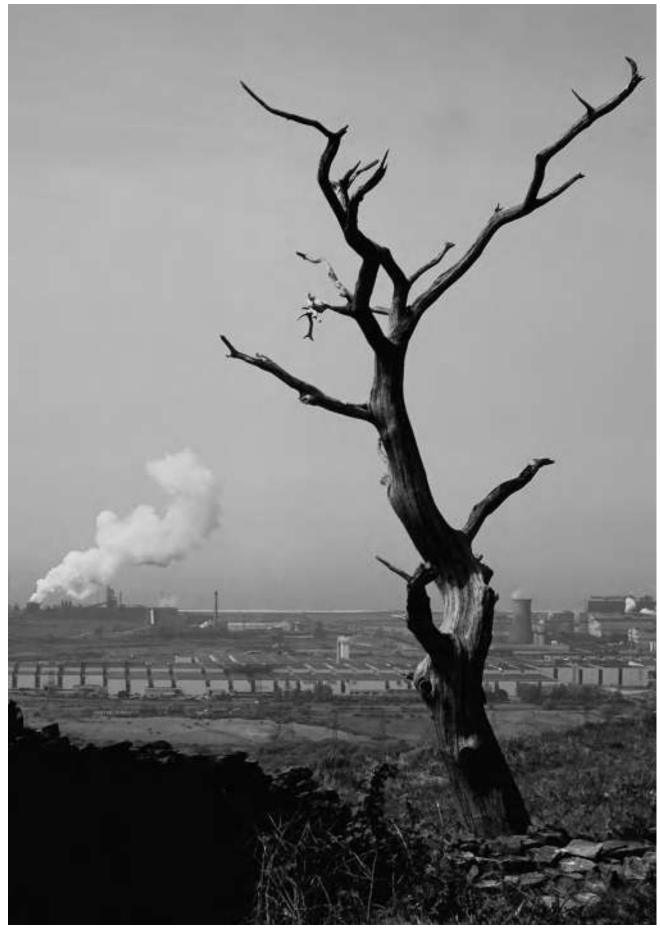
Conservation biology may also be unique in the breadth of its ties to other scientific disciplines and to nonscientific professions. By its nature, conservation biology is multidisciplinary. A full list of complementary disciplines may be difficult to construct, but conservation biology has ties to wildlife management, fisheries biology, the agricultural sciences, forestry, ecology, climatology, population biology, taxonomy, and genetics. In addition to working with scientists from these disciplines, conservation biologists work with journalists and newspaper editors. Some of the most influential conservation biologists—Aldo Leopold, for example—wrote in a journalistic vein.

Finally, conservation biology may be unique in seeking to protect the entire biota, the full range of species. Agricultural scientists are confined to crops and livestock, and the fisheries biologists to certain species of fish; but conservation biologists have every organism as their field of study. Conservation biologists believe that their central purpose is to protect Earth's biodiversity. Because climate change threatens biodiversity, conservation biologists aim, as one of their principal challenges, to stop, or at least slow down, climate change.

EVOLUTION AND EXTINCTION

The goal of biodiversity does not prevent conservation biologists from seeking to preserve evolution, a process that does not a priori favor biodiversity. Species compete for resources. The winners leave offspring to populate an ecosystem. The losers become extinct. Conservation biologists live with extinction as one outcome of evolution. However, they regret the current wave of extinction and pinpoint climate change as one cause of extinction. Humans are causing the current wave of extinction by warming the climate, acidifying rainfall, and thinning the ozone layer. The burning of fossil fuels, the cutting down of forests, the depletion of fisheries, and the overgrazing of ranchland are warming the climate and threatening the biota.

Conservation biologists have committed themselves to preserving land in as close to pristine condition as possible. In 1769, French colonialists legislated that one-quarter of the land on the island of Mauritius was to remain forest, that the island natives plant trees on denuded soils, and that the natives not cut down trees within 656 ft. (200 m.) of the ocean. In 1852, British scientists urged the East India Company, which oversaw the colony of India, to preserve forests in order to ensure abundant rainfall. Their report to the company was among the earliest to link the cutting down of trees with a reduction in rainfall. Before conservation biology had coalesced as a science, conservationists persuaded the U.S. Congress in the 19th and 20th centuries to create a system of national parks that would, in principle, remain unspoiled. Recognizing their role in protecting the habitats of innumerable species, conservation biologists aim to preserve the rainforests in Central and South America.



Conservation biologists battle problems like acid rain, which can result when factories and power plants emit sulfur dioxide.

By the early 21st century, conservation biologists, along with scientists from other disciplines, had established the fact of global warming and had enumerated the dangers of global warming for Earth's biota. Global warming is not a theoretical construct, but a biological reality. The greenhouse effect, the mechanism that causes global warming, threatens to extinguish innumerable species. Biologists, notably conservation biologists, urge political action to counteract global warming. Conservation biologists seek an alliance with policymakers and journalists, the one to implement laws and the other to inform the public of the dangers of global warming. Biologists acknowledge the difficulty of stopping global warming. People in the developed world must find an alternative to the burning of fossil fuels. People in the developing world must find an alternative to cutting down their forests. Biologists must think of innovative ways of protecting the biota while the rest of the world wrestles with the problem of global warming.

Biomass

GLOBAL WARMING IS the increase in near-surface air temperatures as a result of the emission of greenhouse gases and particulate black carbon. Decaying biomass is considered to contribute to this. Biomass is living (or recently dead) plant and other biological material that can be used as fuel. Plant matter grown for use in biofuel (industrial production) is a type of biomass. Another type of biomass is crop residue, which comes from agricultural production and biodegradable waste. Grass species are the biggest contributors of biomass.

Biomass is known as carbon neutral. This means that it does not contribute to global warming, but does not reduce it, either. As plants that produce biomass grow, they absorb carbon dioxide (CO_2) from the atmosphere during photosynthesis. This is known as carbon sequestration, because carbon is removed from the atmosphere. Therefore, a living plant increases carbon sink, but when the plant dies and decays, the carbon is released back into the atmosphere as CO_2 and methane. This is known as the carbon cycle. Thus, the initial stage of carbon sinking through photosynthesis and the later stage of releasing carbon into the atmosphere through the decaying process makes the biomass carbon neutral. Even if the biomass is not burned, the same carbon must be released into the atmosphere by plant decay as a part of its natural life cycle. Therefore, when biomass is burned as fuel, scientists consider it carbon neutral.

Instead of allowing the biomass to decay naturally, the biomass decay process can be sped up by using it in biofuels. This also provides another positive effect toward global warming reduction. Methane is a natural byproduct of biomass decay, but when biomass is burned efficiently, no methane is released into the atmosphere. Therefore, scientists can argue that complete combustion of biomass for use in fuels benefits the environment. However, it can also be argued that biomass burning releases more carbon into the atmosphere instantly, whereas the natural decay process slows down the releasing process. Still, the acceleration of only a few years is not significant in the context of the entire carbon cycle, which takes hundreds of years.

However, controlled forest burning as practiced in developed countries, and slash-and-burn agriculture (shifting cultivation) in developing countries both contribute to global warming. According to M.Z. Jacobson, forest or biomass burning produces particles that cause short-term global cooling, but over decades the gases overwhelm the cooling effect to cause long-term global warming. Therefore, it is prudent not to burn biomass in the field, but to burn or use it in a controlled environment to produce biofuels.

Compared to biomass, fossil fuels act as a carbon positive because the fossil fuels exist in underground storage and they do not release carbon into the atmosphere unless used on the earth as an energy source. As most of the developing and developed nations have already mandated, or are in the process of mandating, 10 percent of fossil fuel use should be replaced by biofuels to reduce fossil fuel use. Thus, the consumption of biomass to produce biofuel will cut down on greenhouse gas emissions into the atmosphere.

Most mainstream environmental groups and environmental scientists support biofuels as a significant step toward slowing or stopping global climate change. However, if biofuels are not produced from biomass in a sustainable manner, they might be detrimental to the environment. Because the production of biofuel from biomass requires a lot of direct and indirect energy consumption, it emits more greenhouse gases into the atmosphere than the carbon released through biomass decay. The Roundtable on Sustainable Biofuels is working to define criteria, standards, and processes to promote sustainably-produced biofuels for global warming mitigation.

Plantation or afforestation to replace the used biomass can make the biomass burning process carbon negative, which is essential to reducing global warming and subsequent climate change. When sustainable biofuel production criteria are defined and properly followed, the use of biomass should contribute positively toward global warming and climate change mitigation processes.

Blizzards

IN HIGH AND mid-latitudes, blizzards are some of the most widespread and hazardous of weather events. They are most common in Russia and central and northeastern Asia, northern Europe, Canada, the northern United States, and Antarctica. It is likely that climate change will give rise to changes in the number, severity, and geographical occurrence of blizzards. Although it is common for the term *blizzard* to be employed to refer to any disruptive winter storm, there is a more precise scientific usage. Blizzards are a winter phenomenon occurring when snow is blown along the ground surface by strong winds. In different countries, official definitions of blizzard conditions vary according to: high wind speed, high wind chill values, low visibility, the presence of falling or blowing snow, and the length of time the conditions persist. Although no particular temperature threshold is associated with these definitions, blizzard conditions may produce extreme wind-chill values through a combination of low temperatures and high wind speeds.

It is possible for blizzards to occur in conditions of clear skies when no snow is falling if conditions are conducive to the movement of existing surface snow, called ground blizzards. In many storms in continental interiors, it is not uncommon for little new snow to be associated with a blizzard, due to a lack of moisture associated with Arctic and Antarctic air masses in winter. In such circumstances, blizzard conditions are largely the result of winds blowing the existing snow cover. However, blizzards in some regions (for example, those in Western Europe and the Asian coast of the North Pacific, and "nor'easters" in the northeastern United States) are characteristically accompanied by heavy snowfall.

Blizzards are produced by strong winds: katabatic winds and those generated by steep sea-level pressure gradients associated with storms in high and mid-latitudes latitudes during winter. A single storm can occur over large areas of a continent and a severe blizzard may persist for a week or more. A blizzard that struck Saskatchewan, Canada, in 1947 lasted 10 days, burying a train in a snowdrift a kilometer long. The most severe blizzards occur in Antarctica, with winds exceeding 93.2 mi. (150 km.)/hour; at some Antarctic stations blizzard conditions occur on over half the days annually.

Historically, high death tolls have been associated with the most severe blizzards. A spring blizzard, in the United States in 1888, killed more than 400 people, and 277 died in a storm in 1993. In addition to the risks resulting from high wind chill values and exposure, blizzards generate other hazards. Whiteouts are often associated with blizzards, producing dangerous travel conditions. The blowing snow, limited visibility, absence of shadows, and lack of contrast between objects can cause a loss of depth perception and conditions in which even nearby objects may be rendered invisible. The persistent winds associated with blizzards may cause severe damage to buildings, and can block transportation links and bury structures in massive snowdrifts. Outdoor activities may come to a standstill. The resulting economic disruption can be extensive. Widespread deaths of domestic animals have occurred due to exposure and when sources of feed are cut off by blizzards. A reported 130,000 head of livestock died in Inner Mongolia as a result of a blizzard that began on New Year's Eve in 2000. However, very disruptive winter storms may not qualify as blizzards (for example, those involving high snowfalls, but without one or more other defining characteristics).

There are significant inter- and intra-annual variations in blizzard frequency and severity that make statistical analysis of past trends problematic. Detailed studies are limited. Nonetheless, at least in North America, historical evidence points to a decline in the frequency and severity of blizzards on the Canadian prairies and a significant decline in the frequency of blowing snow conditions in the Canadian Arctic. On the other hand, there is evidence for the occurrence of stronger blizzards along Russia's Pacific coast.

An increase in the vigor of winter storms in a warmer atmosphere may result in more frequent severe blizzards.

It may be reasonable to assume that in a warmer world there would be fewer blizzards. However, the occurrence of a blizzard is dependent on a specific combination of physical and meteorological factors. A systematic variation in one or more of these, as influenced by future climate change (for example, storm intensity, shifting storm paths, wind velocity, ambient temperature, the amount of snowfall, and the amount and condition of snow on the ground), may affect the number, intensity, and geographical distribution of blizzards.

An increase in the vigor of winter storms in a substantially warmer and energetic atmosphere may result in severe blizzard conditions becoming more frequent. A warmer climate may also be conducive to greater weather extremes. Regional differences in temperature variations in response to climate change (such as between ocean and continents, or between polar and mid-latitudes) may reduce or enhance temperature contrasts and thereby affect the frequency and severity of storms.

There is evidence from some regions that winter storms have increased in intensity; however, some modeling and empirical studies suggest a decrease in the frequency of winter storms. There may be considerable regional variation in the response to climate change (for example, potentially fewer blizzards in North America and more frequent and more severe storms in Western Europe). Storm tracks may also shift. Forecasts are speculative, as there is still a need to verify the conclusions derived from empirical studies of past blizzard patterns and projections from climate models.

Bolin, Bert (1925–2007)

BERT BOLIN MADE numerous contributions to the field of meteorology and its impact on the science of global warming and climate change. He was a Swedish meteorologist who worked globally and served on many international committees. Bolin was born in Nyköping, Sweden, on March 15, 1925, to two schoolteachers. He obtained his B.Sc. from the University of Uppsala in 1946, followed by an M.Sc. in 1950.

Bolin continued to study meteorology, receiving a Ph.D. from Stockholm University in 1956, at the age of 31. One of his mentors, Carl-Gustav Rossby, played an influential role in Bolin's career, when he encouraged the young scientist to enter the field of geochemistry. Bolin rapidly gained expertise on carbon dioxide and its role in biology and chemistry. From 1952–57, he served as executive editor of *Tellus*, a scientific journal publishing investigations in the atmospheric and oceanic sciences. In 1961, he returned to Stockholm University as a professor of meteorology, where he remained until 1990, and then became professor emeritus at that institution.

In 1967, the International Council of Scientific Unions (ICSU) and the World Meteorological Organization (WMO) joined forces to organize the Global Atmospheric Research Program (GARP), of which Bolin served as chair from 1968–71. GARP synthesized a new science that incorporated atmospheric physics, oceanic physics, mathematics, engineering, and other related fields, to study the weather and climate across the globe. Later, the WMO, along with the United Nations Environment Program (UNEP), formed the Intergovernmental Panel on Climate Change (IPCC), of which Bolin was chairman 1988–97. In 1990, he led the IPCC in its first assessment of climate change. The IPCC acts to review all relevant scientific investigations and observations regarding the climate and any human impact on the climate.

Between 1983 and 1986, Bolin acted on the Scientific Advisory Board, which advised the government of Sweden. He then became scientific advisor to the prime minister of Sweden until 1988, and then advised the vice prime minister until 1991. Bolin also served as the scientific director of the European Space Agency, as well as having membership in nine academies of science in different nations. In 1995, Bolin earned the Blue Planet Prize, established by the Asahi Glass Foundation in 1992 as "an international award that recognizes individuals and organizations who have made major contributions to solving global environmental problems." While Bolin's initial studies were on mathematics of atmospheric circulation, he is now recognized for his knowledge of greenhouse gases and his efforts to educate people about global warming.

Bolivia

THIS LAND-LOCKED SOUTH American republic has a land area of 424,163 sq. mi. (1,098,581 sq. km.), with a population of 9,119,152 (2007 est.), and a population density of 21.8 people per sq. mi. (8.4 people per sq. km.). Only 2 percent of the land in the country is arable, with 24 percent used for meadow or pasture, and 53 percent is forested. Largely underdeveloped, Bolivia had a per capita carbon dioxide emission rate of 0.8 metric tons per person in 1990, rising to 1.3 metric tons per person in 1997–99, and then falling to 0.90 tons by 2003. Most of the emissions come from transportation (39 percent), with manufacturing and construction accounting for 20 percent, and public electricity, heat production, and auto producers accounting for the rest. The relatively small part played by electricity generation comes from the heavy use of hydropower in Bolivia, which accounts for 50.1 percent of power generation. However, 48.3 percent comes from fossil fuels, mainly liquid (58 percent) and gaseous (24 percent) fuels.

The effect of global warming and climate change on Bolivia is significant; the average temperature in increased by about 0.18 degrees F (0.1 degree C) each decade since 1939, with the rate of warming doubling in the last 40 years, and then tripling in the last 25 years. With the small amount of agricultural land, global warming will continue to contribute to a declining food supply for an already poor population. Furthermore, it has been causing the ice on mountains in Bolivia to melt, leading to avalanches, occasional floods, and soil erosion.

The Bolivian government of Jaime Paz Zamora took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and that of his successor Gonzalo Sánchez de Lozada ratified the Vienna Convention in 1994. On July 9, 1998, the government of Hugo Banzer Suárez signed the Kyoto Protocol to the UN Framework Convention on Climate Change, which was ratified on November 30, 1999, and took effect on February 16, 2005.

Bosnia and Herzegovina

ONE OF THE former constituent states of Yugoslavia, the Republic of Bosnia and Herzegovina has a land area of 19,767 sq. mi. (51,197 sq. km.), with a population of 3,925,000 (2007 est.), and a population density of 230 people per sq. mi. (76 people per sq. km.). Fourteen percent of the country is arable land, 20 percent is used for meadows and pasture, and 39 percent of the land is forested with mainly pine, beech, and oak trees.

One of the least developed countries in Europe, Bosnia-Herzegovina has one of the lowest rates of carbon dioxide emissions: only 1.2 metric tons per capita in 1992. However, in 1997 the per capita rate rose dramatically to 3.6 metric tons, and then 4.6 metric tons by 1998. Most of these emissions come from electricity production (63 percent), as 37.6 percent of the country's electricity production is generated from fossil fuels. The remainder comes from hydropower. Transportation accounts for 33 percent of carbon dioxide emissions. These figures are reflected in the fact that the use of solid fuels, primarily wood and coal, account for 47 percent of carbon dioxide emissions. Liquid fuels account for 38 percent. The manufacture of cement also has a role in the country's carbon emissions.

Despite the Bosnian War, the government was eager to join international forums, and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention in the same year. On April 16, 2007, the Bosnian government accepted the Kyoto Protocol to the UN Framework Convention on Climate Change, becoming the 168th country in the world to do so.

Botany

BOTANY IS THE study of plants. Botanists study all aspects of plants, including their environment and how they grow. The discipline is one of the oldest sciences and has been closely associated with agriculture, horticulture, pharmacology, and other disciplines concerned with plants. Botany is related to many other sciences such as soil science, chemistry, geography, mathematics, and physics. All the sciences and businesses that use botanical knowledge benefit from pure botanical research.

Since prehistoric times, people have used plants for medicine, food, building materials, and making other items such as musical instruments. Plant knowledge was universal among cave dwellers or hunter-gatherers, whose folklore was passed on for generations. Medicine men or women practiced the development of remedies for diseases and injuries, as well as intoxicants. When settled farming communities arose about 12,000 years ago, horticultural plant knowledge also began to move toward a body of knowledge.

Ancient civilizations of the Egyptians, Indians, and Babylonians coined names for the plants they knew. The Greeks added to plant name descriptions. Aristotle, his student Theophrastus (*An Inquiry into Plants*), Galen the physician, and others gave descriptions to plant names. Aristotle sought the unique form or idea that is found in each plant. This basis would eventually aid the development of taxonomy of plants. He believed in the fixity of the species. This view was challenged by Charles Darwin's theory of evolution of the species, which was a naturalistic explanation for the enormous plant diversity in the plant kingdom.

There are hundreds of thousand of plants in the world. They vary widely, even when related. This creates a major problems for accurate identification. For example, there are a wide variety of plants named in the Bible and in other ancient literature. However, identifying the exact plants named by biblical names is problematic. The same problem occurs when plants are named by other ancient literature; because they were given local names, the specific plants named are hard to precisely identify. For example, in the Hindu *Vedas*, there is frequent mention of the soma plant that was used as an intoxicant. Today, scholars are not sure which plant is the soma plant because of the absence of a universal, standard terminology of identification.

A standard nomenclature was adopted after the voyages of discovery, when a rich new variety of similar and uniquely new plants confronted botanists. Standardized nomenclature was developed using a taxonomy derived from Latin names. Latin, the language of scholarship until the 20th century, was used to assign a universal name to plants with different common names or national names in the many European languages. The use of Latin, a dead language, prevents changes in names that would occur in a living language, thereby creating lasting scientific precision.

The scientific naming has a fixed pattern, in which the first name identifies the genus to which a plant belongs. The second name is the species name, which denominates precisely to which subgroup it belongs. Each genus is a unique class with each of its species being also unique groups. Many plants also have varietal names. For example, the orange tree has a scientific name of *Citrus sinensis*; Naval and Valencia oranges are varieties.

AREAS OF STUDY

As a scientific discipline, botany organizes plants observed in nature into an organized body of knowledge or taxonomy, giving each its unique scientific name in Latin. The features of plants help to identify and name them. These are studied in order to understand the nature and possible uses of plants. The features of plants studied by botanists include plant physiology, cytology and histology, morphology, genetics, pathology, plant ecology, and economic botany. Physiology in botany is the study of the kinds of things that plants do to stay alive. It includes study of how plants make and use food, how the cells of a plant enable it to grow, how they reproduce, and how they are influenced by heat, light, and moisture.

Plant morphology is the study of the form and structure of plants. Morphology is organized around the taxonomy of plants. Cytology and histology are sub-disciples of plant morphology. Histology is the study of how different types of cells are arranged in different plants. Cytology focuses on the specific nature of plant cells. Plants range from single cell to very complex arrangements of cells into soft green leaves, sea weed, or into very hard tropical trees such as mahogany. Plant genetics focuses on the laws of genetic reproduction to describe how plants transmit their characteristics to their offspring. This discipline is very important to many people, from gardeners to farmers.

Plant pathology is caused by a multitude of pathogens. The most damaging are viruses, bacteria, fungi, and molds. However, exhaustion of the soil, or weather, especially that associated with climate change, can cause the death of plants. To prevent crop loss, plant pathology includes the study of ways to fight or prevent plant diseases. Plant ecologists study the relationship between plants and their spatial location. Also important to plant ecology are studies of how plants grow (or do not grow) together. Knowledge of plant ecology can be very helpful in aiding recovery of an area that humans are trying to restore to health.

THE GREENHOUSE EFFECT

Botany is being brought into play in the effort to understand and respond to climate change. Global warming is climate change that is producing a dramatic rise in temperatures around the Earth. Carbon dioxide, methane, and nitrous oxide are naturally in Earth's atmosphere in small amounts; however, they act as greenhouse gases by absorbing some of the long wave radiation that is radiated from the Earth back into outer space.

Sunlight is mostly shorter-wave radiation. Although the layers of the upper atmosphere block some, the portion that strikes the surface of the Earth warms both the oceans and the Earth's surface. However, the polar ice caps and the alpine glaciers of the world reflect much of this radiation. That which heats up the rocks of deserts, or the concrete and brick buildings of urban areas, or even the masses of greenery in forests is absorbed, in part, and returned as a part of cooling as long-wave infrared radiation. Most radiated heat returns to outer space. However, some is retained by the greenhouse gases and radiated back to the surface of the Earth.

The greenhouse gas phenomenon is natural. Without it, Earth would be much colder, by 54 or more degrees F (30 or more degrees C), and would very likely be a block of ice. What is of great concern at the present is that humans are causing global warming. The term *anthropogenic* is used to describe the human emissions of greenhouse gases, mainly carbon dioxide, that are causing a rise in global temperatures, the melting of the ice caps and the alpine glaciers, and a change in wind patterns that bring rain.

CLIMATE ZONE CHANGES

Of particular concern to botanists, as well as others, are the global warming effects that are producing a shift in climate zones. For example, the warming of the Arctic regions is a threat to polar bears that need sea ice as a platform for their hunting, but it is also a threat to plants that are adapted to colder temperatures and are disappearing because of global warming. As global temperatures rise, plants in the latitudes away from the equator are affected. Many will spread northward or southward as temperatures rise; however, many species do not migrate well. This is especially true of plants (and animals that feed on them) that are located in mountainous areas. Adapted to cold temperatures in high elevation, global warming pushes them ever higher up the mountain sides until, for some, there is literally no place to go.

The changing temperatures are also affecting the hardiness zones used by farmers and gardeners to decide which plants to grow. However, global warming is not bringing a simple northward or southward movement away from the equator. The shifting flows of energy in the planetary weather patterns are making some places drier, some colder, others warmer, and others wetter.

Some botanists have hypothesized that if global warming continues, areas that have been agricultural zones for growing wheat, corn, or other crops may be lost and not easily replaced by other sufficiently warm, but less fertile, regions.

Many scientists are concerned that climate zones as they are currently known will vanish entirely by 2100. Using greenhouse gas emissions scenarios that range from low to high, it is possible that enough climate change will occur to cause major ecological transformations. Entire plant species will disappear, pine forests would become grasslands, and rainforests would become savanna. In places like Wyoming, grasslands would disappear. Higher temperatures would cause places such as Wyoming's grasslands to be much drier in the summer and to be much more threatened by fires. Researchers estimate that existing climates will disappear from almost half of the planet. New climates will develop in about 40 percent of the of the Earth's land mass. The places hardest hit will be the tropics, which have the most biodiversity.

Botanists report that many plants, including the cherry trees of Washington, D.C., are blooming days earlier than 30 years ago.

Duke University has conducted a study of the central plains of the United States in the areas where the plains have changed from grasslands and forest because of climate change in the geologic past. After the last ice age, periods of warming and cooling caused the grasslands and the forest areas to radically change. The grasslands would expand eastward into the eastern forests. Tree mortality would be affected by seed-eating predators and the ways in which seed dispersal affects biodiversity.

Botanical evidence of global warming is accumulating at a rapid rate. Botanists in Boston have found that plants are blooming over a week earlier than they did a century ago. The plants studied are in arboretums where long-lived plants or descendants of the same species of plants provide a standard of comparison. The flowers of living plants can be compared with museum specimens that were gathered at specific dates. These plants and dates have been compared to determine that plant life is showing evidence of global warming.

BOTANICAL EVIDENCE FOR GLOBAL WARMING

Botanical evidence for global warming is being extracted from the rich trove of journals and records kept by gardeners and farmers in areas such as New England. Henry David Thoreau's writings are an early version of this form of information that is allowing comparisons to be made with weather in prior decades and the current weather patterns. It takes at least 30 years of records to have sufficient data to make statements about the climate of an area. Those who have consistently kept records of the arrival of birds, of the blossoming of plants, for 30 or more years, have data that can be used to verify climate changes. Amateur naturalists, hunters, fishermen, bird watchers, and local nursery growers, as well as farmers, are supplying records that can demonstrate climate change. When compiled, if the field observations of amateur naturalists are close to the trends observed in scientifically collected data, then the scientific inferences of global warming and its effects gain additional support.

Another botanical observation that provides evidence of global warming is the famous blossoming of the cherry trees in Washington, D.C. Scientists from the Smithsonian Institute have produced evidence that the cherry trees are blooming seven days earlier than they did a mere 30 years ago. The change is apparently due to global warming. Studies by the Smithsonian's Department of Botany have found that records from the last 30 years show that between 1970 and 2000, almost all of the species of common plants studied bloomed earlier in 2000 than in 1970, by at least four and a half days.

Dutch botanists have begun studying epiphytes in order to understand the impact of climate change. Epiphytes are organisms that grow on living plants. They include algae, lichens, mosses, ferns, bacteria, and some fungi. Their specific focus has been on lichen species in the Netherlands. Lichen distribution and species diversity have changed significantly over the last 30 years. At first, the changes were because of reductions in pollution; later changes correlate well with temperature increases. Other European scientists have found that bryophyte species in central Europe are subtropical and are now expanding their range. The changes are indicative of botanical changes being wrought by global warming. In Costa Rica and in the Bolivian Andes mountains, epiphytes are also being used as indicators of global warming. A number of species of epiphytes have moved to higher elevations. Others in lower elevations have diminished, which suggests stresses caused by temperatures that exceed the species tolerances.

In Japan, studies conducted between 1981 and 2005 have found that 17 species and hybrids of cherry trees from Mt. Takao in Tokyo are flowering earlier previously. Each species is blooming between three to five days earlier for each one degree C increase in temperature. The effects of the changes on the gene flow and the pollination patterns are as yet unknown. Many botanists believe that Africa will suffer the most from increasing global warming and the resulting botanical changes. In Australia, the grasslands of Tasmania are also currently threatened, according to botanists studying the area.

Botswana

BOTSWANA IS A landlocked country in sub-Saharan Africa bordered to the south by South Africa and to the north by Zimbabwe and Namibia. It is a semi-arid country, dominated to the southwest by part of the vast Kalahari Desert. Only about 0.65 percent of the land is arable. Its main environmental issues are periodic droughts, limited access to fresh water, overgrazing, and desertification. The population is approximately 1.8 million people. Botswana has one of the world's highest rates of HIV-AIDS prevalence, with an estimated 37.3 percent of the adult population infected with the virus. This has put an enormous strain on the country's financial resources, and has made it even more difficult to deal with environmental issues.

Current climate models predict a regional decrease in rainfall of 10–20 percent by 2070. A 10 percent decline in rainfall would leave Botswana with just 23 percent of its current surface water flow; a 20 percent decrease would leave the country's few water sources completely dry. Researchers have also found that the dunes of the Kalahari Desert are beginning to shift for the first time in 16,000 years, reacting to vegetation loss and global shifts in wind patterns. This will push the dunes into Botswana's already stressed agricultural regions by 2100.

A study of crocodile populations along the Nile River near Okavango, Botswana, conducted by Alison Leslie, has shown that rising temperatures are leading to a decrease in the number of male crocodiles. Male offspring are produced only within a certain range of temperatures, and as the average temperature is increasing, more and more broods are all female, or female-dominated. This will eventually lead to a decline in the species.

Botswana is not a high CO_2 emitter, although studies show a 43 percent increase in emissions 1990–98. In 1998, per capita CO_2 emissions were 2.4 thousand metric tons, higher than the sub-Saharan average, but less than half the world average. About 66 percent of emissions came from the burning of solid fuels such as wood and charcoal, while 34 percent came from liquid fuel use. Botswana has signed a number of international environmental accords, including the Kyoto Protocol and conventions on biodiversity, climate change, desertification, protection of endangered species, the ozone layer, and wetlands. However, the government has ratified none of these conventions.

BP

BP (BEYOND PETROLEUM) is the world's third largest investor-owned oil company. At the close of 2006, it had nearly 97,000 employees, 18 refineries, 24,600 service stations, and proven oil reserves of 17.7 billion barrels of oil and gas equivalent, and it operated in over 100 nations. In 2006, BP's sales were $266 billion, with profits of $22.5 billion, compared to $19.3 billion in 2005, and $15.4 billion in 2004. It is also a major producer of solar and other renewable sources of energy. It is a significant contributor to greenhouse gas (GHG) emissions, but has also been a leading industry advocate of addressing climate change. BP is organized into three key segments: exploration and production; refining and marketing; and gas, power, and renewables.

BP is the product of numerous mergers during the 20th century. British Petroleum's retail operations were centered in Britain and Western Europe, with crude oil reserves predominantly in the Middle East until the late 1960s, when it discovered large oil fields in Alaska and the North Sea. At this time, it expanded into U.S. retailing through an ownership stake in Sohio (Standard Oil of Ohio). It bought full control of Sohio in 1987, rebranding the stations as BP and establishing its BP America division. That year, the British government completed selling its shares of BP. Amoco (Standard Oil of Indiana), a major Midwest U.S. retailer and the world's largest natural gas producer, was acquired in 1998, creating BP Amoco.

ARCO (formerly Atlantic Richfield) concentrated on the U.S. West Coast, and also held large Alaskan reserves, and British lubricant manufacturer Castrol and its parent, Burmah Oil, were acquired in 2000. That year the name was changed to BP and a new unified global brand was created, although the ARCO brand was retained on the U.S. West Coast. In 2002, BP bought Aral, a major German gasoline retailer, rebranding BP stations in several European nations under the Aral name. It also entered an $8 billion joint venture in Russia (TNK-BP) in which it has 50 percent ownership.

Under Lord John Browne, CEO 1995–2007, BP attained a reputation as an environmental leader in the oil industry. Browne publicly stated in 1997,

> the time to consider the policy dimensions of climate change is not when the link between greenhouse gases (GHG) and climate change is conclusively proven, but when the possibility cannot be discounted and is taken seriously by the society of which we are part. We in BP have reached that point.

BP then became the first company to withdraw from the Global Climate Coalition, an industry group opposing action on global warming. In 2007, BP was a founding member of the U.S. Climate Action Partnership, a coalition of over 25 corporations and several environmental groups advocating strong governmental action to reduce GHG emissions.

BP believes that addressing climate change involves several elements: precautionary action; urgent, but informed, action over the next 50 years; sustainable GHG emission reductions at the lowest possible cost; an inclusive approach involving many different parties, policies and regulations relying on market mechanisms, research and development; and public education. It is in favor "of mandatory emission caps and policies that set a price for carbon in a way that can change behavior and encourage innovation." The company has a related business strategy of engaging in energy efficiency, fuels switching; carbon sequestration; and solar, wind, biomass, and hydrogen power.

In 1998, BP began tracking GHG emissions and set voluntary reduction goals, which it met ahead of schedule. In 2004, a seven-year, $450-million energy-efficiency program began to cut GHG emissions and costs. BP estimates that customers' CO_2 emissions from use of its conventional hydrocarbon products were 606, 570, and 539 Mte in 2004, 2005, and 2006, respectively. One of the main ways BP is looking into further cutting GHG emissions is through limiting gas flaring and venting.

In 2004, BP Solar (a merger of solar companies previously purchased by BP and Amoco) had a 20 percent share of the global solar panel market, with 2,000 employees. BP currently has a $70 million project to expand solar casting capacity at a plant in the United States, and is tripling its capacity in facilities in Spain and India over a three-year period. BP currently operates two wind farms in the Netherlands and bought a leading wind producer in the United States. It intends to raise its wind generating capacity from 30 megawatts (MW) to 450 MW by 2010.

BP's hydrogen projects are more limited, derived from fossil fuels, accompanied by carbon sequestration and storage. BP is pursuing a relationship with

General Electric to develop new hydrogen technologies. Its natural gas operations include combined-cycle gas-turbine power stations and steam-turbine power generating plants. BP plans to invest $500 million in biofuels research and development over the next 10 years in a new Energy Biosciences Institute, and is funding many other external research projects into various low-carbon technologies and topics.

While generally lauded by environmentalists since 1997, BP has come under increasing criticism. BP's production of hazardous wastes is substantially higher than its industry competitors; a 2005 Texas refinery fire killed 15 persons and injured 170, and corrosion in an Alaskan pipeline managed by BP resulted in an oil spill of over 200,000 gallons and necessitated shutting down the pipeline for several months in 2006.

In 2007, a BP refinery received a permit from the state of Indiana to increase its discharge of ammonia and sludge into Lake Michigan coincident with a refinery expansion, resulting in tremendous negative publicity and calls for a consumer boycott. BP eventually announced that it would not increase its discharges, although the permit still remains valid. BP is alleged to have engaged in human rights abuses at various extraction and pipeline locations, including Columbia, West Papua, and Azerbaijan. BP has also been criticized for continuing to derive almost all its revenues from fossil fuels, despite the publicity it gives to its renewable energy business and its "beyond petroleum" slogan.

Brazil

WITH THE 10TH largest economy and fifth largest population in the world, Brazil is an important enactor of climate policy. Its energy matrix is relatively "clean"—80 percent of the generated electricity comes from hydropower, and 45 percent of the country's total energy consumption comes from renewable sources. Most of Brazil's CO_2 emissions come from biomass burning, as a result of deforestation. Deforestation is responsible for between 10 and 25 percent of the global human-induced carbon emissions and 60 percent of all Brazil emissions. Although total fossil fuel CO_2 emissions have increased steadily and reached 90 million metric tons in 2004, Brazil's per capita emission rate of 0.50 metric tons of CO_2 per year remains well below global average rates.

Climatic change is expected to impact Brazil in many different ways, from increases in semi-arid areas in the northeast, to higher rates of rainfall in the southeast. Lower rainfall rates in northeast Brazil will result in even more extreme drought spells and further challenge the availability of water in a region already historically ravaged by climate-related poverty. In addition, groundwater recharge may also decrease dramatically (by as much as 70 percent) further affecting the availability of water resources. Less water will also negatively affect irrigated agriculture and hydroelectricity production in the region.

Negative impacts are also predicted for Brazil's rich biodiversity, especially in areas such as the Amazon and Atlantic rainforests, or fragile ecosystems such as the Pantanal wetland, which may lose up to 40 percent of its species diversity with temperature increases of about 3.6 degrees F (2 degrees C) above pre-industrial levels. The Amazon forest may go

Deforestation, such as in this open pit mine in Minas Gerais, is responsible for 60 percent of Brazil's CO_2 emissions.

through a "savannization" process in which increases in temperature and decreases in soil moisture may lead to the gradual replacement of the tropical forest by vegetation similar to that in Brazil's savannahs. This savannization will be accompanied by possible extinction of species and loss of biodiversity. Drier weather may also increase the frequency of forest fires in the region, which, in turn, would contribute to further CO_2 emissions.

Other possible negative impacts include coastal cities and coral reefs being affected by rising sea levels, the expansion of vectorborne diseases, and possible increases in the frequency and intensity of weather-related disasters, such as flooding and cyclones. One sector of special concern is agriculture, because of its critical importance to Brazil's economy, and because of its role in the country's biofuel programs, essential to meeting mitigation goals for CO_2 emissions. Regarding human vulnerability to climate change, although, overall, Brazil fares relatively well when compared to other countries, the high level of socioeconomic inequality and large pockets of poverty suggest that significant portions of the population may be highly vulnerable to climate change and will need specific policies to increase their levels of adaptive capacity.

Brazil's climate policy, both domestic and international, has been, at times, aggressively proactive (as with the design and pursuit of Clean Development Mechanisms, or CDMs) and remarkably reactionary (as in the government's reluctance to support initiatives to curb deforestation as part of its climate policy portfolio). Brazil has been a leader in the Kyoto negotiations to introduce carbon-trading mechanisms such as CDMs, which allow for developed countries and businesses to count greenhouse gas (GHG) reductions generated by projects carried out in less developed countries (LDCs). Currently, Brazil is the country hosting the largest number of CDM projects.

Brazil has also sought to block initiatives to subject LDCs to stringent carbon emission reduction targets. Brazilian government representatives have been particularly sanguine in defending the historical contribution argument, which maintains that, because carbon dioxide remains in the atmosphere for more than a century, on average, climate change has been primarily caused by early polluters, or developed countries, that should be responsible for its mitigation. Another argument against emission targets for LDCs is that these countries have a long way to go to reach levels of per capita carbon consumption comparable to current levels of developed countries, and, therefore, should be exempt from carbon emission caps in the near/mid-term.

The Brazilian government has been particularly sensitive to any mitigation scheme that involves the Amazon rainforest, and has been reluctant to endorse initiatives such as Avoided Deforestation, which is supported by a coalition of conservation interests and rainforest-rich countries. This scheme would allow developing countries to participate in the Kyoto Protocol by electing to reduce their national emissions from deforestation. Forest-rich countries would be allowed to issue carbon certificates, similar to the Certified Emissions Reductions (CERs) of the CDM that could be sold to governments or private investors.

Domestically, Brazil has invested substantially in an energy matrix reliant on renewable resources. Brazil's flagship biofuel program is based on sugarcane and dual-fuel car technology (cars run on sugarcane alcohol and/or gasoline). The sugarcane biofuel program is worth over $8 billion a year and generates a million direct jobs. Brazil's bio-diesel program is based on oil seeds such as castor and sunflower crops that produce clean energy, absorb carbon monoxide, and are labor intensive.

Broecker, Wallace (1931–)

WALLACE BROECKER IS an American oceanographer, Newberry Professor of Geology at Columbia University, and scientist at the Lamont-Doherty Earth Observatory who made major contributions to chemical oceanography, especially oceanic mixing based on radioisotopic distribution. Broecker set the research agenda for the field of paleoclimatology, thanks to his ability to devise coherent pictures of how all the different elements of the Earth shape the planet's climate. In particular, Broecker focused on the influence of oceans in triggering abrupt climate changes. His research has made him one of the most often-quoted scientists in contemporary debates about global warming. A *New York Times reporter* described him as the "iconoclastic guru of the climate debate."

Broecker was born on November 29, 1931, in Chicago, Illinois, where his father ran a gas station. He grew up in a fundamentalist Christian family and attended Wheaton College, a fundamentalist institution, before transferring to Columbia University in 1952. Broecker soon rebelled against his religious fundamentalist background. The skepticism that informs much of his scientific interest in the exceptions to general rules may be the result of this rebellion against the stifling religiosity of his family.

Broecker stayed at Columbia for his entire academic career. He earned his doctorate in 1958 and, a year later, became assistant professor. In 1961, he became associate professor, and in 1964, he was appointed full professor. In 1977, Broecker was named the Newberry Professor of Geology and, two years later, he was elected to the National Academy of Sciences and named chair of the Geochemical Society.

Broecker is the author of more than 400 articles and seven books. He began his research in the 1950s, developing techniques to measure the radiocarbon content of ocean water. He used his data to trace ocean circulation patterns over time. His researches connecting climate change with radiocarbon dating of marine shells found in sediment deposits on the sea bottom helped to date the abrupt end of the most recent ice age, approximately 11,000 years ago.

In the 1970s, Broecker was among the leaders of the Geochemical Ocean Sections (GEOSECS) program, which gathered information from the world's oceans through radiocarbon dating. In the mid-1980s, Broecker devised his theory of global ocean circulation, which is often called Broecker's Conveyor Belt. He theorized the circulation of chemical elements in the sea, the thorough mixing of surface and deep waters of the ocean that takes place every 1,000–2,000 years, and the rate of gas exchange between the atmosphere and the ocean.

Broecker came to the conclusion that climate is extremely volatile. It can cool down, as well as warm up very quickly, and these alterations can produce global changes. The Earth's climate is subjected to the on and off action (thus the conveyor metaphor) of deep ocean currents that transport great amounts of heat around the planet. Broecker used radiocarbon dating of samples of ocean water to study the world's oceans. He was one of the first scientists to stress the importance of the carbon cycle and to be able to work out its chemical processes. His research also pointed out the ocean's influence on atmospheric carbon dioxide levels.

While researching changes in the Earth's climate in the past 200,000 years, Broecker discovered that major climate shifts actually occurred much more rapidly than was previously thought. Focusing on the Younger Dryas, an event dating back 11,000 years when temperatures in northern Europe suddenly plummeted and remained low for about 1,000 years, Broecker concluded that the transition periods from warm to cold and back again may have taken as little as 20 years. This cold spell, Broecker explains, was due to a temporary disturbance in the global circulation of the world's oceans. Because this global current is linked to the atmosphere, the emission of greenhouse gases through fossil fuel combustion could cause a major interference in today's climate.

Broecker likens climate to "an angry beast" that "we are poking with sticks." He has had no qualms in explicitly stating that if world temperature continues to rise, the conveyor belt could slow down or stop, causing disruptive events throughout the world. The most disruptive of these events would be what he calls brief, but large ,"flickers" in global temperature as the climate readjusts itself in fits and starts. These flickers would be largely unpredictable and could produce drastic climate changes in periods as short as five years. This would lead to agricultural disasters.

Thanks to his investigation of oceanic cycles and the connection between the oceans and the atmosphere, as well as his research into chemical cycles such as the carbon cycle, Broecker has improved knowledge of how climate changes. He has also supplied fundamental information to devise possible strategies to deal with the problem of global warming.

Luca Prono
University of Nottingham

Brunei Darussalam

LOCATED ON THE north coast of Borneo, Negara Brunei Darussalam has a land area of 2,226 sq. mi. (5,765 sq. km.), and is divided into two parts. It has a population of 383,990 (2007 est.), and a population density of 168 people per sq. mi. (65 people per sq. km.). The country has abundant petroleum and gas supplies, which produce most of the its wealth, with one percent of the land being arable, and another one percent used for meadows and pasture. Unlike most of the other major petroleum-exporting countries, some 85 percent of the country is forested, with logging restricted and largely for local consumption, such as in the making of furniture and other higher-value activities.

In spite of its abundant forests, Brunei has the 15th highest per capita emission of carbon dioxide in the world. In 1990, its emission rate was 33.7 metric tons per person, but this was steadily reduced to 10.7 metric tons per person in 1998, after which it rose dramatically, before being reduced to 12.7 metric tons per person in 2003. In terms of its carbon dioxide emissions by source, 55 percent is from gaseous fuels, 28 percent from liquid fuels, 13 percent from gas flaring, and 4 percent from the manufacture of cement.

Electricity production, which is entirely from fossil fuels, accounts for 38 percent of the emissions. With an extremely high standard of living, much of the electricity consumption is spent on household use and air conditioning. Until the mid-1990s, there was very limited public transport in the country (with the exception of the water taxis at Bandar Seri Begawen, the capital). The system has been greatly improved, although there remains a high level of private car ownership, with the result that transportation accounts for 16 percent of the country's carbon dioxide emissions.

The Brunei government sent observers to the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, but so far the government has not expressed an opinion on the Kyoto Protocol to the UN Framework Convention on Climate Change.

Justin Corfield
Geelong Grammar School, Australia

Bryan, Kirk (1929–)

KIRK BRYAN IS an American oceanographer and Senior Research Scholar at Princeton University whose research has dealt with the construction of models for ocean circulation and the roles played by oceans in the climate system. Bryan is considered the founder of numerical ocean modeling. Climate models are computer-based simulations that use mathematical formulas to recreate the chemical and physical processes that drive Earth's climate. Bryan's original model is still considered an insight of enormous importance for climate science and weather forecasting. Earlier knowledge of the oceanic and atmospheric circulation, and their interactions, was based purely on theory and observation.

According to Bryan, the world's oceans are one of the least-understood elements in the climate system. His research aims to understand the role of ocean circulation in the Earth's current climate, and its variations over the recent geological record. To gain a better understanding of ocean circulation, Bryan has systematically compared data and has established a hierarchy of coupled models of increasing complexity. Bryan's work is geared toward a comparison of the atmosphere and the ocean, and their roles in the global heat and water balance.

THE BRYAN-COX CODE

Bryan started his research at the Geophysical Fluid Dynamics Laboratory in the 1960s. The laboratory was then located in Washington, D.C. (it has since transferred to Princeton University). With a team of colleagues, Bryan developed numerical schemes to calculate the equations of motion describing flow on a sphere. These schemes led to the "Bryan-Cox code," used in many early simulations, which allowed the development of the Modular Ocean Model currently used by many numerical oceanographers and climate scientists.

The "Bryan-Cox code" was used to create the first simulation models that calculate realistic circulation of oceanic regions. The models are often very complex, and their output is difficult to interpret. The Bryan-Cox model calculated the three-dimensional flow in the ocean combining the continuity and momentum equation with the hydrostatic and Boussinesq approximations, and a simplified equation of state. These models are called primitive equation models because they use the most basic form of the equations of motion. The equation of state allows the model to calculate changes in density due to fluxes of heat and water through the sea surface, so the model includes thermodynamic processes.

The Bryan-Cox model used large horizontal and vertical viscosity and diffusion to eliminate turbulent eddies of diameters smaller than about 311 mi. (500 km.). It also had complex coastlines, smoothed seafloor features, and a rigid lid. The rigid lid was necessary for eliminating ocean-surface waves, such as tides and tsunamis, which move far too fast to be accounted for by the time steps used by all simulation models. Criticism of the model concerns the lid. Islands substantially slow the computation, and the sea-floor features must be smoothed to eliminate steep gradients.

The Geophysical Fluid Dynamics Laboratory Modular Ocean Model (MOM) is perhaps the most widely used model that grew out of the original Bryan-Cox code. It is made up of a large set of modules that can be configured to run on many different computers to model many different aspects of the circulation. The source code is open and free. The model is commonly used for climate studies and to assess the ocean's circulation over a wide range of space and time scales. The Parallel Ocean Program Model also grew out of the Bryan-Cox code.

The Bryan-Cox code allowed scientists to understand how the ocean and atmosphere interact with each other to influence climate. The Bryan-Cox model also predicted how climate changes are determined by changes in the natural factors that control climate, such as ocean and atmospheric currents and temperature. This pioneering model included all the basic components of climatic factors (atmosphere, ocean, land, and sea ice), but covered only one-sixth of the earth's surface, from the North Pole to the equator and 120 degrees of longitude east to west. Bryan's most recent research, therefore, has focused on the development of more general models that will provide an accurate representation of the effect of mesoscale eddies.

Bryan is also interested in using coupled ocean-atmosphere models to determine climate predictability in middle- and high-latitude areas. Thanks to joint research with Stephen M. Griffies, Bryan has also concluded that the North Atlantic Ocean changes less rapidly than other oceans in terms of salinity and temperature, which are important factors in producing climate change. Bryan has been awarded the Maurice Ewing Medal of the American Geophysical Union for his contributions to the field of ocean science.

Bryson, Reid (1920–)

REID BRYSON IS an American atmospheric scientist, geologist, meteorologist, and emeritus professor at the University of Wisconsin, Madison. At Wisconsin, he founded the Department of Meteorology, the Center for Climatic Research, and helped found the Institute for Environmental Studies, which he directed 1970–85. According to the British Institute of Geographers, Bryson is the most often quoted climatologist in the world. Throughout his long career, he has advanced general understanding of climate, linking it with human ecology. He has focused on anthropogenic climate changes (changes generated by human interventions) and has also dealt with paleoclimatology, which seeks to understand ancient weather patterns.

Bryson is perhaps most famous for his statement that global warming is not the result of human actions, which has sparked controversy even within his own department. He served on the council of the Smithsonian Institution and has written five books. He is a member of the United Nations' Global 500 Roll of Honor in which scientists are included for their outstanding achievements in the protection and improvement of the environment. In addition to his distinguished career as a scientist, Bryson is also a published poet, and his scientific book *Climates of Hunger* has won the Banta Medal for Literary Achievement, a prestigious literary award.

Born in Michigan in 1920, he received his B.A. degree in geology at Denison University in 1941, and obtained his Ph.D. in meteorology at the University of Chicago in 1948, the 30th in meteorological doctorate awarded in the United States. Before completing his postgraduate degree, Bryson had already developed an interest in climatology serving as a major in the Air Weather Service of the U.S. Army Air Corps. In this capacity, he prepared the weather forecast for the homeward journey of the Enola Gay.

He joined the faculty of the University of Wisconsin, Madison, in 1946 and was hired by the departments of Geography and Geology. In 1948 he was the founding chairman of the Department of Meteorology, now known as the Department of Oceanic and Atmospheric Sciences. Because his wide-ranging academic interests also included disciplines such as history and archeology, Bryson soon shifted the department's research in an interdisciplinary direction. He retired in 1985, but has continued to be an active researcher.

Bryson's research does not look only into the short-range phenomena that make up the weather, but also into climatic patterns over the millennia. He has also been fascinated by inherently unobservable predictions and discoveries. He worked out past climates from analysis of ancient tree rings. He came to the conclusion that arid parts of India had previously been much wetter through an analysis of primordial pollen gains. Consequently, he devised a system of land use that helped reduce the overgrazing that had caused the dryness.

Bryson has developed new approaches to climatology, such as air-stream analysis and quantitative, objective methods of recreating past climates. He has also pioneered the use of computers to study long-range climatic changes, setting up computer models concerning such topics as the past history of the monsoon in Rajasthan, model simulation of Pleistocene ice volume, and Pleistocene climatic history.

Bryson's role in contemporary debates on global warming is controversial. Although in the 1960s he was one of the first to point out the impact of human action on climate change, in 2000 the scientist claimed that the role of humans in shaping climate was minimal. Bryson claims that there is little evidence that humans and carbon dioxide (CO_2) cause global warming. According to Bryson, the Earth has been constantly warming up in the past centuries, even when the emission of CO_2 was extremely low. The phenomenon of global warming is, thus, due to emergence from an ice age.

In addition, Bryson argues that the data used for computer predictions about future climate overemphasize the role of CO_2 and do not account for the effects of clouds (water vapor) in absorbing radiation coming from the Earth. To Bryson, whose positions on the subject have made him a controversial figure in the scientific establishment, global warming is just a commercial concern for contemporary researchers seeking funding for their projects. He has described Al Gore's Academy Award-winning documentary, *An Inconvenient Truth,* as untrue and unscientific, going as far as saying, in his characteristically contentious style, that it made him throw up.

The scientific community has challenged Bryson's conclusions on global warming, pointing out that his argument is based on incorrect data and personal attacks against other climatologists. For example, his claim that humans have not produced much CO_2 in the past 300 years is countered by the fact that, from 1750 to 2005, atmospheric CO_2 concentrations increased by 35 percent. CO_2 emissions, scientists predict, will at least double this century, barring a switch away from fossil fuels. Moreover, climate models and paleoclimatic data show that the CO_2 effect on climate is not marginal, especially when amplified by positive feedbacks in the climate system.

Budyko, Mikhail (1920–2001)

MIKHAIL IVANOVICH BUDYKO was an environmental scientist who was internationally recognized for his pioneering work on the Earth's energy balance, surface hydrology, and climate change, and the role of climate in regulating Earth's biosphere. His work brought about the scientific discipline termed *physical climatology*, which, in contrast to *empirical climatology*, is based on the first principles quantitative analysis. Budyko strongly emphasized the importance of the Earth's surface and atmosphere thermal balances, which are at the heart of all scientific problems related to climate change. His approach allowed fast and successful development of the mathematical tools for analysis of recent climate changes, interpretation of past ones, and prediction of future changes.

Budyko was born January 21, 1920, in Gomel, a small Belorussian town (then in the Soviet Union), and before World War II moved to Leningrad (now St. Petersburg), Russia, to pursue his higher education. He received his Master of Science degree in Hydro-Aero-Dynamics in 1942 from the Division of Physics of the Leningrad Polytechnic Institute. Immediately following, he was employed as a scientific researcher in the Voeikov Main Geophysical Observatory (MGO), the oldest Russian meteorological research institution, which during World War II was evacuated from Leningrad to Sverdlovsk (near the Ural Mountains). Within two years (in 1944), Budyko earned his Candidate Degree (Ph.D.), and, in 1951, he defended his Doctoral Degree, the highest scientific degree in Russia.

In 1954, he became a head of the MGO, where he remained for the following 21 years. He was the youngest MGO head since its founding in 1849. His fast ascent in the scientific community gained Budyko a high level of scientific recognition both within and outside Russia, and inspired a new generation of scientists in seeking careers in climate change and radiative transfer.

Among Budyko's scientific achievements is the development of a procedure to calculate the components of the thermal balance of the Earth's surface. His method allowed for calculating the components of the heat balance from measurements of the lapse rate of atmospheric temperature and humidity of the surface layer of the atmosphere. Using these techniques, Budyko compiled the first maps of the annual thermal balance components in the southern area of the European part of Soviet Union, determined the latitudinal distribution of the thermal and moisture balance components of land and ocean surfaces for the Northern Hemisphere, and established the factors governing the characteristics of this distribution.

In his follow-up research, Budyko developed a method for calculating the radiation balance of land from data on the water balance. Based on this research, he introduced the "Budyko aridity index," which gathers and analyzes information on hydrothermal regimes of a particular Earth region. In 1956, with other Russian scientists, Budyko developed a "periodic law of climatic zonality," that the same values of the aridity index can be met in different geographical zones. For his work on thermal balance, Budyko was awarded the Lenin National Prize in 1958, the first among climate scientists.

In 1961, Budyko recognized anthropogenic (human-induced) global warming. Primarily through analysis and interpretation of observational data, Budyko developed a quantitative relationship between surface temperature and incoming solar radiation, using it to formulate the energy-balance global change model, one of the earliest developed. Using it, he deduced that the Earth's climate might be sensitive to small disturbances in the radiative balance.

In 1964, Budyko became a Corresponding Member of the Academy of Sciences of the Soviet Union. In 1970, Budyko became interested in understanding interactions among the climate system, biosphere, and human agricultural activities. He and his colleagues carried out theoretical and experimental investigations to explore the dependence of the photosynthetic productivity of agricultural crops on the principal meteorological factors. Also, he was interested in how to calculate the thermal balance of a person's body when adjusting to the thermal conditions in different climates. For this research, Budyko received the Professor Lithke Gold Medal of the Russian Geographical Society in 1972.

GLOBAL WARMING, SNOWBALL EARTH, AND NUCLEAR WINTER

Beginning in 1972, Budyko played an important role in studies of the greenhouse effect under the auspices of Working Group VIII of the U.S.-Soviet Union Bilateral Agreement on the Protection of the Environment. He believed that, in spite of the then observed cooling, an increase in greenhouse gases would bring the climate system back to the warming tendency because, as he showed, the formation of the Earth's ecosystems is strongly connected to periodic changes in atmospheric concentrations of oxygen and carbon dioxide. Based on this, he pushed for the development of three important concepts: global warming, snowball earth, and nuclear winter. The latter played an important role in understanding of global consequences from possible nuclear war and helped in accelerating the process of ending the Cold War.

In 1975, Budyko moved his research to the State Hydrological Institute (Leningrad), where he created a new department for Investigating Climatic Changes and the Hydrologic Cycle of the Atmosphere. In 1980, he took the lead in applying the paleoanalog approach to project future anthropogenic global warming. Thus, he introduced the possibility of estimating climate sensitivity via reconstruction of greenhouse gas radiative forcing and retrieving past global temperature changes for the same periods.

In 1987, Budyko was awarded the International Meteorological Organization (IMO) Prize by the World Meteorological Organization. In 1989, the Russian Academy of Sciences awarded him the A.P. Vinogradov Prize, and, in 1991, he received a Diploma of the First Degree from the Russian Knowledge Society. In 1992 Budyko become an Academician of the Russian Academy of Sciences and, in 1995, he won its A. Grigoryev Prize. In 1994, Budyko received the Professor R. Horton Medal of the American Geophysical Union for his contribution to the study of the hydrologic cycle, and, in 1998, he was awarded the prestigious Blue Planet Prize.

In 1998, Budyko became a scientific leader of the Research Center for Interdisciplinary Environmental Cooperation (INENCO) of the Russian Academy of

Sciences, which was established to promote basic scientific research in the fields of environmental protection, rational exploitation of natural resources, and relevant ecological issues. Mikhail Ivanovich Budyko died in 2001, at the age of 81, in St. Petersburg, Russia.

Bulgaria

BULGARIA IS A country in southeastern Europe that lies between Romania and Turkey and has a population of about 7.3 million. Projections warn of its significant vulnerability to climate change. It participated in the U.S. Department of Energy's Country Studies Program Department, creating an inventory of greenhouse emissions and potential mitigation. A defining event took place in 1997; a global change conference integrated efforts of scholars across a wide range of disciplines and established the Scientific Coordination Center for Global Change (SCCGC) in the Bulgarian Academy of Sciences. The conference summarized climate change research about emissions, climate variability and change, hydrology, agriculture, water resources, economics, demographics, data acquisition, and policy-making.

Severe water rationing in the capital of Sofia, due to mismanagement and drought, triggered a serious water conflict 1994–95. The SCCGC initiated a project studying drought from 1982 to 1994 as an analogue of future climate change. This seminal work explored impacts on environmental elements, society, economy, and human health, including computer models of climate scenarios and recommendations to policy-makers. Introducing drought- resistant crops is imperative, as well as increasing the altitude of artificial forests. Studies demonstrate future seasonal change in watersheds, and pollution during low summer flows.

A 1997–98 public opinion survey compared concerns and knowledge about climate change and emissions in the United States, Bulgaria, and Japan; such issues did not rank high among Bulgarians. A recession after 1989 led to a reduction of carbon dioxide emitted by energy and industry, the latter now surpassed by transportation, with a growing number of old and inefficient vehicles. Another nuclear power plant and a gas network for heating are in the works. Energy efficiency is improving by changing windows and adding insulation, although growing affluence results in larger homes and air conditioner usage.

The media in Bulgaria have not given persistent attention to climate change. Extreme events such as floods, droughts, and storms are treated as sensational, but quickly forgotten. Communication from scientists does not seem to effectively reach policymakers. Agriculture and tourism have come to the forefront of the economy, and increase the country's vulnerability to climate change. Agriculture was marked by intensive irrigation until 1989 (10 percent of nation's area was irrigated), but recurring droughts, such as in 2007, threaten harvests.

Warmer winters cause losses for ski resorts, while droughts lead to water scarcity in Black Sea resorts and inland. Floods occurred repeatedly in 2005 and 2007, amid prolonged droughts and extensive forest fires. Landslides were triggered in traditionally vulnerable areas, and in newly-constructed ski runs. According to the Intergovernmental Panel on Climate Change's 4th assessment, Bulgaria, like much of the Mediterranean, will face increasingly severe summer droughts in future decades.

Burkina Faso

BURKINA FASO IS a landlocked country in West Africa with a population of about 14.3 million. The terrain is mostly savanna and relatively flat. Three major river systems cut through Burkina Faso: the Mouhoun, the Nakembé, and Nazinon; only the Mouhoun, along with the smaller Comoé, flows year-round. Access to clean water has been stressed in recent years, leading to tension between communities, especially in the north of the country. Only 18 percent of the land is arable, and recent decades have brought recurring droughts and increased desertification, along with overgrazing and soil depletion.

Current climate models indicate that Burkina Faso, like much of West Africa, is drying up and flooding at the same time. After a decades-long dry spell punctuated by severe droughts, the country is now moving into a new cycle, where hot, dry periods are broken by heavy, unpredictable rains. This has led to catastrophic flooding, most recently in August 2007, when at least 6,000 Burkinabe were left homeless after two days of heavy rains. This unpredictability is expected to put pressure on crops and livestock, and lead to increased incidence of disease among animals and humans.

The Burkinabe government has taken several steps to mitigate and cope with climate change. Recently, they have changed the laws in such a way as to grant farmers ownership of the trees on their own property. As a result, fewer trees are being cut down. They have also joined in a regional initiative to enhance biodiversity by encouraging farmers to use more sustainable farming methods.

Burkina Faso is not a significant contributor to carbon emissions. CO_2 emissions produced by the Burkinabe dropped 30 percent 1990–98, with annual emissions at just 0.1 thousand metric tons per capita. Of this, the burning of liquid fuels produced 98 percent. The country is a signatory to a number of international environmental conventions, including agreements on biodiversity, ozone protection, wetlands protection, endangered species protection, and the Kyoto protocol; however, the government has not formally ratified any of these conventions.

Burundi

BURUNDI IS A landlocked country in Central Africa, south of Rwanda. It is home to about 8.4 million people, most of whom live in abject poverty; annual income is about $100 and life expectancy is just 45 years. About 36 percent of the land is arable. Natural disasters include droughts, alternating with rains, often causing landslides in the mountainous interior of the country. Overgrazing has led to soil depletion, while clear-cutting of the forest has caused erosion and loss of habitat.

Most climate experts believe that Burundi will be one of the countries hardest hit by global warming, as temperatures rise and stress an already weakened population. Burundi lies on the eastern shore of Lake Tanganyika, which contains about 18 percent of the world's liquid fresh water and is vital to the survival of millions of people across Central Africa. In the past four years, the lake has receded about 50 ft. (15.2 m.) from the shore as feeder rivers have slowed.

Aside from being a key source of drinking water, Lake Tanganyika is crucial to the region's food supply: fish from this lake supply 25–40 percent of the region's protein needs. However, fish yields have been dropping as a direct result of global warming. A 2003 study found a 0.6 degree C temperature rise along the lake, combined with a decrease in local wind speeds. This has decreased circulation within the lake, negatively impacting the its unique ecosystem. This is likely to grow worse, with most estimates indicating a temperature rise of 2.7 degrees F (1.5 degrees C) in coming years. Farmers throughout the country note that weather has grown more erratic in recent years, resulting in diminished crop yields. Some models estimate that crops could decline by as much as 50 percent by 2020. In a region already plagued by civil and cross-border wars, there are fears of increased violence over resources as food and water supplies diminish.

Burundi is not a significant contributor to carbon emissions, with total CO_2 emissions in 1993 at 231,000 metric tons. This was a 19 percent increase over 1990 totals, but still considerably lower than regional averages. An estimated 92 percent of their emissions come from liquid fuel sources, and only 8 percent from solid fuel. The country is a signatory to a number of international conventions on climate change, including biodiversity protection, desertification control, protection of the ozone layer and endangered species, and the Kyoto Protocol.

Bush (George H.W.) Administration

THE ADMINISTRATION OF President George H.W. Bush has received mixed reviews from historians and environmentalists for its handling of the global warming issue. Bush, the 41st president of the United States, came into office in 1988, having promised during the campaign that he would be the "environmental president." Over the next four years, Bush won praise from the environmental community for pushing needed revisions of the Clean Air Act through Congress. However, Bush was also criticized for his handling of several environmental issues, in particular, wetlands conservation, the *Exxon Valdez* oil spill, and global warming. Faced with mounting scientific evidence for human-caused global warming and calls from European allies to take strong steps to reduce carbon emissions, Bush warned against the likely economic impact of mandatory reduction programs, and called for further study of the nature and extent of global climate change.

Bush's cautious position on global warming surprised many, because his campaign rhetoric had appeared to signal an intention to take a more aggressive stance. In one of his most famous campaign speeches, Bush stood in front of Boston Harbor and contrasted his environmental credentials with those of his opponent, Massachusetts Governor Michael Dukakis. On the subject of climate change, Bush declared:

> those who think we are powerless to do anything about the greenhouse effect are forgetting about the White House effect. As president, I intend to do something about it.

Specifically, Bush pledged to host an international conference on global warming within a year of taking office. Bush's apparent resolve was remarkable, in particular because his predecessor in the White House, Ronald Reagan, had been reluctant, until his tenure as president was nearly over, even to acknowledge global warming as a potential problem.

As president, however, Bush charted a significantly less-ambitious path on climate change than environmentalists had hoped. The United States did not host a global warming conference in 1988, despite proposals put forth by Environmental Protection Agency Administrator William Reilly. As calls mounted for Bush to keep his campaign promises on global warming, White House officials went on the offensive against critics of the president. Spokesman Marlon Fitzwater repeatedly warned of potentially drastic consequences for the U.S. economy posed by proposed solutions to global warming, such as a carbon tax or restrictions on coal-fired power plants. Fitzwater's comments reflected a growing tendency within the Bush administration to see the economic costs of an aggressive stance on global warming as too high for comfort.

Chief of Staff John H. Sununu, a noted mechanical engineer, also questioned the veracity of global warming science, in particular the ability of computer models to predict long-term changes in climate. In a scandal that outraged many in Congress, including Senator Al Gore of Tennessee, a junior official at the White

House Office of Management and Budget secretly edited the congressional testimony of National Air and Space Administration (NASA) Institute of Space Studies Director James Hansen, to weaken Hansen's conclusion that global warming was accelerating. Most significantly, the White House initially eschewed international efforts to develop a comprehensive strategy to fight climate change under the auspices of the United Nations. This last development, though less sensational than the editing of Hansen's testimony (an incident from which the Bush Administration immediately distanced itself), portended that little action on global warming would be taken while Bush was in office.

A steady stream of criticism ultimately moved the Bush Administration to take a more active role in international efforts to study and address global warming, but the president still fell short of satisfying the demands of most environmentalists in the United States and abroad. The White House hosted a conference on global warming in Virginia in 1990, and agreed to take part in international negotiations on a climate change treaty, starting with talks in Geneva in 1989. These negotiations ultimately produced the Framework Convention on Climate Change, signed by 154 nations at the United Nations Conference on Environment and Development, also known as the Earth Summit, at Rio de Janeiro in 1992.

The Framework Convention was a step forward in efforts to combat global warming, but many blamed Bush for the treaty's relative toothlessness. The Bush Administration engaged in Cold War–style brinkmanship with the rest of the international community over the Framework Convention, a strategy that epitomized all that environmentalists found most frustrating about the Bush presidency. Though the Earth Summit was to be attended by over 150 heads of state, including those from each of the world's major industrialized nations, Bush claimed that the United States would not attend unless its demands were met. Well aware that the conference would be all but meaningless without the participation of the United States, treaty negotiators acquiesced to many of Bush's demands. At the insistence of the Bush Administration, the Framework Convention did not require specific reductions in carbon emissions from any nation, but, rather, directed each nation to reduce its emissions in such a manner, and by such an amount, as suited its own circumstances.

This lack of mandatory cuts in carbon emissions was a severe disappointment to many of the parties involved in producing the treaty. However, the convention also mandated annual Conferences of the Parties, in order to continually update efforts to address global warming. The Kyoto Protocol, which established legally-binding emissions reduction targets for the first time, was the result of the 1997 Conference of the Parties in Kyoto, Japan.

Though more engaged with the issue of global warming than his predecessor in the White House, George H.W. Bush proved a disappointment to many environmentalists. However, Bush's actions against global warming nonetheless paid important dividends. Bush's leadership on revisions to the Clean Air Act indirectly aided in the fight against global warming, by making it harder to build coal-fired power plants. Most importantly, the Framework Convention, though weaker than many had hoped, created a framework for future negotiations through which nations could work together to address global warming. The Kyoto Protocol would not have happened without the foundation of the Framework Convention, and future international efforts may also rely on channels laid down through this treaty, which Bush helped to bring to fruition.

Bush (George W.) Administration

GEORGE WALKER BUSH (b. July 6, 1946) was the 43rd president of the United States, serving two terms between January 2001 and January 2009, with the first inauguration taking place on January 20, 2001. During his presidency, Bush would be both sharply criticized and highly praised for his stance on environmental issues and, over the years, would be seen to accept global warming verbally while politically denying it. Nevertheless, Bush would eventually come to support research into alternative energy means, if not for environmental preservation, for national security measures.

In his first year in office, Bush retreated from the Kyoto Protocol, which had been established as a way to limit emissions of greenhouse gases from global, economically-leading nations. Bush chose not to support the Kyoto Protocol despite that fact that the United States Senate had voted 95–0 in favor.

REJECTING THE PROTOCOL

Bush gave several reasons for choosing not to support the Protocol. First, that it would have been traumatically expensive for the nation's economy to follow the Protocol, because only one fifth of the world's population was to be held accountable for it. Second, he nations of China and India had not yet signed the Protocol. Third, Bush didn't feel there was enough scientific evidence for human-caused global warming. In the year 2005, Department of State documents that were revealed that showed a strong influence of the ExxonMobil Corporation on domestic environmental policy. Additionally, the Exxon-led anti-Kyoto Protocol group Global Climate Coalition (GCC) was noted for influencing President Bush's decision to reject the Kyoto Protocol.

The year after Bush retreated from the Kyoto Protocol, the Environmental Protection Agency (EPA—an agency of the United States federal government) issued a Climate Action Report stating that recent decades' global warming was, in fact, most likely due to human impact. Despite this report, Bush continued to doubt the science behind global warming and claimed that the EPA's report was not to be trusted.

Next, in the year 2002, Bush attempted to weaken the Clean Air Act of 1963 (which was amended in 1967, 1970, 1977, and 1990) with his Clear Skies Act (eventually presented to, and rejected by, the Congress as the Clear Skies Act of 2003). The Clear Skies Act proposed to raise the caps on mercury, nitrogen oxide, and sulfur dioxide emissions by large amounts, to postpone pollution standard enforcement until the year 2015, and to permit companies to modernize using including non-compliant equipment.

Several people in high positions in the U.S. government have publicly denounced Bush's repeated denial of global warming and his consistent dismissal of the scientific evidence. For example, James Hansen, the Director of the Goddard Institute at the National Aeronautics and Space Administration (NASA), in the year 2004, accused Bush and his administration of hiding the dangers of greenhouse gases from public awareness. Joseph Romm, formerly an official at the Department of Energy, accused Bush and his administration of consistently denying and delaying steps that could reduce carbon dioxide emissions and global warming.

Another federal employee, Rick Piltz, of the U.S. Climate Change Science Program co-wrote climate reports. He, along with other employees, claimed that climate reports were repeatedly edited by Bush administration officials to lessen the appearance of a global warming threat. Piltz gave the example of a review draft that was returned from the White House with handwritten edits by Phil Cooney, chief of staff of the Council on Environmental Quality and former lobbyist for the American Petroleum Institute. In the report cited by Piltz, a statement about global warming being enhanced by energy production was crossed out by Cooney. In another section, the review draft warned of rapid changes in the Earth; Cooney changed this line to read "may be undergoing change". Piltz claims these examples are only two of the many unscientific, but political, changes that Cooney made to the review draft.

Despite Bush's repeated denial of global warming and the need for political action, individuals in the United States recognized the value of the Kyoto Protocol and its suggestions and chose to follow the regulations, anyway. A 2005 article from BBC News of the United Kingdom, cited nine American states, 187 mayors (not necessarily only from those nine states), and several American-based international companies that signed up to heed Kyoto-based recommendations.

During his two terms in office, Bush eventually seemed to accept global warming as a fact and the necessity of public policy supporting alternative strategies. On August 8, 2005 Bush signed the Energy Policy Act of 2005, passed by Congress on July 29 of

An oil pipeline in Alaska. The Bush administration sought to open the Arctic National Wildlife Refuge to oil drilling.

that year. The Energy Policy Act supports alternative energy production and research, with tax incentives and loan guarantees.

Despite his repeated attempts to weaken regulations for environmental protection, not all Bush's actions were detrimental to the environment. For example, in 2006 Bush declared that the 84 million acres comprising the Northwestern Hawaiian Islands a national monument. This marine habitat holds 7,000 species of marine animals, including fish and birds. Out of these 7,000 species, greater than 1,500 species are unique to Hawaii. The area of land mass protected totals 139,000 sq. mi. (223,699 sq. km.).

Additionally, although the decision to do so was not related to global warming, but rather to national security and the relief from our dependence on foreign oil, Bush pledged in his 2007 State of the Union Address to reduce the consumption of fossil fuels and to expand research into alternative energy sources.

In preceding years, the Bush administration tried several times to open oil drilling in the 19-million acre Arctic National Wildlife Refuge (ANWR) in Alaska, an area that ANWR supporters call the "last untouched wilderness" of the United States. There is a 2,000-acre plot where the proposed drilling would take place. Although the House of Representatives has repeatedly approved the bill, the Senate has repeatedly blocked its passage.

Under President Bush, the position of Secretary of Energy was held by Spencer Abraham (2001–05) and later by Samuel Bodman. Administrators for the EPA were Christine Todd Whitman (2001–03), Michael Leavitt (2003–05), and later, Stephen L. Johnson.

California

IN SEPTEMBER 2006, California's governor signed a landmark piece of legislation intended to reduce the state's vulnerability to global warming and climate changes. Arnold Schwarzenegger intended to take California back to 1990 levels of carbon production. California has long been considered a trailblazer for the nation. The first tuition-free public colleges and universities were in California, as were the first significant tax revolts. California has the world's fifth or sixth largest economy, with 36 million citizens.

The 1960s, which witnessed such social and economic changes in California, were also nearly the peak of California smog. Geographically, the state is divided into a cool and wet northern area and a hot and dry southern one. The southern part, especially around Los Angeles, became home to the nation's worst smog in the 1970s. There were times when athletes, playing on sunny California shores, could not see the San Bernardino Mountains because of the air pollution. With its intricate network of freeways, some of them boasting 16 lanes of traffic, the Golden State had a new, foggy horizon, and some people wondered if it was still the last refuge for Americans wanting a freer way of life.

Southern California's troubles with smog and air pollution improved considerably during the 1980s with greater use of unleaded gasoline and prohibitions against carbon emissions, but the state was simultaneously beginning another social change. Millions of immigrants, some legal and some illegal, were crossing the Mexican border with California. The state in 1962 had surpassed New York as the most populous of the 50 American states. Around 1999 California population reached 34 million, and it was considered the first true minority-majority state, meaning that people of Anglo-Saxon descent had become a social minority.

The fact that California had more people than any other state, as well as more cars, led to increased emissions from automobiles. Though the smog and air pollution had been contained, there were an increasing number of natural disasters that alarmed Californians. The 1994 Northridge Earthquake was followed by mudslides; the summers of 1995 and 1997 brought serious forest fires; and autumn 2007 saw one of the most destructive firestorms of all, carried by the notorious Santa Ana Winds. After Hurricane Katrina hit New Orleans, Californians were acutely aware of the dangers posed to their coastal cities. A comparable typhoon or hurricane, both of which are rare on America's West Coast, would have wreaked extensive damage. In the summer of 2006, Governor Schwarzenegger pushed for a new law to require California and its people to reduce carbon emissions.

The timing was fortuitous. Former Vice President Al Gore's documentary, *An Inconvenient Truth,* debuted at the box office in the summer of 2006, making the painful facts about global warming more apparent than ever. In the wake of Hurricane Katrina, citizens and legislators alike felt a pressing need to address the problems of global warming, and on September 26, 2006, Schwarzenegger signed Assembly Bill No. 32, which was designed to reduce carbon emissions to 1990 levels by 2020, set mandatory caps in 2012, and reduce emissions to 80 percent of 1990 levels by the year 2050. All these were to be implemented by the California Air Resources Board (CARB).

Critics emerged from the right and the left. Conservatives lamented the amount of power given to the state regulation board, and declared that global warming was a scientific hoax, put over on an unsuspecting population, while liberals (at least with respect to an environmental point of view) said that the levels of 1990 were anything but healthy: that it was insufficient to use as a benchmark. The bill went into law just the same, marking the boldest step implemented by a single state to that date.

California Institute of Technology

THE CALIFORNIA INSTITUTE of Technology, also known as CalTech, or simply Tech, is a private university and research institute located in Pasadena, California. Established in 1891, it offers graduate and undergraduate instruction, and research, in pure and applied science and engineering. CalTech maintains a strong emphasis on the natural sciences and engineering. CalTech also operates and manages the National Aeronautics and Space Administration's (NASA's) Jet Propulsion Laboratory (JPL), an autonomous spaceflight complex that oversees the design and operation of most of NASA's space probes. Staffed by a faculty of some 1,000 distinguished and creative scientists, CalTech is considered one of the world's premier scientific research centers.

The Division of Geological and Planetary Sciences offers a number of undergraduate and graduate programs in geophysics, planetary science, and environmental science and engineering. They also offer research programs that focus on global issues such as climate change, environmental problems, glacier movement, evolution of atmospheres, and global change. The Environmental Science and Engineering (ESE) Program offers a coherent program of education and research spanning global climate studies, engineering solutions, and environmental problems, such as toxic waste remediation. Scientists from the Division of Chemistry and Chemical Engineering, Division of Engineering and Applied Sciences, and Division of Geological and Planetary Sciences collaborate on many topics involving the environment, atmosphere, hydrosphere, biosphere, and lithosphere.

Professor of Planetary Science Yuk L. Yung has authored two books and more than 100 scientific papers. His research focuses on atmospheric chemistry and global change. Dr. Yung and his team have developed a two-dimensional model description of chemistry interacting with global-scale dynamical fields for studying the terrestrial atmosphere and other planetary atmospheres. Such a model is necessary for analysis of global data sets. They are also developing a three-dimensional chemical tracer model.

An effort has been initiated between CalTech and JPL to utilize global data sets for the study of global environmental change. John Seinfeld, the Louis E. Nohl Professor and professor of Chemical Engineering, has performed extensive research in atmospheric chemistry, physics, and aerosols. Professor Seinfeld's research has made a major effort in atmospheric modeling aimed at urban and regional air pollution and global climate.

CalTech also offers a series of seminars known as Caltech Public Events. They offer an event sponsored by the Engineering and Applied Science Division called Global Warming: Science and Solutions.

This free event is a one-hour school day performance offered to children grades 3–12 to improve their understanding of global warming.

Cambodia

THIS SOUTHEAST ASIAN country was a French colony until it gained independence in 1953. The country was devastated by war from 1970–75 and 1978–91, leading to the destruction of much of the country's infrastructure. It has a land area of 69,898 sq. mi. (181,035 sq. km.), a population of 13,971,000 (2006 est.), and a population density of 201 people per sq. mi. (78 people per sq. km.). Altogether, 13 percent of the land in the country is used for arable purposes, with a further 11 percent used for meadows and pasture. Officially, about 74 percent of the country is forested, but there has been massive deforestation since the 1980s, in spite of government claims to have limited the problem. This, in turn, has led to soil erosion, made worse by flooding of some areas. In fact, the flouting of environmental laws by government officials and businesses has long been a major problem in the country.

A poor and undeveloped country, Cambodia has little electricity production, with 62.1 percent generated from fossil fuels and 37.8 percent from hydropower. Cambodia's per capita carbon dioxide emissions have been extremely low, with negligible rates recorded, and 0.04 metric tons per person generated in 2003. Cambodia ranks 205th in the world's CO_2, emissions, only slightly less than Mali, and a rate only higher than Burundi, the Democratic Republic of the Congo, Afghanistan, Chad, and Somalia. Of Cambodia's carbon dioxide emissions, 77 percent comes from liquid fuels, which is due to cars or buses. The remaining 23 percent come from cement manufacturing. There is also a reasonably high per capita emission of carbon monoxide.

With much of Cambodia low-lying, parts of the country have regularly faced problems from floods, and with the rising water levels, the floods have become more frequent. Flooding could increase mosquito-borne diseases such as malaria and dengue fever. Most of the country's fishing industry is located in the Tonlé Sap Lake in central Cambodia and the Mekong River, and thus is less likely to face problems related to the warming of the Indian Ocean, with overexploitation causing a far bigger problem. The Cambodian government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention in 2001. It accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on August 22, 2002, which took effect on February 16, 2005.

Cameroon

LOCATED IN CENTRAL Africa, the Republic of Cameroon has a land area of 183,568 sq. mi. (475,442 sq. km.), a population of 17,795,000 (July 2005 est.), and a population density of 97 people per sq. mi. (37 people per sq. km.). With 80 percent of the population involved in agriculture, arable land accounts for 13 percent of the country. A further 4 percent is used for meadows and pasture. Fifty-four percent of the land is covered in forest. The forestry industry specializes in tropical hardwoods such as mahogany, ebony, and sapele.

With an underdeveloped economy, Cameroon has a low rate of carbon dioxide emissions, with 0.1 metric tons per capita in 1990, rising to 0.23 metric tons in 2003. About 87 percent of Cameroon's carbon dioxide emissions come from the use of liquid fuels, 4 percent from solid fuels, and 13 percent from the manufacture of cement. Most of these carbon dioxide emissions are generated by transportation (61 percent), with 21 percent from residential use. The public transport network in the country is not well-developed, although there is an efficient train service connecting the northern and southern parts of the country.

The Cameroon government of Paul Biya ratified the Vienna Convention in 1989, and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. The government accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on August 28, 2002. It took effect on February 16, 2005.

Canada

CANADA IS OFTEN seen as one of the coldest places in the world. It is the second largest country in the world (after Russia), located at the top of the North American continent. The United States and Canada share the world's longest unprotected border (known as the 49th parallel of north latitude). In December 2007, Canada's population reached 33,091,228, most of whom live in the southern parts of the country, mainly near the St. Lawrence River and in the Great Lakes regions. The most well-known Canadian cities are Montreal, Toronto, Vancouver, and the nation's capital, Ottawa. Many tourists and visitors visit Canada's natural landscapes and rivers, rather than its cities and museums.

There are 10 provinces and three territories, including the newly named Nunavut province. Canada is surrounded by three oceans: the Pacific, Atlantic and the Arctic. The magnetic North Pole is located in Canada. A member of the Commonwealth and an active member of the G7/G8 summits, Canada is also one of four regions to be part of the Inuit Circumpolar Conference (ICC), along with Greenland (Denmark), Alaska (the United States), and Russia. Canada has been the site of international conferences and agreements pertaining to global warming, including the Montreal Protocol.

The average temperature in Canada varies according to season and location. Winters are long and snowy in almost all Canadian regions, usually lasting from November until April. In Canada's capital Ottawa, the yearly average temperature is 43 degrees F (6.3 degrees C), although in winter weather can get as low as 6 degrees F (minus 14 degrees C).

THE KYOTO PROTOCOL IN CANADA

Canada signed the Kyoto Protocol on April 29, 1998, and it was ratified by the Canadian government on December 17, 2002. However, when the Conservative Party of Canada won the 2006 election (after four terms of the Liberal Party), the leadership of Steven Harper realized that the Kyoto targets had not been met. Canada was, in fact, far from its objectives. Between 1993 and 2005, greenhouse gas emissions in Canada rose about 25 percent higher than under the previous Liberal-led government.

As a consequence, the new Canadian government recognized in 2006 that the goal of the Kyoto commitments was not achievable until 2050 (missing the initial deadline of 2012). In 2007, the federal minister of environment, Rona Ambrose, explained that promises made by the previous government (the Liberal Party of Canada) were impossible to meet, and asked for a realistic compromise that would not disrupt the Canadian economy: "In the real world, the emissions reductions needed in Canada to achieve the Kyoto target are not technically feasible in that time frame," said Conservative minister Ambrose, adding: "That is why we need new targets and a new Kyoto framework."

In 2007, John Baird was named as the new Conservative environment minister by Steven Harper, although no changes in policy were decided in regard to the Kyoto target. The ministery at least acknowledges the existence of climate change as an important issue for Canadians.

In December 2007, Baird made a statement after the United Nations Climate Change Conference in Bali (Indonesia): "Climate change is a global problem requiring global solutions, and we've seen that with today's agreement. We have a track record of leadership on the environment at the G8, APEC, the Commonwealth and the United Nations." In early 2008, Baird also made a commitment in order to take action to help developing countries fight climate change.

As a political response, many provincial governments (equivalent to a state government in the United States), such as Quebec and British Columbia, declared they would independently strive to reach the initial target. Moreover, the establishment of a carbon exchange in Montreal (known as the Montreal Climate Exchange) has existed since 2003, including a special agreement with the Chicago Climate Exchange (CCX).

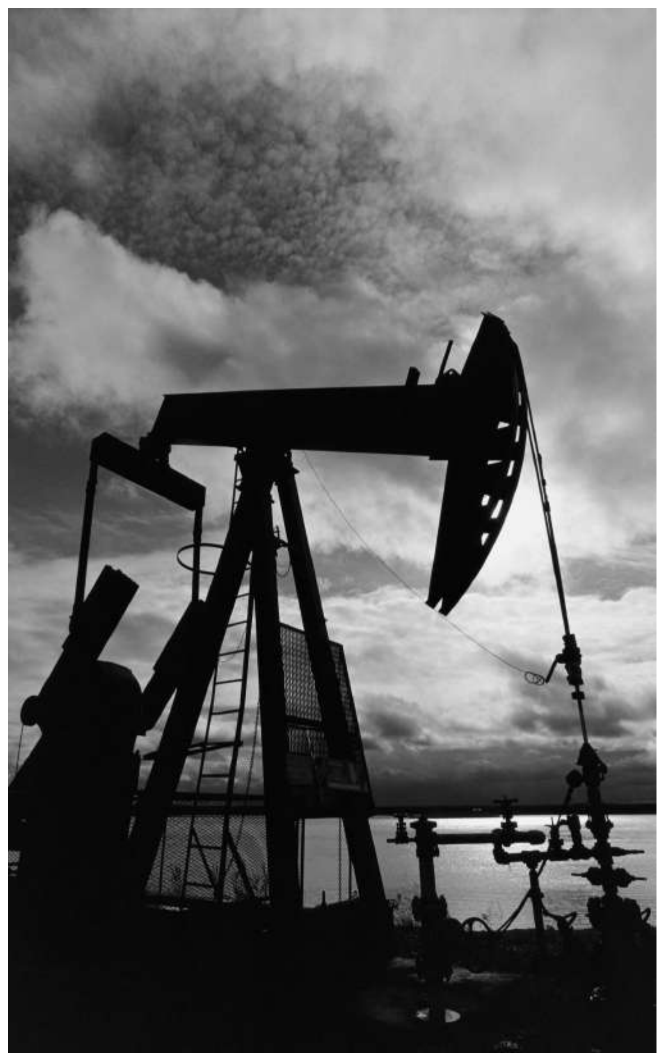
In 2008, polls confirmed that a majority of Canadians wanted their federal government to act in the spirit of Kyoto, although they do not always have a clear idea of the terms of the agreement.

Things might change in the future, as the former Liberal environment minister before 2006, Stéphane Dion, was leading the Liberal Party in 2008, the second-most popular party in Canada. An experienced politician, Dion cultivates an image of himself as a "Canadian Al Gore," dedicated to environment; he even named his dog "Kyoto."

According to the numbers from the Carbon Dioxide Information Analysis Center (at Oak Ridge National Laboratory, Tennessee), Canada produced 133.9 millions of tons of CO_2 in 1997, 4.42 tons per person. Comparative statistics show that countries, such as Japan and Russia, produce more CO_2 overall, since their population is higher in number, but their average per capita is less than Canada. This perhaps because Canadians live in very cold regions and enjoy a high standard of living. The Organisation for Economic Cooperation and Development (OECD) stated that the CO_2 emissions in Canada were 17.49 per capita in 2003. Only two countries, the United States and Luxembourg, had a higher ratio.

ENERGY IN CANADA

Since 2004, Canada has been led by minority governments, which means a more difficult position in terms of negotiating with other parties and the private sector. The protection of the environment has to rely on consensus. Each new initiative is often seen as "too little, too late," by environmental groups and leaders. On April 5, 2005, the government of



An oil derrick in operation in Canada's Northwest Territories. Oil has been drilled in Canada since the 1850s.

Peyto Lake, in Banff National Park, Alberta, is fed by the meltwaters of Peyto Glacier. Glacial silt floats on the lake, giving the water a bright turquoise color. The Canadian Rockies that nestle the lake are widely visited by tourists.

Canada and the automotive industry reached a landmark voluntary agreement to reduce annual greenhouse gas (GHG) emissions from Canada's vehicle fleet by 5.3 megatonnes (Mt) in 2010, according to the Joint Government-Industry GHG MOU Committee, October 2007.

According to the Ministry of Energy of the Government of Ontario, Canada produces a third of the world's uranium. However, Canadians are not always in favor of nuclear power, which remains controversial, even among environmentalists. The province of Quebec uses only one nuclear plant and relies mainly on hydropower (Hydro-Quebec), while in the neighboring province of Ontario, nuclear power provides half of the power. Also located in Ontario, the Nanticoke coal-fired power plant is the largest station of its type in North America.

The Alberta oil sand deposits became an issue in the 1990s. Production costs are very expensive and oil can only be produced at a profit when a barrel is worth more than $60, which has been the case for more than a decade. Despite the controversy over energy resources, Alberta and Saskatchewan have become increasingly populated, requiring more energy supplies, and there are more interprovincial migrations toward these two provinces.

CANADA AND THE UNITED STATES

Issues and diverging conclusions regarding environmental problems and pollution have often caused diplomatic conflicts between Canada and the United States, especially in the early 1980s. The Canadian government stated that air pollution in the Great Lakes region was mainly caused by U.S. industries, and the action of winds, which brought pollution from the south to the north of the border.

Moreover, three short Canadian documentaries took the position that air pollution and acid rain occurring in central Canada were partly caused by U.S. factories located near the Canadian border. These three films were officially labeled as political propaganda by the U.S. State Department.

These film essays, bringing environmental issues to light, were: *Acid From Heaven* (1982) by George Mully; *Acid Rain: Requiem or Recovery?* (1982) by Seaton Findlay; and *If You Love This Planet* (1982) by Terri Nash. The latter was about nuclear hazards in the United States. The U.S. government required U.S. theatres or movie rental stores showing or loaning any of these controversial films to report the usage to the State Department.

A PARADISE LOST: THE CANADIAN ARCTIC

Since most Canadians have not visited the Arctic region, they only know the area from images seen on television and in the media. As climate appears to be warming up, the Canadian arctic region is becoming more attractive for neighbors like Russia, the United States, and Scandinavian countries, which see a possible road for transportation of commerce. The Canadian government reaffirmed its right to that region, but it is becoming more contested by countries that would like to change the Canadian route into an international zone, as has always been the case for Antarctica. Most Canadians do not agree with that international suggestion.

Davis Guggenheim's film, *An Inconvenient Truth,* (starring Al Gore) was a huge success in Canada. It was presented in English and French in many Canadian schools, and was sometimes screened more than once. Furthermore, the DVD of the film *An Inconvenient Truth* was often lent for free by video stores in Quebec, in order to make the film's message more accessible.

Other films about climate change had similar success, such as the documentary *The Arctic Mission* (2004), coproduced by the National Film Board of Canada (NFB). An important Canadian documentary film, titled *The Refugees of the Blue Planet* (2005), and directed by Hélène Choquette and Jean-Philippe Duval, showed the environmental refugees who left their home because of the rising water levels in Brazil, the Maldives, and even in Canada. Another poetic film essay, directed by Pierre Perrault and titled *Cornouailles* (1994), explored the tundra and musk-ox in the Arctic region near the Elsmere Islands, in the north of Canada.

Debates about climate change and global warming are still ongoing in Canada. A few Canadian universities have programs in environmental education, such as the Université du Québec à Montréal, Université Laval in Quebec City, and also in Yellowknife (Yukon).

Canadian Association for Renewable Energies

INCORPORATED IN 1998, the Canadian Association for Renewable Energies is an organization dedicated to the promotion of feasible applications of renewable energy in Canada. The objectives of the association are to promote greater awareness of the benefits of renewable energies to Canada's economy, environment, and society; advance the adoption of renewable energies; and undertake research that will optimize renewable energy technologies. Membership is open to institutions, corporations, and individuals.

At the peak of the association's activity, it provided a range of services to members, including information dissemination, access to information requests, domain hosting and email services, public relations services, and participation on expert advisory committees. Funding for the association is private, primarily from contracts and membership fees. One of the first projects of the association was an electronic daily news service, TRENDS in Renewable Energies. This service later partnered with the International Solar Energy Society as part of Refocus Weekly.

The association maintained extensive websites, featuring information on the theory and application of renewable energy technologies, particularly those related to heat-pump applications. They maintained their online news feed until December 2006. The association is closely tied to the Earth Energy Society of Canada, formerly the Canadian Earth Energy Association, which was formed in 1989 to promote ground source/geothermal heat pumps. It administered a $20 million program during the 1990s devoted to installing ground heat-pump systems.

The association has been involved in a variety of projects. They began offering the first green internet hosting service in Canada in September of 2001. The service is powered by green energy produced by wind turbines in Alberta; the electricity from the turbines is distributed by ENMAX and both generation and distribution are certified under Canada's Ecologo program. This initiative can thus be seen as a carbon offsetting program. A slight premium is charged to cover the extra cost of the green energy. A related program that provided green domain tagging is no longer in operation. The program is a good example of innovative use of the bundled green power available in parts of Canada. Bundled green power allows customers to pay for green power directly on their electricity bill. Though the specific electricity used by the consumer is not necessarily being generated by a green power method, their payment ensures that a certain percentage of the total power generated will be green. Another option is the "Green Power Certificate," which is billed separately. This approach supports the development and use of green electricity.

The Green Heat Partnership was formed in 2001 to encourage the adoption of space and water heating applications that use renewable energy technologies. Partners include the Earth Energy Society of Canada, the Canadian Solar Industries Association, the Canadian Biomass Association, and other private partners. Technologies being showcased by the initiative include heat pumps, solar thermal water heaters, solar thermal air heaters, and biomass combustors.

Geothermal heating and cooling systems work well in the Canadian climate. They collect and transfer heat from the ground using a series of pipes filled with fluid. Operating the systems in reverse provides air conditioning, eliminating the need for separate heating and cooling systems. The systems are very energy efficient, providing significant cost savings to users. The systems can also be used to heat hot water.

In 2006, both the Earth Energy Society of Canada and the Canadian Association for Renewable Energies were named in a lawsuit over the ownership of the term *GeoExchange*. As a result of the costs of this suit, the Earth Energy Society ceased operation in November 2006.

Cantor Fitzgerald EBS

CANTOR FITZGERALD EBS (CF EBS) was a division of Cantor Fitzgerald, a leading investment and brokerage services company in the United States. While Cantor Fitzgerald is based in New York City, CF EBS was based in Los Angeles, California. It is now CantorCO2e, based in both Great Britain and California. As emissions caps are set for companies and enforcement is strengthening, a novel business has emerged: emissions trading. If a company cannot reach emissions levels at or below the cap, it can purchase the right to have the difference of emissions (or credit) from a company with a lower emissions rate. In effect, the company exceeding emissions is fined, while the company with lower emissions receives a financial benefit.

Bernie Cantor and John Fitzgerald established Cantor Fitzgerald as a bond brokerage firm in 1945. The company expanded with a division of Equity Capital Markets 20 years later. In 1972, Cantor Fitzgerald provided the first electronic marketplace to manage U.S. government securities by developing the field of screen brokerage. That same year, the company acquired a controlling interest in the smaller company, Telerate.

As screen brokerage continued to develop, Cantor Fitzgerald opened an office in London in 1983, offering screen brokerage to clients around the globe. The following year, they opened an office in Japan, managing the brokering of Eurobonds. Cantor Fitzgerald acts as a mediator between buyer and seller for the purchase of Eurobonds, which are in a currency of a specific country, but are traded and regulated outside of that county in a different currency. To specify the initial country's currency, the name of that currency is found in the name of the Eurobond. For example, a Eurobond in Japanese currency is called a Euroyen. In 1998, Cantor Fitzgerald traded U.S. Treasury futures via electronic exchange. Two years later, a new branch of investment banking was created. The company continued in its pioneering of electronic services by staging the first wireless bond trade, using a BlackBerry® handheld device.

Cantor Fitzgerald offers multiple financial services, including brokerage services, investment services, sales and trading, news distribution, and mobile gaming, whereby patrons of a casino can use a personal digital assistant (PDA) to gamble outside of the casino in approved areas such as the casino pool. In the brokerage services sector, Cantor Fitzgerald offers Cantor Clearing Services (CCS), CantorCO2e, Cantor LifeMarkets, Cantor Fitzgerald Telecom Services (Cantor Telecom), and Cantor Spectrum & Tower Exchange (CS&TE). CCS deals with equities, fixed income, and futures transactions.

Cantor LifeMarkets, established in 2004, deals with life insurance and its benefits to the financial sector. For example, Cantor LifeMarkets manages an online marketplace for life insurance policy trading. Cantor Telecom deals with wire line telecommunications as well as wireless communication. CS&TE brokers unused radio frequencies, along with rooftop space and other goods in communications infrastructure. CantorCO2e is the current version of what was initially Cantor Fitzgerald EBS.

CF EBS began making headlines in 2006 when it joined the market for crude oil products. Then, in 2007, CF EBS joined with CO2e.com LLC, becoming CantorCO2e. CantorCO2e headquarters are in London as well as San Francisco, California. The company has partnered with Price Waterhouse Coopers to create the website CO2e.com. This website serves as a carbon marketplace accessible around the clock, as well as access to Cantor associates who act as consultants to help companies blueprint their emissions reduction investment plans.

Brokerage services offered by CF EBS include brokerage of emissions, as well as biodiesel, ethanol, and renewable energy; these latter three are considered new forms of energy. Additionally, CF EBS brokers renewable energy certificates, and runs an Institutional Trading Department for brokerage of energy securities. CF EBS also provides consulting services to clients looking to switch to cleaner technology. For example, CF EBS works with clients that produce biodiesel and are looking to establish the infrastructure to sell this biodiesel as fuel. The slogan of CantorCO2e is "Energy. Environment. Innovation." On October 3, 2007, CantorCO2e established an online marketplace for global CO_2 emissions trading, allowing clients around the globe to trade emissions voluntarily.

Cape Verde

A CHAIN OF islands in the mid-Atlantic, the Republic of Cape Verde was a Portuguese colony until it gained independence in 1975. It has a land area of 1,557 sq. mi. (4,033 sq. km.), with a population of 420,979 (July 2006 est.), and a population density of 326 people per sq. mi. (126 people per sq. km.). The country is very poor. Only 11 percent of the land arable, and a further 6 percent is used for meadows and pasture.

The soil is largely volcanic. Owing to a large population, and compounded by overgrazing and deforestation, there have been regular food shortages in the country from droughts. These may not all be due to global warming, as droughts have been recorded in the area since the 17th century. Over many centuries, Cape Verdeans have migrated overseas. Electricity production comes from fossil fuels. The country's carbon dioxide emissions are very low, ranging from 0.2 metric tons per capita in 1990, rising to 0.30 metric tons per capita in 2003. This is entirely due to the use of liquid fuels, and in spite of the small size of the islands, public transportation in Cape Verde is extremely limited.

The government of António Mascarenhas Monteiro took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention in 2001. It accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on February 10, 2006, making it the 158th country to accept the Kyoto Protocol; it took effect on May 11, 2006.

Capitalism

CAPITALISM IS AN economic system of market-driven services and production carried out by private individuals and business firms. Karl Marx coined the term *capitalism* as an opposite to communism/Marxism. Other terms that refer to this economic system include *free enterprise* and *market economy*. The term *mixed economy* refers to the combination of a market economy and taxation for governmental spending. Adam Smith originated the philosophy behind capitalism in his treatise *An Inquiry into the Nature and Causes of the Wealth of Nations* (1776). He argued that societal well-being could be the secondary result of the combination of self-interest, private ownership, and consumer-driven competition.

Capitalism is a socioeconomic system where the infrastructure for production is privately owned; the market coordinates buyers and sellers; everyone involved in the system has the freedom to look out for their own self-interest with maximum return from the invention of resources, labor, and time; consumers are free to spend money as they choose, creating competition for their business and as a whole; and government supervision is minimal.

Trade over long distances to procure goods was the stimulation throughout history for such developments as overland caravans to the Middle East and Asia; shipping routes from Asia to Europe and from the Americas to Europe; and the colonization of Africa, Asia, and the Americas. Emphasis on production came with industrial advancement. Before that time, however, an important figure in the capitalist system began to emerge: the entrepreneur, or risk taker. A key element in capitalism is the undertaking of activity in the expectation that it will yield gains in the future. Because the future is unknown, both the risk of loss and the possibility of gain exist.

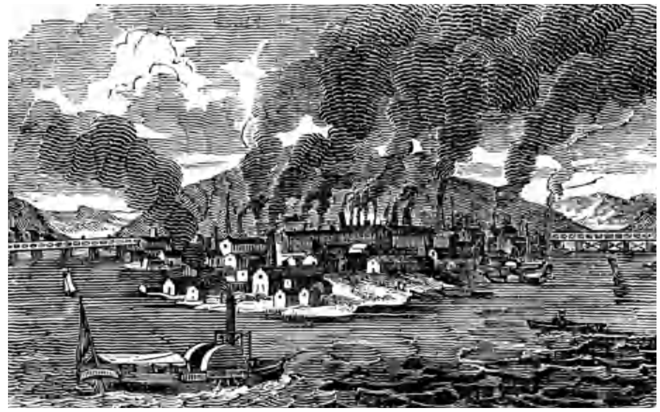
The assumption of risk involves the specialized role of the entrepreneur. The Renaissance and Reformation brought about social change, as people demanded a right to be involved in their government and to control their personal destinies. With this emerged contemporary forms of government, with judicial, legal, and organizational structures necessary for economic growth and capitalism.

Governments began to take advantage of this form of trade to make a profit. They saw that the influx of gold and silver from a favorable trade balance would stimulate to economic activity, thus enabling the state to levy more taxes and gain more revenue. The Industrial Revolution changed the face of business, moving from small enterprises to large enterprises that employed many workers to produce large quantities of goods, and used machines for work previously done by humans or animals. Production became more specialized and factory units became the prime producers, while entrepreneurial activities became part of peripheral economic activities.

Situations for workers declined as big business demanded child labor, long working hours, and dangerous workplaces. These conditions were the impetus for Karl Marx to develop his treatise promoting communism, with business owned collectively by society, and with collective sharing of goods, services, and profits. Capitalism also experienced setbacks, with cycles of expansion, as well as economic collapses and unemployment. Corporations sought control of manufacturing with monopolies and trusts.

Public involvement led to antitrust legislation passed by the U.S. Congress to make monopolies illegal, and to the use of government power to force competition. Capitalism continued to expand and prosper because of the potential for individuals to create wealth and improve living standards. However, as the Cold War came to an end in the 1980s and the former Soviet Union nations turned to free enterprise (though with mixed success at first), nations with a free economy rose to the challenge of the changing times and adapted.

Democratic governments intervened in the economy to correct the worst abuses inherent in capitalism. Action was taken to encourage collective bargaining and build a strong labor movement in order to offset the concentration of economic power in large industrial corporations. The foundation for the modern welfare state was laid through the introduction of Social Security and unemployment insurance, measures designed to protect people from the economic hazards endemic to a capitalist system.



Early capitalist industry left its mark. Current atmospheric CO_2 is about 30 percent above pre-industrial 18th-century levels.

Social welfare spending by governments continued to grow; in the United States, these expenditures (along with those for defense) account for the overwhelming proportion of all federal spending. Economic growth slowed, and many nations, particularly the United States, where national, corporate, and personal debt had reached record levels, dropped into recession, with rising unemployment. The early 21st century situation needs to be seen from the perspective of the long history of capitalism, particularly its extraordinary versatility and flexibility. New demands imposed on the economic system include ending environmental pollution, as the unregulated growth of industry and the use of fossil fuel as a primary energy source have led to global warming and climate change.

Carbon Cycle

THE CARBON CYCLE describes the biogeochemical cycle, or routes by which carbon atoms are exchanged through nested networks of environmental systems from the atmosphere into the biosphere, through photosynthesis and back again with respiration, decomposition, and biomass burning. Elemental carbon is a traditional component of the hydrosphere, the atmosphere, the geosphere (rocks, such as limestone; coal; and soils), as well as the biosphere (all living things).

The carbon cycle also involves the process of removal and uptake of carbon on a global scale. This process involves components in food chains, in the atmosphere, as carbon dioxide; in the hydrosphere; and in the geosphere. The major movement of carbon results from photosynthesis and from respiration. Carbon is present in the planet in the following major reservoirs: as the gas, carbon dioxide (CO_2) in the atmosphere; as organic matter in soils; as organic molecules in living and dead organisms found in the biosphere; in the lithosphere as fossil fuels and sedimentary rock deposits such as limestone, dolomite and chalk; and in the oceans as dissolved atmospheric CO_2 and as calcium carbonate shells in marine organisms.

The carbon cycle has a large impact on Earth, both globally and locally. At the global scale, the carbon cycle influences Earth's climate by regulating the amount of CO_2, a principal greenhouse gas, in the atmosphere. Terrestrial ecosystems store as much carbon as the atmosphere, so plants and soils play an important role in regulating climate. The carbon cycle also plays a primary role in keeping ecological systems in balance, since it is involved in basic ecological processes such as plant growth and accumulation, and the death and decay of plant material.

As a principal building block of organic matter, carbon is utilized by biotic components of an ecosystem, especially by organisms for structural growth: a portion of elemental carbon that a living thing takes in is usually incorporated into its tissues. Thus, the carbon cycle is one of the most important biogeochemical cycles to humans, because it is a vehicle through which one of the primary elements required for the formation of human tissues is cycled, and also because it is a means through which elemental carbon is introduced to plants, the basis of human food.

The carbon cycle is also important to the human climate system because it sets the background for the environment, through CO_2 and methane (CH_4), which are major drivers of global climate temperatures. The carbon atoms present in the atmosphere, hydrosphere, biosphere, and the geosphere are able to move from one of these environmental systems to another as part of the carbon cycle.

The carbon cycle is sometimes conceptualized as four major carbon sinks, interrelated by nested systems of pathways for transport of carbon atoms. The carbon reservoirs are the air (atmosphere), considered as the starting point of the cycle; the sea water and oceans (hydrosphere), which include biotic and abiotic marine biota; the sediments (fossil fuels); and the terrestrial biosphere, which includes fresh water systems (lenthic or lotic), as well as nonliving organic substances, such as soil carbon. The carbon cycle is primarily controlled by a series of biological, physical, chemical, and geological processes within the environment.

In the atmosphere, carbon exists primarily as the gas CO_2. It is this form that plants transform into carbohydrates via photosynthesis, releasing oxygen in the process. This process is mainly carried out in autotrophs (terrestrial and aquatic plants such as algae and cyanobacteria). They produce their organic compounds using atmospheric CO_2, with solar radiation providing the source of energy for the process. However, a minor group of autotrophs harness chemical energy sources for the production of their organic compounds through a process called chemosynthesis. Through the food chain, carbon is transferred as autotrophs (producers) and eaten by heterotrophs or as heterotrophs feed on other organisms. When the plants and animals die, their carcasses, stems, or leaves decompose, releasing the carbon trapped in them into the geosphere. Some could be buried, and over time, will become fossil fuels. Food webs serve as part of a carbon atom's journey through the carbon cycle. Carbon is returned to the biosphere during cellular respiration.

Biomass burning has the ability to transport substantial amounts of carbon into the atmosphere. When humans burn fossil fuels to run industries, power plants, cars, airplanes, and jets, a significant portion of carbon is transferred directly into the atmosphere as CO_2. When autotrophs and heterotrophs die, their remains may settle as sediments in fresh water and marine ecosystems. The carbon trapped in sediments is eventually released into the aquatic environments through geological and chemical processes. Marine animals use the released carbon to build their skeletal materials. Ultimately, the stored carbon compounds in these organisms up the web are broken down by decomposition, and the carbon is released as CO_2 back into the cycle to be used by plants.

The world's oceans act as sinks for CO_2, and, in general, contain more than 90 percent of the carbon involved in the global cycle. The concentration of atmospheric CO_2, which is an important driver of climate change, influences the temperature of the Earth's surface, which is largely determined by the ocean. The levels of CO_2 in surface water, and, hence, in the atmosphere, are usually kept lower than that in deep water by two principal natural processes: the solubility pump and the biological pump.

Carbon Dioxide

CARBON DIOXIDE IS a naturally occurring gas. Chemically, it is stated as CO_2, which means that each carbon dioxide molecule has two oxygen atoms bonded to a single carbon atom. CO_2 has many practical applications. CO_2 measurements are now being used as a way to test the cardiovascular system. This new tool has the promise of not being as invasive as other diagnostic methods. CO_2 can be frozen into dry ice, and has numerous chemical uses. It is often a byproduct from chemical reactions. It has a number of common uses, such as providing the fizz in soft drinks.

Humans and other animals also expel CO_2 when they exhale. In the respiratory processes of humans, mammals, birds, reptiles, and fish, oxygen is breathed into the lungs and CO_2 is exhaled. Their breath contributes to the CO_2 cycle. In the CO_2 cycle, plants take in CO_2 and in the photosynthesis process make chlorophyll and oxygen from the CO_2 as it combines with water, minerals, and other products in the plant's chemistry.

Plants are able to store huge quantities of carbon in hydrocarbon compounds. CO_2 plays a vital role in plant growth. There are also tremendous quantities of CO_2 locked in fossilized hydrocarbons, such as coal and oil. In addition, peat bogs and the plant material frozen in the Arctic tundra are repositories of vast quantities of organic material and, thus, of carbon and CO_2.

The Earth's atmosphere is composed of a number of gases, including: nitrogen, oxygen, CO_2, water vapor, argon (an inert gas), methane, varying amounts of ozone, and other gases such as nitrous oxide. The greenhouse effect is a natural phenomenon that is caused by these gases. Without the greenhouse effect, the biosphere of Earth would either never have existed, or it would die because the Earth's climate would be too cold. CO_2 and other gases such as methane, ozone, and others act as a thin blanket that retains heat that would otherwise be radiated out into space. Instead, these gases capture some of the long-wave infrared radiation and return it to the Earth's surface.

Sunlight enters the Earth's atmosphere as white light of all wavelengths, from ultraviolet to infrared waves. Some wavelengths of energy, such as gamma rays and x-rays, are adsorbed or reflected in the upper levels of the atmosphere and do not affect the surface of the Earth. Most of the sunshine that strikes the surface of the Earth is white light sunshine. It is in the visible light spectrum, which is seen by human eyes, and ranges from purple to red in a spectrum of increasing wavelengths. Just beyond the visible red spectrum is infrared radiation. About 60 percent of the sun's radiation is infrared, which is radiation invisible to humans and most animals. The tongues of snakes have infrared sensors to detect the heat of animals in the dark. Camera film can be designed to detect infrared radiation, making it visible to humans.

Carbon dioxide and other gases, such as methane and ozone, act as a thin blanket that retains heat that would otherwise be radiated out into space. Without this natural greenhouse effect, Earth's climate would be too cold for much life.

As sunshine strikes the Earth, much of it is reflected away by clouds, the polar icecaps, desert surfaces, and other bright surfaces. When the Earth, buildings, plants, or other objects adsorb it, some of it is emitted from surfaces as heat. Radiant heat is composed of infrared wavelengths. There is a range of infrared wavelengths radiated skyward. Most of these infrared wavelengths pass through the atmosphere and emerge to vanish into outer space. However, CO_2 adsorbs some infrared wavelengths.

CO_2, water vapor, and trace gases all absorb some of the heat energy of the Earth. Carbon dioxide absorbs infrared waves that are from 13–100 micrometers (.0004–.004 in.) in length. Water vapor absorbs infrared waves that are between 4–7 micrometers. The infrared waves that are between 7–3 micrometers, on the other hand, are not usually absorbed. Instead, they pass easily through the atmosphere and into space. The major infrared window is the infrared wave range between 7–3 micrometers. This means that the major work of the greenhouse effect is accomplished by CO_2. In contrast, although methane absorbs 30 times as much energy per molecule compared to a molecule of CO_2, the amount of methane in the atmosphere has not increased as dramatically as the CO_2. While other gases have increased, none have increased as much as has CO_2.

THE KEELING CURVE

Charles David Keeling of California developed a device for measuring the amount of CO_2 in the atmosphere in parts per million. During the Geophysical Year 1957–58, he took many readings at different locations on the surface of the Earth. These included the top of Hawaiian volcanoes that were (at the time) far from industries. He also took readings in all manner of other places and used these to construct the Keeling Curve. The Keeling Curve shows that the amount of CO_2 in the atmosphere has increased dramatically since the beginning of the Industrial Revolution in the late 18th century. In addition, his readings show that the amount of carbon dioxide is increasing rapidly.

Keeling's readings were supported by major studies of ice core samples taken from Greenland and Antarctica. The ice core samples were drilled from deep within the ice caps at opposite ends of the globe. The upper limits of the ages in these cores were estimated to be as high as 160,000 years. What they show is that, on average, the amount of carbon dioxide in the atmosphere until the Industrial Revolution was 270 parts per million (ppm). However, the current reading for carbon dioxide is now 380 ppm and rising. It is estimated that 450 ppm may be a kind of trigger for major weather changes that may be permanent and cause not just global warming, but also permanent climate change that melts the ice caps and causes other long-term climatic changes.

Carbon Emissions

CARBON IS A widely distributed element on the Earth. Pure carbon in one form is graphite. It can also take the form of diamonds after undergoing tremendous pressures and heat in volcanic pipes. Carbon is the basic atom in organic chemistry. Because carbon has four electrons, which can be joined to other atoms, it is able to form an enormous number of compounds. Some are simple and some are complex. The ones that matter the most to the issue of global warming are those that become involved in the chemistry of climate change.

The most common carbon compound that is involved in global warming is carbon dioxide (CO_2). It is a very common emission from a wide variety of sources. Humans and animals, including birds, all exhale CO_2 when they breathe. On the other hand, plants use CO_2 as an essential part of the process of photosynthesis. Plants lock up tremendous amounts of carbon in trees, shrubs, grasses, and other plant materials. When these are buried, they can, under the right conditions of heat and pressure, become natural gas, oil, coal, peat, or other carbon remains.

Most carbon emissions come from natural sources. Volcanoes give off CO_2, as do decaying plants. The Earth naturally has had an abundance of CO_2 in its atmosphere. Without it, the Earth would become a block of ice. CO_2 is the main compound involved in the greenhouse gas effect. This is the effect of sunlight striking the Earth, where it is either reflected immediately from bright surfaces such as the polar ice caps, or it is radiated in infrared wavelengths back into the atmosphere. CO_2 and other carbon compounds such as methane, absorb and reflect back to Earth certain infrared wavelengths. Without this effect, all of the energy would return to outer space and the Earth would be much cooler.

The problem with carbon emissions in the current era is their volume. The rise of China and India as global producers and markets has followed on the huge volume of CO_2 and other compounds that industrialized North America and Europe have spewed into the atmosphere for decades. It is anthropogenic (human-made) increases in the global atmospheric levels of carbon compounds that are blamed for the rises in temperatures globally in recent decades. Burning fossil fuels is probably the greatest source of carbon emissions. The use of oil and its derivatives is a major contributor. Oil is used to make fuel for airplanes, and in automobiles and trucks as gasoline or diesel fuel. In addition, coal has been burned for fuel for centuries. Today, coal-fired power plants burn whole trainloads of coal almost daily. The emissions, unless controlled, add huge quantities of smoke, much of which is CO_2, to the atmosphere, where it increases the temperature of the planet through the greenhouse gas effect.

In addition to the burning of gasoline and coal, natural gas is a major, and still growing, fuel. To this is added the flaring of natural gas at refineries and at oil wells that have an excess of natural gas. It is mostly methane, but when burned, it becomes CO_2 and water vapor. The consumption of huge quantities of natural gas produces CO_2 in large quantities. Other liquefied petroleum gas products used for fuel are propane and butane. These also produce CO_2 when burned.

Carbon emission sources also include livestock, rice paddies, deforestation, and the warming of the arctic tundra where decaying vegetation that has been thawed turns into a natural form of carbon emission. Researchers have concluded that livestock account for 18 percent of current levels of carbon emissions. The emission of cattle and many other farm animals produce gas in the form of methane. However, methane reacts with oxygen in the atmosphere to form CO_2. Modern septic tanks that vent gases produced in their biodegradation of waste material emit methane, which is a gas that adds to the greenhouse gas stocks. Agricultural chemical fertilizers, as well as decaying vegetation, add vast amounts of carbon emissions on the Earth's surface and in the atmosphere. Cement production is another human source of carbon emissions.

The goal is to control global warming by controlling pollution from carbon gases produced by entities such as power plants. One idea is to develop a market in carbon-offset vouchers. Such programs seek to offer an economic incentive for a cleaner environment and a reduction in global greenhouse gases. Carbon emissions can be managed through a combination of government controls and market forces.

Carbon Footprint

A CARBON FOOTPRINT is defined as the total amount of carbon dioxide (CO_2) and other greenhouse gases such as methane (CH_4), nitrous oxide (N_2O), hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6) emitted directly and indirectly to support human activities such as the burning of fossil fuels, deforestation, livestock raising, and agricultural production. Calculating a carbon footprint is a tool for understanding the amount of global warming gases everyday activities create. For example, when heating a living space with oil, gas, coal, or electricity, a certain amount of CO_2 is emitted. In addition, when buying consumer items from a store, the production, transportation, and packaging of these products also create a certain amount of CO_2 and other greenhouse gases. A carbon footprint is the sum of the total amount of CO_2 produced by human activities in a given time frame (typically a year's time). Carbon footprints are generally expressed in annual tons of CO_2.

The carbon footprint is not only a method of estimating the amount of CO_2 and greenhouse gases humans are producing, but a way to understand the chemical nature these substances have in different parts of the atmosphere. CO_2 and other greenhouse gas molecules created from the burning of fossil fuels have different chemical behaviors than their original fossil fuel molecules. Many greenhouse gas molecules produced from human activities accumulate in parts of the atmosphere where they have an undesirable effect. For example, the production of ozone gas (O_3) is desirable in the stratosphere (upper atmosphere) where it protects humans from harmful ultraviolet radiation; however, production of an abundance of O_3 in the troposphere (closer to where humans live) is undesirable because it acts as a lung irritant for people with respiratory illnesses (such as emphysema, asthma, and chronic bronchial inflammatory diseases), and contributes to smog production.

The largest sources of CO_2 from the burning of fossil fuels are: liquid fuels (such as gasoline or diesel), 36 percent; solid fuels (such as coal and wood), 35 percent; gaseous fuels (such as natural gas), 20 percent; international bunkers, four percent; and cement production, 3 percent, according to research by M.R. Raupach. The most common human activity that produces an abundance of CO_2 in the atmosphere is the use of liquid fuels in driving an automobile. Other greenhouse gases that are produced from the burning of liquid fuel in engines include, but are not limited to, methane and ozone gas (CH_4 and O_3).

One method for estimating the amount of CO_2 and other greenhouse gases produced by human activities is determined from a balanced chemical equation (for example, stoichiometry) and then converted to an equivalent amount of CO_2, which allows it to be added together to determine an individual, household, city, state, national, or total global carbon footprint. Human activities on the entire planet produce approximately 27,500 million tons of CO_2 annually.

In 2006, China passed the United States as the number one emitter of CO_2 with 6,200 million tons annually. The United State's emission of CO_2 was 5,800 million tons, according to the Netherlands Environmental Assessment Agency. However, in a per person comparison, the average Chinese citizen is responsible for 10,500 pounds or 4,763 kilograms of CO_2, while the average U.S. citizen is responsible for 42,500 pounds or 19,278 kilograms of CO_2 as a result of heating and electricity for living spaces, driving, traveling by airplane, and purchasing manufactured products.

There are a number of groups and organizations working to create a more scientifically literate population and proposing and implementing programs and policies that reduce CO_2 and other greenhouse gases. A provision in the Kyoto Protocol is the Clean Development Mechanism (CDM), which is an offset that allows more developed countries to invest in lower emission-producing facilities in developing or less-developed countries to avoid reducing emissions in their home countries.

Another proposal is a carbon tax, or the taxation of burning fossil fuels (such as liquid, solid, and gaseous fuels) to reduce CO_2 emissions. Some groups are proposing a carbon label, where consumer products would report their carbon footprint on the label. Other practical methods for reducing carbon footprints are to reduce driving (for example, to use public transportation or bikes), reduce household heating by a couple of degrees, purchase green energy, plant a tree, recycle, and buy products with reduced packaging.

Carbon Permits

CARBON PERMITS MAY be issued to companies through governmental agencies, and allow companies to emit up to a specified level of CO_2. The total number of issued permits from governmental agencies equals the national limit on emissions. CO_2-generating companies may reduce emissions by using lower-carbon coals, or increasing the use of cleaner-generating plants. Generators that reduce emissions below their allotted levels can sell excess emissions permits to other generators. Other generators who exceed the limit of the permit may purchase permits at the market price, instead of reducing emissions, if it is more cost effective. Thus, companies that can easily reduce emissions will do so, and those for which it is harder will buy credits that reduce greenhouse gases at the lowest possible cost to society. Emissions permits can also be banked for future use.

EMISSION TRADING SYSTEMS

The European Union Emission Trading Scheme (ETS) is an example of a carbon permits trading system. The test phase of ETS operated from 2005–07, and is slated for operation in the European Union (EU) during the Kyoto commitment period 2008–12. In the system, the aggregate cap on emissions is set by each EU government agency, and the total number of emissions allowances is defined to provide the owner the right to emit units of emissions. The amount of emissions is capped, whereas the permit prices are uncertain.

These permit prices are determined by economic conditions, generally, stronger economic growth means a higher permit price. Critics claim that the ETS has done more for power-generating companies, than it has curbed pollution. First, power generators emit a tremendous amount of pollution and monopolize the carbon market. Also, permit holders find they have unexpectedly valuable property rights because carbon permits are usually handed out for free, rather than auctioned. Second, there are no signals that the carbon permit is helpful in switching to cleaner fuel. That is not just because gas has been so much more expensive than coal, but because the first phase of the ETS lasts only three years. Because investments to reduce emissions have payback periods of five or more years, investors are wary.

The ETS was originally designed to meet the targets set by the Kyoto Protocol. The Kyoto Protocol was an international treaty negotiated in Kyoto, Japan, in December 1997 that took effect on February 16, 2005. As of December 2006, a total of 169 countries and other governmental entities had ratified the agreement. Its objective is to stabilize the greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system. In the Kyoto Protocol, mechanisms such as International Emissions Trading (IET), Joint Implementation (JI) and the Clean Development Mechanism (CDM) provide options for members to fulfill their targets. IET provides the trading of assigned amount units (AAUs) between Annex I Parties in the Kyoto Protocol, JI enables Annex I parties to get credits for join projects to reduce emissions, CDM enables Annex I parties to get credit for projects resulting in emissions reductions in non–Annex I parties.

In the United States, the example of a successful emission trading system to date is the SO_2 trading system under the framework of the Clean Air Act (CAA). Under this program, SO_2 emissions are expected to fall by 50 percent 1980–2010. Compared to the proven success of the SO_2 trading program in the United States, carbon trading has some specific features that make it more complicated.

Carbon emissions are an international issue, rather than a domestic one. Complexities may arise in setting up baseline projections against which to monitor and verify net emissions reductions, particularly with regard to the CDM. Usually, large amounts of SO_2 come from coal-burning generation plants, making it relatively easy to monitor a plant's fuel use and emissions, rather than to construct and maintain a trading system to ensure compliance. On the other hand, carbon emissions come from many different sources, such as households, commercial and industrial facilities, transportation systems, and fossil-fired generating plants. Therefore, the development and operation of a monitoring and trading system for carbon emissions would be complicated.

CARBON PERMITS VS. CARBON TAXES

There has been debate on the relative merits of carbon permits versus carbon taxes to achieve emission reductions. Carbon permit systems fix the overall carbon emission level, while prices vary. On the other hand, carbon taxes fix the price, while the emission level quantity is allowed to vary according to economic activity. Therefore, carbon permits and carbon taxes are called quantity and price instruments, respectively. There are major drawbacks for each system. Carbon permits create uncertainty about the cost of compliance for firms, because the price of a permit is unknown; carbon taxes cannot guarantee the amount of emissions reduction.

Recently, a third option known as a safety valve has been suggested. It is a hybrid of the price and quantity instruments. The system is similar to a carbon permit system, but the maximum permit price is limited. Permits can be either purchased from the carbon market, or government, at a specified price. This system is designed to overcome the fundamental disadvantages of both systems, while providing flexibility.

Carbon Sequestration

MANY COUNTRIES THAT attended the United Nations Framework Convention on Climate Change in Kyoto promised to learn how to mitigate the problem of climate change by managing the global carbon cycle. This resolve shows the significance of carbon sequestration for alleviating the global warming problem. Carbon sequestration refers to the provision of long-term storage of carbon in the terrestrial biosphere, underground, or in the oceans, so that the carbon dioxide (CO_2) buildup in the atmosphere will decrease or slow.

CO_2 makes up approximately 47 percent of greenhouse gases, making it a primary contributor to global warming. The level of CO_2 in the atmosphere has risen from the last century (pre-industrial) level of 280 parts per million (ppm) to the present level of 375 ppm. Carbon sequestration is intended to reduce the atmospheric CO_2 concentration, which is predicted to exponentially rise because of higher global energy use and extensive deforestation in the 21st century. Carbon sequestration can be accomplished by maintaining or enhancing natural processes such as managing forest ecosystems and storing carbon in biomass and soil, or by artificially sequestering carbon in underground geologic repositories, enhancing net oceanic carbon uptakes, and sequencing the genomes of micro-organisms for carbon management.

The Kyoto Protocol recognizes forestry and land-use change activities as carbon sinks and sources. When plants grow, they absorb carbon dioxide from the atmosphere as part of photosynthesis. This is known as carbon sequestration, because carbon is removed from the atmosphere. Therefore, a living plant helps carbon sink. Forest decay does generate carbon into the atmosphere, but sustainable use of forest biomass in biofuel production reduces this amount. Biofuel also reduces the use of fossil fuels, which are major contributors to greenhouse gas production. By the beginning of the 2010s, most of the countries in the world will mandate a minimum of 10 percent biofuel use. Scientists also agree that world forests have the greatest long-term potential to sequester atmospheric carbon by protecting forested lands, slowing deforestation, encouraging reforestation, and agroforestry. Deforestation, harvesting, and forest degradation contribute 1.8 Gt carbon per year.

Soil is a major reservoir of terrestrial carbon. It is about 3.3 times the size of the atmospheric pool. Therefore, if the soil is enriched through sequestration of atmospheric carbon, global warming can be managed significantly. This will also ensure global food security, because enhancement of soil carbon enhances the soil health for sustainable soil production. No-till farming, residue mulching, cover-cropping, and crop rotation are some of the methods that are employed to sequester carbon into soil. Using pyrolysis technique, half of the carbon in biomass can be reduced to charcoal and, thus, decrease the potential to act as a carbon source. The charcoal is later deposited in soil to increase its carbon content.

Atmospheric carbon can be reduced by enhancing the net oceanic uptake from the atmosphere by fertilization of phytoplankton with nutrients and injecting CO_2 to ocean depths greater than 3,281 ft. (1,000 m.), or into deep geologic formations. This reduction can also be achieved by carbon capture and storage (CCS); for example, collecting CO_2 at point sources (such as power plants) and injecting it directly into the deep ocean. If CCS is applied to modern conventional power plants, CO_2 emission into the atmosphere could be reduced by 80–90 percent. However, this injection into the deep sea might influence sea creatures negatively (due to the decrease in pH of sea water). Therefore, carbon storing in deep geologic formations has the greatest potential. Oil fields, gas fields, saline formations, unminable coal seams, and saline-filled basalt formations are suggested storage sites. Mineral storage of CO_2 is another potential means of carbon sequestration. In this process, CO_2 is exothermically reacted with abundantly available metal (Mg and Ca) oxides, which produce stable carbonates.

More advanced CO_2 capture techniques are being developed as part of carbon sequestration. Presently, there are three techniques in use: post-combustion, pre-combustion, and oxyfuel combustion. In post-combustion processes, CO_2 is captured from flue gases (the gas that exits to the atmosphere through a flue or pipe) at power stations. The pre-combustion technique is widely applied in fertilizer, chemical, gaseous fuel (hydrogen and methane), and power production. In these cases, the fossil fuel is gasified and the resulting CO_2 is easily captured from a relatively pure exhaust stream.

In the third type (oxyfuel combustion) the lignite is burned in oxygen instead of air and produces a flue gas consisting only of CO_2 and water vapor. This is cooled and condensed to a pure CO_2 stream that can be transported to the sequestration site and stored. According to scientists, this technique is very promising, but a lot of energy is needed for the initial air separation. Other ambitious techniques under development are the genetic manipulation of plants and trees to enhance CO_2 sequestering potential and sequencing the genomes of microbes that produce fuels such as methane and hydrogen or aid in carbon sequestration.

Carbon Sinks

A CARBON SINK is defined as a pool or reservoir that absorbs carbon released from another part of the carbon cycle (the net exchange between the biosphere and the atmosphere). If the net exchange is toward the atmosphere, the biosphere is the source, and the atmosphere is the sink. Carbon sources usually release more carbon than they absorb, while sinks soak up more carbon than they emit. Another definition of carbon sink is: any natural or anthropogenic system that absorbs CO_2 from the atmosphere and stores it. Trees, plants, and oceans all absorb CO_2 and, therefore, are carbon sinks. The concept of carbon sinks is based on the natural ability of trees, other plants, and soil to soak up CO_2 and temporarily store the carbon in wood, roots, leaves, and earth.

Fossil fuel deposits are another important carbon store. Buried deep inside the earth, they are naturally separated from carbon cycling in the atmosphere until humans decide to release them into the atmosphere by burning coal, oil, or natural gas. The burning of fossil fuels results in the release of what are known as greenhouse gases (such as water vapors, CO_2, methane, nitrous oxide, sulfur hexafluoride, hydrofluorocarbons, and chlorofluorocarbons).

The downward radiation of long waves from the atmosphere, as opposed to radiation by the sun, is known as the greenhouse effect. A build-up of greenhouse gases in the atmosphere forms a layer that keeps heat from escaping into space and reflects it back to Earth. Because of human burning of fossil fuels, the concentration of greenhouse gases has soared to levels more than 30 percent higher than at the beginning of the Industrial Revolution. Instead of controlling and reducing greenhouse gases, human activities continue to add more than 6 billion tons of carbon per year to the atmospheric carbon cycle, thus exacerbating the situation and increasing the rate of global warming.

While forests act as sinks, deforestation prevents the absorption of CO_2. Therefore, fewer trees mean more CO_2 in the atmosphere. The causes of deforestation include logging for lumber, pulpwood, and fuel wood. The clearing of new land for farming and pastures for livestock, or the building of new housing, are some of the other reasons for deforestation. About 860 acres—the size of New York City's Central Park—are being destroyed every 15 minutes in the tropics.

Oceans are also important carbon sinks. Antarctica's Southern Ocean is a crucial carbon sink into which 15 percent of the world's excess CO_2flows. It is estimated that the world's oceans have absorbed about a quarter of the 500 gigatons of carbon emitted into the atmosphere by humans since the beginning of the Industrial Revolution. Observations have shown that the Southern Ocean's ability to absorb CO_2 has weakened by about 15 percent per decade since 1981. This is attributed to an increase in wind strength over the ocean because of higher levels of greenhouse gases in the atmosphere and long-term ozone depletion in the stratosphere. The strengthened winds influence the processes of mixing and upwelling in the ocean, resulting in an increased release of carbon dioxide into the atmosphere, and, thus, reducing the net absorption of CO_2 into the ocean, showing that climate change, itself, is responsible for the saturation of the Southern Ocean carbon sink.

Cenozoic Era

THE CENOZOIC ERA is the most recent of the nine eras in geological time, and extends from 65 million years ago to the present. The Cenozoic Era catalogues extensive climate changes, ranging from hothouse climates with warm-temperate to sub-tropical forests near both the north and south poles, to icehouse climates with ice sheets kilometers thick covering much of the high latitudes in both hemispheres. The first 30 million years of the Cenozoic were the warmest of the era and were characterized by several extreme warmth events.

The first of these climate maxima is the Initial Eocene Thermal Maximum, which occurred approximately 55 million years ago. Geological evidence suggests that at this time, atmospheric CO_2 concentrations soared to nearly 20 times current levels, and temperatures in the Arctic Ocean approached those of a comfortable swimming pool, approximately 68 degrees F (20 degrees C). This climate maximum persisted for 50,000—100,000 years, before the climate cooled and then continued a gradual warming trend through the longest period of sustained hothouse warmth in the Cenozoic, the Early Eocene Climatic Optimum.

THE EARLY EOCENE CLIMATIC OPTIMUM

The Early Eocene Climatic Optimum lasted for over 2 million years, and was characterized by warm and equable (meaning the climate was relatively similar everywhere) conditions. Deciduous, temperate forests covered Antarctica, and palm trees marched north across Wyoming and into Arctic Canada. Summer temperatures in the Arctic Ocean were approximately 59 degrees F (33 degrees C), almost 30 degrees F (17 degrees C) warmer than today, while ocean surface temperatures in the tropics were hardly different (at most, 9 degrees F, or 5 degrees C warmer) from those at present. This low equator to pole temperature gradient, with tropical and subtropical climate zones spanning much of the globe, is a notable characteristic of early Cenozoic hothouse climates, and understanding the mechanisms by which such a low temperature gradient can be maintained is one of the greatest challenges in paleoclimate science.

Long thought to be a time of gradual cooling, scientists have recently discovered additional thermal maxima during the later stages of the Eocene. The occurrence of all Eocene thermal maxima appear to be modulated by the eccentricity of Earth's orbit, (how much the shape of a planet's orbit deviates from a circle), and these new insights into early Cenozoic climate suggest that hothouse climates are as dynamic as the icehouse climates of the later Cenozoic.

FROM HOTHOUSE TO ICEHOUSE

Abrupt cooling at the Eocene/Oligocene transition (35 million years ago) marked the appearance of the first continent-spanning ice sheet on Antarctica, potentially the first Cenozoic Northern Hemisphere ice sheets, and the transition from hothouse to icehouse climate in the Cenozoic. However, much of the planet continued to experience climatic conditions warmer than the present, with cool temperate forests characterizing Arctic highlands, and warm temperate forests covering much of northern North America and Eurasia.

Research on the early Cenozoic era, when tropical forests grew in Wyoming, is revealing new insights about hothouse climates.

Following the abrupt initial cooling, Oligocene climate continued the overall Cenozoic cooling trend as atmospheric CO_2 levels fell to present values by the latest Oligocene. During this time, the driving influence of Earth's orbital parameters became increasingly evident in the waxing and waning of the Antarctic ice sheet, with frequencies that suggest modulation by not only eccentricity, but also the obliquity (variations in the axial tilt) of Earth's orbit.

Atmospheric CO_2 concentrations remain near modern levels throughout the subsequent Miocene epoch and the variability in both ice volume and climate evident in the first half of the Miocene is also attributable to the action of Earth's orbital parameters. Orbital parameters are also believed to be responsible for the last gasp of the warm climates, the approximately 3-million-year-long (14–17 million years ago) Miocene Climate Optimum.

During the Miocene Climate Optimum, ice volume on Antarctica was low, subtropical forests flourished as far north as central Europe, and the Arctic Ocean returned to a seasonally ice-free state. The Miocene Climate Optimum ended with 1.5 million years of rapid cooling, after which global cooling continued more gradually. In the late Miocene, several notable climate events took place, undisputable evidence for Northern Hemisphere glaciation, the establishment of largely modern vegetation zones, the establishment of a near modern latitudinal temperature gradient, and the inception of the Asian and Indian monsoons.

Global cooling continued through the Pliocene epoch (5.3–.8 million years ago), though global average temperatures in the Pliocene were approximately 5.5 degrees F (3 degrees C) warmer than at present. Peak Pliocene warmth occurred in the middle Pliocene from 4–3.5 million years ago, with Northern Hemisphere boreal forest extending to the Arctic Ocean, and deciduous hardwood forests of southern beech covering coastal Antarctica. In spite of this relative warmth, the global climate was cooling, and the late Pliocene, approximately 2.7 million years ago, is marked by the first major Northern Hemisphere cycle of glaciation and deglaciation. This first glacial cycle was modulated by a 41,000-year frequency that is characteristic of climate forcing by the obliquity and precession (the wobble of Earth's spinning axis) of Earth's orbit and a frequency that paced glacial cycles well into the Pleistocene epoch.

The Pleistocene (1.8 million–10,000 years ago) is the epoch commonly known as the Ice Age and was characterized by repeated waxing and waning of Northern Hemisphere ice sheets. For the first 1.2 million years of the Pleistocene, ice ages were paced by variations in solar energy associated with the 41,000-year obliquity cycle. Approximately 900,000 years ago, Northern Hemisphere ice sheets began to grow significantly larger and by 600,000 years ago, those larger ice sheets were waxing and waning with a periodicity of 100,000 years—a frequency that is not easily explained by simple combinations of Earth's orbital parameters. The reasons for this shift and the exact mechanisms driving this frequency in glacial cycles are two of the more challenging questions in ice age climate dynamics; neither is fully explained.

THE HOLOCENE EPOCH

Northern Hemisphere ice sheets have waxed and waned on 100,000 year timescales for at least 600,000 years and the approximately 10,000 years since the waning of the last Pleistocene glacial maximum are known as the Holocene Epoch. The Holocene is the shortest Cenozoic epoch and Holocene climate change is negligible compared to that in longer epochs. However, due to its recent nature, the records of the Holocene climate are better preserved than those of prior epochs and indicate smaller-scale, but significant, climate changes even within this short time span. Potentially the most significant Holocene climate changes are yet to come, as evidence of anthropogenic climate impacts and modern climate change continues to grow. Depending on the ultimate levels of greenhouse gases released by humans, climate change in the end of the Cenozoic Era has the potential to be as significant as the climate changes of the previous 65 million years.

Center for Clean Air Policy

ESTABLISHED IN 1985, the Center for Clean Air Policy (CCAP) is an independent, nonprofit entity headquartered in Washington, D.C. It adopts market-based approaches to environmental problems as the best way to reach common ground. The CCAP's current domestic and international initiatives promote stakeholder dialogues, education and outreach, qualitative and quantitative research, technical analyses of emission mitigation options, and policy recommendation development. The CCAP attempts to combine active, on-the-ground policy and research, and to advance cost-effective and pragmatic policies. CCAP deals with climate policy issues not only in the United States, but also in Europe, Asia, Central America, and South America.

The CCAP's mission statement is "to significantly advance cost-effective and pragmatic air quality and climate policy through analysis, dialogue and education to reach a broad range of policymakers and stakeholders worldwide." The work of the center, both in the United States and abroad, focuses on four major areas related to climate change: greenhouse gas emission mitigation and economics; emerging technologies and technology investment; transportation and land use; and adaptation. Within the United States, CCAP has four programs that try to involve different subjects in a profitable discussion about the environment.

The Climate Policy Initiative collaborates with leading companies; federal, state, and local governments; and environmental organizations to discuss and advance national climate policy solutions. The scheme intends to function as a forum to educate chief industry and government officials on the extent of the climate problem, and develop a set of pragmatic long-term mitigation and adaptation solutions for climate change in the United States. The Urban Leaders Initiative is a partnership with six large counties and cities to prevent climate change impacts through smart land use and infrastructure planning. The Advancing Climate Action in California assists the state in designing climate solutions through analysis and assessing mitigation options. CCAP's independent analysis of greenhouse gas mitigation options for California concluded that Governor Arnold Schwarzenegger's goal of reducing greenhouse gas emissions to 2000 levels by 2010 could be met at no net cost to California consumers.

The successes in California led CCAP to launch a comprehensive program to develop and implement climate change plans in key states, and pave the way for a strong federal approach. Through a combination of technical analysis and facilitation, CCAP is working with key states at different stages of climate change action to further climate change programs. This initiative deals with greenhouse gas emissions from all sectors of the economy, including transportation and land use, electricity generation, industry, buildings, agriculture, and forestry, and examines the full range of measures. The Transportation and Smart Growth Program focuses on transportation and land-use policies to reduce greenhouse gas emissions and improve air quality. This program also stresses the importance of transportation and planning efforts internationally.

CCAP has three major international initiatives in Europe, Asia, Central America, and South America. The Dialogue on Future International Actions to Address Global Climate Change combines in-depth analysis and development of policy options. A parallel program to the domestic Climate Policy Initiative, the European Climate and Energy Dialogue aims at developing medium- to long-term climate change, energy, and finance policy for the European Union. Finally, the Developing Countries Project entails collaboration with research teams in China, India, Brazil, and Mexico to identify technologies and approaches to reduce greenhouse gas emissions.

Through its projects, the CCAP claims to have reached important goals and to have played a major role in shaping climate change policies. In particular, the CCAP lists as its major successes the landmark sulfur dioxide trading program in the Clean Air Act, the original design for the European Union's CO_2 trading system, the development of the NOx reduction and trading program in the eastern United States, and the comprehensive climate policy strategy for New York state, which directly led to the successful creation of Regional Greenhouse Gas Initiative (RGGI). In addition, the CCAP worked with three U.S. utilities to finance the first carbon reduction project, the retrofit of a coal-fired heating plant in the Czech Republic. It has also devised, with stakeholders, the original design rules for the Clean Development Mechanism adopted as the Marrakech Accords.

CCAP has also been actively involved in the development of the Clean Development Mechanism (CDM) under the Kyoto Protocol. The center helped to design the rules for the CDM through work with developing countries. The Canadian Government hired CCAP to facilitate an informal workshop on streamlining the CDM in preparation for the United Nations Convention on Climate Change in Montreal, where CDM strengthening was a key issue. CCAP gathered negotiators from 30 developed and developing countries to discuss technical and legal issues surrounding development and implementation of the CDM. CCAP continues to develop the debate between developed and developing countries on the CDM.

Center for Energy Efficiency

BASED IN MOSCOW, the Center for Energy Efficiency (CENEf) is a nonprofit independent Russian organization founded in 1992 to promote energy efficiency and environmental protection in Russia. The Pacific Northwest National Laboratories of Battelle Memorial Institute, the World Wildlife Fund, the Social and Ecological Union (in Russia), and Mikhail Berner, president of the Russian Energy Manager's Association, founded the center. Initial sponsorship was provided by the World Wildlife Fund, the U.S. Environmental Protection Agency (EPA), the Charles Stewart

Mott Foundation, the U.S. Department of Energy, the U.S. Agency for International Development (USAID), and the John D. and Catherine T. MacArthur Foundation. CENEf has been self-sustaining since 1996. As stated by Pacific Northwest National Laboratories, the center was created to slow the rate of carbon dioxide emission, a key greenhouse gas that causes global warming, and to create new markets for American energy technologies.

CENEf was founded with the intention to develop model legislation and policy proposals to implement energy efficiency measures in Russia during its transition to a market economy, while considering economic, environmental, and social impacts implied in such transition. CENEf identified energy efficiency-related issues and developed policy papers on these issues, initiated energy-efficiency projects, and promoted economic cooperation between Russian and foreign companies to manufacture energy-efficient equipment and provide energy-efficiency services. CENEf has also prepared and disseminated materials for mass media to promote public education and has organized energy-efficiency training programs for nongovernmental organizations.

CENEf also publishes two quarterly newsletters, *Energy Efficiency* and *Energy Manager*, which reach 2,200 Russian city officials, utility managers, and industrial energy managers. It has strong contacts with city and regional governments throughout Russia. CENEf has developed long-term, energy-efficiency investment plans for municipal utilities in Kostroma, Chelyabinsk, Lytkarino, Dzerzhinsk, Zheleznogorsk, and the Orlov region. Participating cities have already invested more than $2 million of their own funds, and will eventually acquire and install roughly $65 million worth of equipment. CENEf also organizes seminars and training programs for industrial energy managers across Russia and holds an annual workshop and trade show each May.

Because of its strong contacts at the municipal level, CENEf is a partner of the Alliance to Save Energy (ASE) and of its Municipal Network for Energy Efficiency (MUNEE) project to promote exchanges of information among municipal leaders and to disseminate practical information on energy efficiency. CENEf traced 19 good examples of energy efficiency in Russia, and developed a municipal energy-efficiency policy through a database of city officials involved in energy issues. The database serves as a line of communication across the country to inform municipal leaders about low- and no-cost methods of reducing energy expenses in their city budget. CENEf's involvement in the MUNEE project is of particular importance because of the trouble that Russian cities have monitoring energy costs. In response to this need, CENEf devised a software package called Energy Attestat that can monitor energy use in up to 100 buildings. It has played a leading role in the creation of energy-monitoring tools and in disseminating them through all the MUNEE countries.

POLICY INVOLVEMENT

CENEf has long stimulated debates on energy efficiency in Russia. In January 1993, it developed a draft federal law, "On Improving Energy Efficiency," which was submitted to the former Supreme Soviet of the Russian Federation and then to the State Duma. The Draft Law was published in 1993. This was an important precedent for public discussion of energy legislation. Since then, CENEf has played an active role in the development of Russia's energy policy. It has contributed to, and commented on, many official energy policy documents for various government agencies. CENEf's first years were marked by suspicion, as it operated in a political climate where centralized administrative control was still strong. In spite of this hostility, from 1992 to 1999, CENEf managed to set up over 40 specialized institutions to develop and implement energy-efficiency policy at the federal and regional levels.

CENEfis committed to improving standards of living in ways that respect the environment. It participated in the Second and Third Assessment Reports of the Intergovernmental Panel on Climate Change (IPCC), identified effective strategies for reducing greenhouse gas emissions, participated in the Joint Implementation Program and the assessment of the environmental characteristics of combustion processes, and developed recommendations to improve combustion efficiency to minimize harmful emissions. CENEf has also produced publications and organized workshops to disseminate international documents on the limitation of greenhouse gas emissions developed in Kyoto Protocol and the United Nations Framework Convention.

Center for International Climate and Environment Research

THE CENTER FOR International Climate and Environment Research (CICERO) is a nonprofit, independent research institution established in association with the University of Oslo by the Norwegian government in 1990. CICERO conducts experiments and performs research regarding issues, such as climate change and greenhouse gas emissions. Additionally, it offers recommendations to alleviate the detrimental effects of climate change. CICERO has published an array of articles and continues to undertake research projects that serve to deter the process of global warming. CICERO has three objectives: to recommend policies that reduce greenhouse gas emissions, to encourage global participation in adopting climate and environmental policies, and to propose policies that accomplish long- and short-term goals. CICERO's work influences a wide range of audiences, including national and international organizations, government agencies, and academics.

CICERO's research branch has three main programs, focusing on scientific basis and international agreements; mitigation and costs; and the impacts, vulnerability, and adaptation of climate policies. The primary purpose of the scientific basis division is to perform scientific analysis and to incorporate its findings into practical policies and recommendations. In the scientific basis program, the center's researchers explore the effects that greenhouse gases such as carbon dioxide (CO_2), nitrous oxide (N_2O), and perfluorocarbons (PFCs) have on climate. The researchers monitor the effects climate policies have on the global climate system. Many of the published studies discuss how the distribution of greenhouse gases is affecting atmospheric composition. Aside from scientific research, scholars in this division also take part in policy development. Researchers work on creating ways to track the emission of greenhouse pollutants, while others are involved in climate policy negotiations.

The second program looks into the socioeconomic costs and benefits of greenhouse gas emissions and climate policies. This division's objective is to diminish the detrimental effects brought on by climate change. It also applies economic models in order to evaluate the advantages and disadvantages of policies. Scientists examine the impacts greenhouse gases have on energy stability. Besides focusing on how climate fluctuation affects regional populations, climate experts also focus on how it affects the agriculture industry. More specifically, researchers examine the effects pollution and the thinning ozone have on crop growth and yield. The relationship between climate change and the environment is also studied; some of the research topics include acidification, deforestation, and soil erosion. Moreover, scientists examine the connection between climate change and natural disasters such as floods, water shortages, and forest fires.

The third research division identifies the problems caused by climate fluctuations, to discover the attributes that increase regions' susceptibility to climate fluctuations. Additionally, experts take on multidisciplinary research efforts to study how variables such as trade and globalization impact the climate and the environment. Scientists in many different disciplines, such as economics, political science, anthropology, and resource development, work together to construct theoretical and empirical models to assess countries' vulnerabilities to climate change. The team of experts provides solutions to allow a region to accommodate the changes in climate, while minimizing their damaging effects, and measuring the efficacy of these strategies.

CICERO has trained many scholars involved in climate study. It also disseminates research data and policy recommendations. *Cicerone2*, a magazine published by the center, presents recent research findings on climate and environment issues. It also discusses climate policies and regulations. *Cicerone2* also comments on international climate change conferences. CICERO also holds forums to encourage scholars, policymakers, and government officials to discuss the latest developments on climate and its related policies. Its experts attend conferences and international meetings such as the United Nations Framework Convention on Climate Change to present data and commentary.

CICERO is involved in several projects. Some of these include examining what effects energy regulations have on energy sources that are not sensitive to changes in price. Others aim to develop a model to translate the damage caused by environmental pollution into numeric value. The team of scientists at CICERO also collaborate with Chinese experts and policymakers on identifying how different population cohorts are affected by climate policies. The organization also devotes attention and resources to climate issues in Norway. A notable upcoming project focuses on how different communities in Noway cope with global warming.

Charlene Wu
Johns Hopkins University

Center for International Environmental Law

ACCORDING TO ITS website, "the Center for International Environmental Law (CIEL) is a nonprofit organization working to use international law and institutions to protect the environment, promote human health, and ensure a just and sustainable society." It aims to: use law to contribute to solve environmental problems and promote sustainable societies, introduce principles of ecology and justice into international law, strengthen national environmental law systems and support public interest movements, and educate and train public interest environmental lawyers.

CIEL advises key participants in the international policy arena on how to work toward a sustainable, enforceable emissions-reduction framework. It is widely recognized as a leading legal research institute, earning respect for objective analysis and strong commitment to the environment. A key part of CIEL's strategy is to provide legal support and advice to other environmental organizations and representatives of indigenous and other local communities, helping build their capacity to advocate for a just and effective climate regime.

ARCTIC AND SUBARCTIC ISSUES

To strengthen the global response, CIEL's Climate Change Program focuses on impacts to people and ecosystems of the Arctic and subarctic. The program works to protect the Earth's climate system through promotion of human rights, forest conservation, and biodiversity protection. According to the Intergovernmental Panel on Climate Change, the destructive effects of climate change will not only affect the environment, but also Arctic peoples. Average annual temperatures in the Arctic have increased by approximately double the increase in global average temperatures.

The direct impacts of global warming include higher temperatures, sea-level rise, the melting of sea ice and glaciers, increased precipitation in some areas, and drought in others. Indirect social, environmental, economic, and health impacts will follow, including increased death and serious illness in poor communities, decreased crop yields, heat stress in livestock and wildlife, and damage to coastal ecosystems, forests, drinking water, fisheries, buildings, and other resources.

During the past several decades, the Arctic has warmed at an alarming rate, and it is projected to continue to warm by as much as 18 degrees F (10 degrees C) by 2100. This warming trend has had a devastating impact on Arctic ecosystems, including sea ice, permafrost, forests, and tundra. Warming has contributed to increases in lake temperatures, permafrost thawing, increased stress on plant and animal populations, and the melting of glaciers and sea ice. Research has revealed decreases in sea ice extent and cover.

In Shishmaref, Alaska, a small Inuit village in the Chukchi Sea, seven houses have had to be relocated, three have fallen into the sea, and engineers predict that the entire village of 600 houses could disappear into the sea within the next few decades. Shishmaref's airport runway has almost been met by rising seawater, and its fuel tank farm, which seven years ago was 300 ft. (92 m.) from the edge of a seaside bluff, is now only 35 ft. (10 m.) from the bluff. The town dump, which has seawater within 8 ft. (2 m.) of it, could pollute the nearby marine environment for years if inundated. Advancing seawater has contaminated Shishmaref's drinking water supply.

If global warming continues unchecked, it threatens to destroy their culture, render their land uninhabitable, and rob them of their means of subsistence. Subsidence due to permafrost melting is destroying homes, roads, and other vital structures in the Arctic. The harm caused by carbon dioxide emissions already violates some fundamental internationally recognized human rights such as those recognized in the American Declaration of the Rights and Duties of Man: the right to life (Art. I), the right to residence and movement (Art. VIII), the right to inviolability of the home (Art. IX), the right to preservation of health and to well-being (Art. XI), the rights to benefits of culture (Art. XIII), and the right to work and to fair remuneration (Art. XIV).

International tribunals have recognized that harm to the environment that affects one's home can violate these rights. For example, in *Lopez Ostra v. Spain*, the European Court of Human Rights held that Spain's failure to prevent a waste treatment plant from polluting nearby homes violated the petitioner's "right to respect for her home and her private and family life," and held the state liable for damages.

CIEL and Earth Justice petitioned the Inter-American Commission of Human Rights on behalf of the Inuits. The commission has in the past recognized the relationship between human rights and the environmental effects of development activities, and its interpretation of this relationship suggests that it would recognize the human rights implications of the effects of global warming. The United States has not ratified the convention, and, as such, is not subject to the jurisdiction of the court. However, a report by the commission examining the connection between global warming and human rights could have a powerful impact on worldwide efforts to address global warming. Recognition by the commission of a link between global warming and human rights may establish a legal basis for holding responsible countries that have profited from inadequate greenhouse gas regulation and could provide a strong incentive to all countries to participate in effective international response efforts.

The Arctic may warm by as much as 18 degrees F by 2100, and research has already found a decrease in sea ice and cover.

CIEL's Climate Change Program works to develop and strengthen the rules within the international climate change legal regime. Its primary goal is to get the rules right so that the Kyoto Protocol can become a genuine tool for environmental protection and sustainable development. During the course of climate negotiations, proposals developed by the center have been included in the negotiating texts and supported by governments and international institutions. The key areas of focus for the center's Climate Change Program include: accounting rules that ensure verifiable emissions reductions, promote sustainable development, conserve biological diversity and respect other ecological values; compliance and monitoring systems for enforcing the Kyoto Protocol; participation of the public, including directly affected local communities and civil society in the Kyoto Protocol; and domestic policy to combat global warming.

Center for Ocean-Atmospheric Prediction Studies

THE CENTER FOR Ocean-Atmospheric Prediction Studies (COAPS) at Florida State University (FSU) carries out research in air-sea interaction, ocean and coupled air-sea modeling, climate prediction, statistical studies, and predictions of social/economic consequences of ocean-atmospheric variations. Students in COAPS come from a wide variety of departments including meteorology, mathematics, computer science, and physical oceanography. COAPS is funded by several federal agencies, producing original published papers that advance our understanding of the ocean and the atmosphere and their role in shaping the Earth's climate. It has over 50 people working on research grants totaling more than $3 per year. COAPS faculty are members of the meteorology and oceanography departments. It has graduate students as well as undergraduate research scholars.

COAPS's areas of research are quite broad. It places a particular emphasis on research to improve hurricane storm surge predictions in the Gulf of Mexico and to develop an understanding of the regional distributions of hurricane activity in the United States. This aspect is of particular importance to Florida and coastal residents. Among other topics, COAPS research includes understanding oceanographic measurements obtained from satellites for sea-surface winds, sea-surface shape, and ocean color. It also encompasses climate forecasting for farmers in Florida, Georgia, and Alabama using coupled atmosphere-ocean global and regional models.

Weather and crop reports are offered to Florida, Georgia, and Alabama farmers through the Florida Climate Center. In addition, COAPS has created AgClimate, an interactive website with climate, agriculture, and forestry information, to assist farmers to manage their crops for maximum outcome. AgClimate uses crop simulation models along with historic and forecast climate data so farmers can compare probable outcomes under different climate conditions. AgClimate tools are aimed at providing farmers with opportunities for adaptating to seasonal climate forecasts so as to limit the production risks caused by climate variability. Tools provide information for specific counties as well as regional overviews.

The research on air/sea interaction focuses on the transfer of energy from the atmosphere to the ocean. Areas of interest cover theoretical modeling, analysis of in situ observations, satellite-based observations, flux coupling for ocean and atmospheric models, and analysis of spatial/temporal variability in surface turbulent fluxes. The In-Situ Fluxes Project at FSU aims to provide better products for marine surface variability. In particular, it addresses the transfer of energy between the ocean and the atmosphere, as well as variables related to this problem (wind speed, wind vectors, sea-surface temperature, air temperature, humidity, surface pressure, and wave characteristics).

FSU In-Situ Fluxes produces monthly averages, based solely on in situ observations (ships and buoys). The FSU Satellite Fluxes largely rely on satellite observations that offer finer resolution in space and time. The project provides a new set of ocean surface forcing fields to understand the global climate system and favor climate prediction. The long-term monthly fields are suitable for seasonal to decadal studies, and the related hybrid satellite and numerical weather prediction (NWP) fields can be employed for daily-to-annual variability and quality assessment.

COAPS is carrying out research on climate change with the National Center for Atmospheric Research (NCAR). Together the two centers are building a new version of the Community Climate System model (CCSM), using the Hybrid Coordinate Ocean Model (HYCOM) as the oceanic model. The CCSM is one of the most respected models in the climate research community. In this project, the CCSM is not employed with the conventional depth vertical coordinate, but with an oceanic model that uses hybrid vertical coordinates. Comparisons will be performed between the new CCSM/HYCOM and the standard (CCSM/POP) version. After the validation of the new coupled model, decadal to centennial time scale experiments will be conducted to study climate change (decades to centuries) and climate variability (seasonal to inter-annual). These experiments will include Intergovernmental Panel on Climate Change (IPCC) integrations as well as investigations of the response and feedback of the ocean to external climate forcing.

COAPS recognizes the Earth's climate as a dynamic system with regional and local variations. It studies climate variability by looking at variations in daily maximum and minimum temperatures across the United States. Researchers examine the trends in temperature at both automated national weather service sites and cooperative observing stations. COAPS also works on the dynamical forecasting/hindcasting of Northern Hemisphere tropical Atlantic basin hurricane activity. To address hurricane prediction, it employs the FSU/COAPS climate global atmospheric model (T126L27) and the FSU/COAPS atmospheric model coupled to the newly-developed Max Planck global ocean model with orthogonal curvilinear coordinates.

In this same area, COAPS examines crop yields as determined by a dynamical downscaled atmospheric model. Climate variability has been shown to be a significant factor in agricultural crops. The seasonal climate shifts due to El Niño–Southern Oscillation (ENSO) phase in the southeastern United States significantly influence corn, wheat, cotton, tomato, rice, and hay production. COAPS uses the FSU/COAPS global and regional models in hindcasting/forecasting crop yields over the southeastern United States. Finally, COAPS compares statistically-downscaled climate data and data generated by dynamical models. The global and regional models used for these studies are all dynamical COAPS is comparing studies using statistical downscaling techniques against dynamical methods. COAPS research has pointed out that the advantage of statistical methods is that they are relatively inexpensive computationally and can be performed at any spatial resolution. Seasonal characteristics and higher moment statistics are some of the comparisons being carried out.

OCEAN MODELING

Ocean-modeling activities at COAPS include model development, research, and graduate instruction. COAPS uses models of various complexity, architecture, and horizontal and vertical coordinate representation as the principal tools. Models employed at COAPS vary from very high-resolution regional models to basin-scale and global models. The models currently used at COAPS are: Navy Coastal Ocean Model (NCOM); Finite Volume Community Ocean Model (FVCOM); Hybrid Coordinate Ocean Model (HYCOM); Regional Ocean Model System (ROMS) (regional/coastal); HYCOM (basin-scale); Hamburg Ocean Primitive Equation (HOPE); HYCOM (global). Model experiments are routinely run on the local COAPS computers as well as at various supercomputer centers (FSU, Naval Oceanographic Office [NAVOCEANO], National Center for Atmospheric Research [NCAR]).

Modeling studies address a wide range of topics from exploring physical processes in the deep and upper ocean to improving ocean forecasting. Coupling of the ocean models with different atmospheric/flux models gives researchers the chance to study air-sea interaction at a wide variety of time scales. For example, regional models coupled to the BVW atmospheric heat flux model are used to simulate more realistic analyses of the air-sea interaction and ocean response during hurricanes. The global models are coupled to either the COAPS/FSU global atmospheric model or to the NCAR Community Atmosphere Model (CAM) within the CCSM. These coupled models are used to investigate climate variability or climate change.

High-resolution numerical models are used at COAPS to study the physical environment of the Gulf of Mexico, which has long been an area of expertise. Researchers have explained why the actual height of the storm surge generated by Hurricane Dennis on the North Florida Coast was 8–10 ft. instead of the predicted 3–5 ft. The result of the project pointed out that, although Dennis had only modest winds off West Florida, these winds drove water on shore which morphed into a barotropic shelf wave that propagated to St. Marks, Florida, nearly doubling the surge caused by local winds. This research had important consequences as it led the National Oceanic and Atmospheric Administration (NOAA) to modify storm surge forecasting methods in the Gulf of Mexico, by including larger model domains to account for remotely-generated sea level anomalies.

For their study on the Gulf of Mexico, researchers at COAPS use two models. NCOM developed at the U.S. Naval Research Laboratory (NRC), is a three-dimensional primitive equation ocean model that has been optimized for running on supercomputers. The NCOM representations serve as a virtual laboratory for studying the physics of the ocean circulation within the Gulf of Mexico. Projects encompass studies of the Loop Current and its eddies within the deep ocean, the circulation on the continental shelves near the coast, the interaction of eddies with the waters of the continental shelves, and the impacts of river discharge on the ocean environment. Additionally, the model is used to advance the understanding of numerical methods, ocean prediction systems, and air-sea interaction.

The second configuration is based the HYCOM, which operates in near real time by the NRL at Stennis Space Center. More specifically, the goal is to further develop this configuration within the framework of the Northern Gulf Institute into a coupled ocean-atmosphere-biogeochemical modeling system. This modeling configuration will include: forcing from a high resolution regional atmospheric model, a wave model to improve the flux computations, real-time river discharge, tidal forcing, and a complex biogeochemical model. COAPS is developing a very high-resolution regional model of the northeastern Gulf and will become part of this Gulf of Mexico HYCOM modeling system.

COAPS works in the field of physical oceanography and ocean prediction within the Global Ocean Data Assimilation Experiment (GODAE), which provides a framework for attempts to combine numerical models and observations via data assimilation to provide ocean prediction products on various spatial and time scales. GODAE supplies a global system of observations, communications, modeling, and assimilation that will deliver regular, comprehensive information on the state of the oceans. COAPS believes that studies in physical oceanography and ocean prediction will result, not only in increased knowledge of the marine environment and ocean climate, but also in improved predictive opportunities that will benefit commercial and industrial sectors of society. The development of this ocean prediction capability will allow a better scientific understanding of ocean physical processes and their influences on marine ecosystems. COAPS works within a large partnership of institutions to develop the performance and application of eddy-resolving, real-time global and basin-scale ocean prediction systems using HYCOM. This partnership is sponsored by the U.S. component of GODAE.

RISK ASSESSMENT

COAPS has a special area of research in risk assessment in the categories of storm surge, freeze forecasting, and fire weather. COAPS is developing new methods to predict the amount of storm surge that will hit the Gulf Coast during a storm that can be very destructive for coastal property. COAPS has played a central role in the research of climate variability related to the ENSO.

The center is involved in the Southeast Climate Consortium and has developed variability and forecast tools applicable to agricultural interests in the southeastern United States. These tools are centered on shifts in the traditional climate variables (monthly averaged temperature and precipitation), but also on extreme events such as droughts, severe weather, hurricanes, and damaging freezes. Through an examination of historical freeze events in central and south Florida, COAPS has revealed a strong connection between ENSO and the occurrence of damaging freezes. Specifically, the severe or damaging freezes tend to occur during the neutral ENSO phase and are much less likely during El Niño or La Niña.

Based on the analysis of more than 50 years of historical weather observations, COAPS makes available a probabilistic freeze forecast for the winter season which is released every fall, based on the state of the tropical Pacific Ocean. The forecast is widely disseminated; it is available online on agclimate.org, is published in agricultural newsletters and publications, and is also presented at winter weather workshops throughout the state. Going to the opposite extreme, COAPS has cooperated with the Florida Division of

Forestry in research projects to identify the connection between ENSO and wildfire burn acreage in Florida. As an extension and continuation of that research, COAPS, funded by the Florida Division of Forestry and the United States Department of Agriculture Forest Service, has developed a prototype wildfire risk forecast system for Florida and the Southeast.

COAPS is also active in satellite studies of the ocean and atmospheric variability. It uses weather radar observations and scatterometers, which estimate near-surface wind speed and direction, as well as surface stress. COAPS also employs a wide variety of instruments to measure wind speed and sea surface temperature.

Center for Science and Environment (India)

THE CENTER FOR Science and Environment (CSE) was established in 1980 by a group of engineers, scientists, journalists, and environmentalists to increase public awareness of science, technology, environment, and development in New Delhi, India. The center became functional with a small group of writers in 1981, and, in its first year, it was involved in producing an information service on science and society-related issues such as energy, environment, health, human settlements, and the impact of science and technology at the grassroots level.

Anil Agarwal, an environmental journalist, advocate, and analyst, was its original founder. His biggest achievement has been to spread the environmental message in India and abroad. Also notable was his invaluable role in arguing for equity in global environmental management in the process that led up to the Rio Earth Summit. He worked to put environment on the global political and civil society agenda from a Southern Hemisphere perspective. Most importantly, through his writings and advocacy, he played a vital role in providing the answers for an environmentally sound development strategy for countries such as India. Sunita Narain, CSE's present director, has carried on with advocacy for the Global South, and has played an important role in climate change negotiations. The center has advocated for the Global South and developing countries. According to its briefing paper, "Equity is a prerequisite for any global agreement, particularly when dealing with the pollution of a global common property resource such as the atmosphere."

CSE helps the public to search for solutions that people and communities can implement, and/or push the government to create a framework for people and communities to act on their own. CSE is considered one of India's leading environmental nongovernmental organizations specializing in sustainable natural resource management. Its strategy of knowledge-based activism has won it wide respect and admiration for its quality of campaigns, research, and publications worldwide. CSE promotes solutions for India's numerous environmental threats, including ecological poverty and extensive land degradation, and rapidly-growing toxic degradation of uncontrolled industrialization and economic growth.

In late 1981, the center embarked upon a major exercise, the *State of India's Environment*, the first citizen's report on the environment. It was a unique document that was prepared in active collaboration with concerned academics, activists, and citizens' groups across the country. The report had a critical impact on the unresolved worldwide debate on environment versus development. The cynics argued that northern India, already affluent, now also wanted clean air and water for their health, and nature parks for recreation. The report detailed how environmental destruction usually targets the poor, who survive on the resources provided by nature. Any development that destroys the environment exacerbates poverty and increases unemployment by destroying the survival base of the poor. This is particularly true of India, which has a large number of biomass-dependent people and a high population density; therefore, a developing country such as India has to take care of its environment even more than an industrialized country. The report generated much debate and was widely read and reviewed nationally and internationally. The United Nations Environment Programme in Nairobi called it a model for all countries to follow.

The second citizens' report was perhaps the first report that showed how environmental degradation has a disproportionate impact on women. Since then, this idea has been widely accepted. The *State of India's Environment* also caught the attention of the Indian Prime Minister Rajiv Gandhi, who invited the center, in 1986, to address the nation's Council of Ministers and the Parliament on the importance of sustainable development.

The third citizens' report, the *State of India's Environment: Floods, Floodplains and Environmental Myths*, was published in 1991. It broke new ground by arguing that the severe floods in the Gangetic Plain and the Brahmaputra River Valley (areas that are more flood-prone than any other region of the world) can be controlled by better management of the floodplains, not the rivers' uplands, as conventional belief dictated.

The fourth citizen's report, *Dying Wisdom: The Rise, Fall and Potential of Traditional Water Harvesting Systems*, was published in 1997, the completion of an eight-year exercise that documented India's millennia-old traditions in water management and rainwater harvesting. This seminal publication on water management started a nationwide interest in community and household-based water harvesting initiatives. It argued that the management of water should be everybody's business. Several Indian states, including Madhya Pradesh, Gujarat, and Andhra Pradesh, and even the central government launched major rainwater harvesting initiatives to combat drought and widespread land degradation.

Incorporating nationwide research efforts, the fifth citizens' report, the *State of India's Environment*, was published in 1998. The fifth report came in two parts. The first part was a comprehensive dossier on environmental issues, events, policies, and practices. The second provided statistical analyses on different aspects of India's environment. CSE's citizens' reports have been the combined product of networking, constituency-building, and intellectual leadership. They have received national and international acclaim and have been translated into several Indian languages.

In early 1992, CSE organized the first South Asian nongovernmental organization summit to discuss the agenda of the forthcoming United Nations Conference on Environment and Development meeting at Rio de Janeiro, and to prepare common positions of South Asian nongovernmental organizations. The summit helped to promote a common understanding in the region on critical global environmental issues. Four staff members represented CSE at the Rio conference. The director, Anil Agarwal, was a member of the official Indian delegation. The team intervened in the forest convention debate and mobilized public opinion in favor of the view that the world's forests are best managed by the local communities. The industrialized countries, on the other hand, had proposed a system in which economic interests in the developed nations and professional foresters could control the levers of forest management.

While Rio established environment firmly in the political agenda, implementation of the agreement has been hesitant and slow. CSE has identified its key function as an agency monitoring international developments, research, and analysis of issues, and initiating an informed public debate in India, in particular, and the developing world, in general. CSE's researchers have tried to develop a policy framework for participatory and environmentally-sound development. Some of the significant concepts that have emerged from CSE's past research programs are: the need for ecosystem-specific and culture-specific approaches to economic development; participatory, legal, and institutional mechanisms for rural development; the importance of traditional knowledge systems; and just and equitable governance for global environmental problems.

Natural Resource Consultant

Central African Republic

A FORMER FRENCH colony in central Africa, the Central African Republic is entirely landlocked and has an area of 240,534 sq. mi. (622,984 sq. km.), with a population of 4,216,666 (2007 est.), and a population density of 17.5 people per sq. mi. (6.8 people per sq. km.). The country is poor, with 3 percent of the land arable, and a further 5 percent used for meadows and pasture. In spite of this, many of the desperately poor people in the country survive through subsistence farming.

Some 64 percent of the country is forested, which helps reduce its already extremely low carbon dioxide (CO_2) emissions from the country. CO_2 emissions per capita from the Central African Republic have never exceeded 0.1 metric tons per person, reaching 0.06 metric tons per person by 2003. These come entirely from the use of liquid fuels, and the country has a poor public transport network. It has also faced problems with water shortages, not only due to global warming and climate change, but also from the growing of cotton that has been used to manufacture velvet.

The government of André Kolingba took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and it ratified the Vienna Convention in the following year. The government has so far not expressed an opinion on the Kyoto Protocol to the UN Framework Convention on Climate Change.

Geelong Grammar School, Australia

Chad

A FORMER FRENCH colony, Chad has a land area of 495,753 sq. mi. (1,284,000 sq. km.), with a population of 10,146,000 (2005 est.), and a population density of 20.4 people per sq. mi. (7.9 people per sq. km.). Although 85 percent of the people work in agriculture, only three percent of the land is arable; a further 36 percent of land is used for pasture, much of it with extremely poor soil. Some 26 percent of the country is forested, and this has lessened the already extremely low carbon dioxide (CO_2) emissions. Its per capita emission rate is 0.01 metric tons per person, the second lowest rate in the world, only slightly more than Somalia.

All of Chad's CO_2 emissions come from liquid fuels. The country has a very small public transportation system, with most people traveling long distances by hitching rides with trucks. The railway line planned in 1958 to link Bangui in the Central African Republic with N'Djamena, Chad's capital, was never completed. As a result, many of the elite and middle-class use cars, adding to air pollution. The government of Hissène Habré ratified the Vienna Convention in 1989. His successor, Idriss Déby, took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992.

Although the Déby government has not expressed its stance on the Kyoto Protocol to the UN Framework Convention on Climate Change, Chad is likely to be one of the countries most affected by climate change and global warming. This is particularly apparent through the marginalization of agricultural land, the reduction of rainfall, the increased demand for water for agricultural irrigation, and temperature change. These environmental factors have led to a dramatic reduction in the size of Lake Chad, which has decreased in size from 9,650 sq. mi. (25,000 sq. km.) in 1963, to 521 sq. mi. (1,350 sq. km.) in 2007.

Chamberlin, Thomas C. (1843–1928)

THOMAS C. CHAMBERLIN was an American glacial geologist and educator who, at the turn of the 20th century, challenged the generally accepted Laplacian theory that the Earth was formed by hot gases and was gradually becoming cooler. He suggested the planetesimal hypothesis, arguing that the planets were formed after a star passed near the Sun, pulling away material from both bodies that later condensed into the planets. Chamberlin was one of the first scientists to emphasize the role of carbon dioxide in regulating the Earth's temperature, thus anticipating the current debates on global warming. Chamberlin also founded the *Journal of Geology*, acted as its editor for many years, and was the first director of the U.S. Geological Survey's Pleistocene Division (1881–1904).

Chamberlin was the first geologist to demonstrate that there had been multiple Pleistocene glaciations in North America. He offered early analyses of moraines, drumlins, eskers, and boulder trains. Starting from these features, he worked out regional glacial flow patterns and calculated the outermost limits of the two last glacial advances.

Chamberlin was born on September 23, 1843. At the time of Chamberlin's birth, his family was living in Mattoon, southern Illinois, but they soon moved north to Beloit in Wisconsin. The future scientist grew up in a religious family (his father was a Methodist minister), where education was held in high esteem. With his four brothers, Chamberlin attended a preparatory academy, and then Beloit College, where he developed a strong interest in natural science. The young Chamberlin was immediately attracted to geology, in spite of the apparent conflicts with his strong Methodist background. While studying at Beloit College, where he was an outstanding student, Chamberlin directed the church choir.

To finance his education, Chamberlin worked in country schools and, upon his graduation in 1866, he became a teacher, and later, principal in a high school near Beloit. He became a particularly popular speaker within the community, giving lectures on science and organizing field trips. In 1867, he married Alma Wilson. The couple had one son, Rollin, who also became a distinguished geologist. Chamberlin went to the University of Michigan for the academic year 1868–69 to strengthen his overall science background and thereafter became very critical of the classical curriculum in colleges. He then went on to teach natural science at the Whitewater, Wisconsin, Normal School, and joined the Beloit faculty in 1873, where he was professor of geology, zoology, and botany.

In 1873, Chamberlin was recruited to work part time with other geologists on a comprehensive geological survey of Wisconsin, the task that marked the beginning of his career in glacial geology. In 1876, due to the reorganization of the survey, Chamberlin was appointed chief geologist and, over the next six years, he supervised the completion of the project. The resulting publication, consisting of four large volumes of the highest academic standards, brought Chamberlin to national attention and led to his appointment as head of the glacial division of the national survey in 1881.

Six years later, the board of regents of the University of Wisconsin in Madison invited Chamberlin to be president. During his tenure, Chamberlin introduced many reforms aimed at strengthening the science curriculum and recruiting outstanding faculty members. He also established the extension program, offering farmers new knowledge that could be helpful to them. He introduced seminars as a core element of teaching and started formal postgraduate study with a Ph.D. program. In 1892, Chamberlin accepted the chair of the geology department at the University of Chicago, a position that he kept for the next 26 years. As a chair, he made the department one of the world's leading institutions in the field and established the Walker Museum.

While at Chicago, Chamberlin worked with astronomer Forest R. Moulton to define the planetesimal hypothesis. Their research was published in *Two Solar Families* (1928). With Rollin Salisbury, he coauthored *Geology* (1904–06), probably the most influential American textbook of geology before World War II. At a time when single, comprehensive introductory textbooks were not common, *Geology* had a profound impact. In 1909 Chamberlin worked for the Rockefeller Foundation, spending five months in China to organize an aid program for the country.

Chamberlin retired in 1918. Although he is best remembered for the planetesimal theory, Chamberlin's interest in glaciation led him to question prevailing notions of a gradually cooling earth, making him an important forerunner of global warming debates. The cycles of glacial formation, growth, and retraction that he identified suggested that the Earth was warming up, rather than cooling down. To find an explanation, Chamberlin investigated climatic change, focusing on changing levels of carbon dioxide in the atmosphere.

As far as methodology was concerned, Chamberlin argued that evidence should never be accepted uncritically. Researchers should always maintain an open mind, testing several hypotheses at once. This is known as the method of multiple working hypotheses, which he pioneered in spite of a certain dogmatism that his conclusions tended to acquire later in his career. Chamberlin was awarded countless honors and prizes during. He was president of the Geological Society of America (1894–95), president of the Wisconsin (1885–86), Chicago (1897–1915), and Illinois (1907) academies of science, president of the American Association for the Advancement of Science (1908–09), member of the National Academy of Sciences (1903), and the first Penrose Medalist of both the Society of Economic Geologists (1924) and Geological Society of America (1927). He was also a member of the American Philosophical Society and the American Academy of Arts and Sciences and received six honorary degrees. Chamberlin died on November 15, 1928, in Chicago.

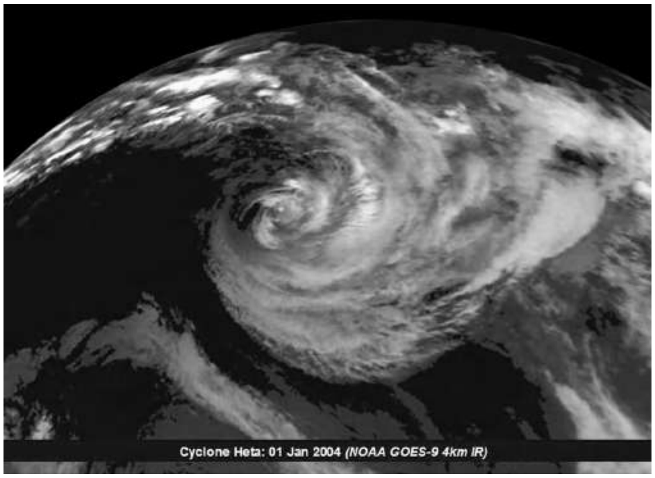
Chaos Theory

NONLINEAR DYNAMICAL SYSTEMS that have sensitive dependence on initial conditions may exhibit chaotic behavior. In other words, if initial conditions are available only with some finite precision, two solutions starting from undistinguishable initial conditions (i.e., whose difference is smaller than the precision) can exhibit completely different future evolutions after time. Thus, the system behavior is unpredictable. Sensitive dependence on initial conditions can occur even in deterministic systems whose solutions are not influenced by any stochastic effects. Chaos theory attempts to find an underlying order in such chaotic behavior

In the early 1900s, H. Poincare noticed that simple nonlinear deterministic systems can behave in a chaotic fashion. While studying the three-body problem in celestial mechanics, he found that the evolution of three planets could be complex and sensitive to their relative initial positions. Other early pioneers in chaotic dynamics from a mathematical viewpoint include G. Birkhoff, M.L. Cartright, J.E. Littlewood, S. Smale, and A.N. Kolmogorov, for a wider range of physical systems. Experimentalists also observed chaotic behaviors in turbulent fluid motion and radio circuits.

Weather is, without a doubt, one of the best examples of chaotic behaviors in nature. Future weather can never be predicted correctly beyond a certain period of time. The first identification of chaotic behavior in atmospheric sciences was made accidentally by E. Lorenz in 1960s. To study the problem of predicting atmospheric convection, he developed a simple deterministic model with 12 variables. Simplified models such as these are quite useful in shedding light on the corresponding complex system. He followed a numerical approach by solving the model on a digital computer. On one occasion, he repeated a numerical experiment using an initial condition that was rounded-off to the first three digits (e.g., 0.506) from the original six digits (e.g., 0.506127), expecting that the difference between the two solutions would remain very small. To his surprise, the new solution stayed close to the original one for about a month of the model simulation, and then suddenly transitioned to a completely different behavior. This discovery has come to be known as the "butterfly effect."

By repeating similar experiments, Lorenz also noticed that transitions happened randomly, irrespective of the size of the perturbations in the initial conditions. To conduct further investigations, Lorenz developed a simpler model, with three variables, able to mimic the chaotic behavior of the 12-variable model, in terms of sensitivity to the dependence on



NASA hurricane animation may help predict storms more accurately. Weather is the best example of a chaotic behavior.

initial conditions. By plotting the solutions, he discovered another astonishing aspect of chaotic behavior: all solutions were attracted to a densely nested curve with a shape of double spirals. Starting from an arbitrary initial condition, a solution eventually reached the double spirals and never left them. It looped around one spiral, occasionally made a transition to the other spiral, then looped around, returning to the first spiral, and so on. The curve clearly moderates the chaotic behaviors of this model and is called the *strange attractor*. Qualitative and quantitative description of chaotic behavior can be made by understanding the properties of the strange attractor.

Since then, advances in scientific computation brought full appreciation to the significant implications of chaotic behaviors in a variety of fields. Many mathematical concepts and techniques have been developed to study such behaviors and make quantitative statements about them. Collectively, they form the chaos theory. Naturally, much of the chaos theory was developed to study and demonstrate the predictability limit.

Fundamental questions in today's atmospheric sciences include the extent of the predictability of weather and climate, as well as the reliability of forecasts made by numerical models. Not only simple but also many realistic models are known to exhibit chaotic behaviors. Chaos theory implies that a single definitive forecast made by such a model will fail because future evolution is unpredictable. This unpredictability is due to the impossibility of obtaining the exact initial condition with arbitrarily high precision, even if the model truthfully describes the evolution of the complex system. Instead, chaos theory suggests the need for "probabilistic forecasts" that express the uncertainty associated with a forecast. For example, the probabilistic forecast of tomorrow's precipitation may be expressed as "95 percent to exceed 0.1 inch," while a definitive forecast may be "0.1 inch."

To represent the uncertainty, and establish a probability distribution associated with a forecast, most leading weather forecast centers use the ensemble forecast approach, in which an ensemble of forecasts is made starting from the initial conditions slightly different from the best possible estimate of the current state of the atmosphere. If all forecasts in the ensemble stay close together, then real future evolution is likely to be close to the mean of the forecasts. In contrast, if the forecasts show a wide spread, then the forecast is considered to have high uncertainty. Uncertainties can be quantified if the ensemble consists of a large number of forecasts. Probabilistic forecasts can be used to study and quantify impact of human activities on future climate change by running the ensemble forecasts of multiple climate models under certain forcing scenarios as described in the Intergovernmental Panel on Climate Change (IPCC) reports.

Carl Palmer
Independent Scholar

Charney, Jule Gregory (1917–81)

JULE GREGORY CHARNEY was an American meteorologist who contributed to the advance of numerical weather prediction and to increased understanding of the general circulation of the atmosphere by devising a series of increasingly sophisticated mathematical models of the atmosphere. Charney was one of the dominant figures in the field of atmospheric science in the decades following World War II. Jule Gregory Charney was born in San Francisco, California, on January 1, 1917, to Ely Charney and Stella Littman. His parents were Yiddish-speaking Russian Jews who worked in the garment industry and were left-wing militants. The family moved to Los Angeles in 1922.

Charney earned several degrees from the University of California at Los Angeles (UCLA): an A.B. in mathematics in 1938, an M.A. in mathematics in 1940, and a Ph.D. in meteorology in 1946. In that same year, Charney married Elinor Kesting Frye, a student of logic and semantics at UCLA. The couple had two children, Nora and Peter. In 1967, Charney married a second time, to Lois Swirnoff, a painter and color theorist who was a professor at UCLA and Harvard.

While completing his Ph.D., 1942–46, Charney was an instructor in physics and meteorology at UCLA. The entire October 1947 issue of the *Journal of Meteorology* was devoted to the publication of his dissertation, entitled "Dynamics of Long Waves in a Baroclinic Westerly Current." This paper emphasized the influence of long waves in the upper atmosphere on the behavior of the entire atmosphere and provided a simplified method of analyzing perturbations along these waves.

After graduation, Charney worked for a year as a research associate at the University of Chicago. During the academic year 1947–48, he held a National Research Council postgraduate fellowship at the University of Oslo, Norway. While in Oslo, he developed a set of equations for calculating the large-scale motions of planetary-scale waves known as the quasi-geostrophic approximation. Charney's method replaced the horizontal wind by the geostrophic wind as the term representing the vorticity. He did not make this replacement in the term representing the divergence. Thanks to this change, Charney was able to come up with a manageable set of filtered equations calculating large-scale atmospheric and oceanic flows.

Two years after his graduation, Charney joined the Institute for Advanced Study in Princeton, New Jersey. Charney served as director of theoretical meteorology in a project to develop a computer program. With his team, he constructed a successful mathematical model of the atmosphere and showed that numerical weather prediction could be done using the Electronic Numerical Integrator And Computer (ENIAC), which took 24 hours to generate a forecast, and von Neumann's stored-program computer to create a forecast in five minutes. In 1954, Charney contributed to establishing a numerical weather prediction unit within the U.S. Weather Bureau. He is considered to have pioneered the use of computers in forecasting.

In 1956, the Massachusetts Institute of Technology (MIT) hired Charney as professor of meteorology and 10 years later he was made Alfred P. Sloan professor there. His research dealt with the dynamics of atmospheres and oceans. From 1963 to 1966, he chaired the National Research Council's Panel on International Meteorological Cooperation.

From 1968 to 1971, he coordinated the U.S. Committee for the Global Atmospheric Research Program (GARP). This international project, which lasted for an entire decade, aimed to measure the global circulation of the atmosphere, to represent its behavior, and to develop better predictions of its future state.

Charney's role was fundamental in setting the global agenda and vision of GARP. The scientist repeatedly stressed that researchers should view the atmosphere as a single, global system. Charney was always a convinced supporter of international cooperation in meteorology and constantly pointed out that the lack of global observations prevented examination of the global side of the discipline.

During his long career, Charney received many awards and honors. He was a fellow of the American Academy of Arts and Sciences, the American Geophysical Union, and the American Meteorological Society. He was a member of the U.S. National Academy of Sciences and a foreign member of the Norwegian and Royal Swedish Academies of Science.

The most important awards that Charney garnered were the Meisinger Award (1949), the Rossby Medal (1964) (both by the American Meteorological Society), the Losey Award of the Institute of Aeronautical Sciences (1957), the Symons Medal of the Royal Meteorological Society (1961), the Hodgkins Medal of the Smithsonian Institution (1968), and the International Meteorological Organization prize (1971). He was extremely popular as a visiting professor and guest lecturer. The University of Chicago awarded him an honorary D.Sc. in 1970.

Charney's career was complemented by his political commitment. After the invasion of Cambodia and the Kent State shootings in May 1970, he conceived his most ambitious political project, setting up the Universities National Antiwar Fund, raising money from academics to support anti-war candidates in the upcoming elections. Charney died from cancer in Boston, Massachusetts, on June 16, 1981. The American Meteorological Society honors Charney's memory by presenting an award named after him to reward individuals for "highly significant research or development achievement in the atmospheric or hydrologic sciences."

Chemistry

CHEMISTRY IS THE academic discipline concerned with the study of the composition, structure, properties, and speed of change of matter. The main building blocks of matter of interest to the chemist are elements, atoms, and molecules. A chemical element is a pure substance comprised only of one type of atom. The atom is the smallest unit of an element and is comprised of subatomic particles called protons (positively charged), neutrons (no charge), and electrons (negatively charged). The neutrons and protons reside in the central core of the atoms called the nucleus, whereas the electrons are smaller and free moving. The number of electrons in a given atom balances the protons, and this number is characteristic of any atom of a given element.

Dmitri Mendeleev, a Russian chemist, produced the first periodic table in 1869. In this table, elements are arranged in increasing order of the number of protons and are placed in columns based on common properties. The first element in the periodic table is hydrogen, which is comprised of only one proton and one electron. Other elements of interest include carbon, which has atoms containing 6 protons, oxygen with 8, and iron with 26. Although the number of protons and electrons is characteristic of an atom of a given element, the number of neutrons may vary. Two atoms of the same element, with different numbers of neutrons, are called isotopes. Carbon, for example, has three naturally occurring isotopes with 6, 7 or 8 neutrons; these are named carbon-12 (^{12}C), carbon-13 (^{13}C) and carbon-14 (^{14}C), as both the number of neutrons and protons is taken into account in the nomenclature. Of the three isotopes, only ^{12}C is stable.

Atoms are described as physically stable if the atom itself does not decay into its constituent parts or to smaller atoms. The vast majority of the elements toward the top of the periodic table are stable, whereas those with a greater number of protons (more than 85) toward the bottom of the table are not. The most stable element is iron. In contrast to their physical stability, the vast majority of elements are chemically reactive. The term *chemical reactivity* describes the reaction between atoms that combine to form molecules and compounds. An atom is unreactive to other atoms/molecules (inert) if it has a closed outer shell of electrons. The number of electrons required to do this varies as a function of the size of the atom (as predicted by quantum theory). The periodic table reflects this by placing the stable elements on the right-hand side, referred to as the inert or nobel gases. All other elements will undergo chemical reaction in which electrons from each atom are shared in order to achieve the same number of electrons as a nobel gas.

Chemistry is conventionally divided into three subdisciplines: organic, inorganic, and physical. Organic chemistry studies the reactions of molecules that have a carbon and hydrogen skeleton, with additional atoms of oxygen, nitrogen, phosphorous, and sulfur. Organic chemistry is so named, as these are the elements that make up life; most of its applications are the pharmaceutical and petrochemical industries. Inorganic chemistry deals with the reactions of molecules without a carbon and hydrogen-based skeleton, and has a wide range of applications, from catalysts to nuclear reactors. Physical chemistry is the study of the underlying structure of matter and the mechanisms and speed of chemical changes that underpin the other subdisciplines. Physical chemistry is also concerned with the interaction of radiation and matter. Other important subdivisions include biochemistry (study of organic molecules in cells), analytical chemistry (study of techniques to separate and quantify chemicals), atmospheric chemistry, ocean chemistry, and biogeochemistry.

GLOBAL WARMING AND CLIMATE CHANGE

Chemistry is relevant to global warming and climate change in three important ways. Climate change is governed by chemical phenomena; the underlying chemistry of global warming centers on the phenomena commonly described as the greenhouse effect. In short, this term refers to the theory that the temperature at the surface of the Earth is maintained higher than would be calculated from a simple radiative budget due to the adsorption of longer-wave radiation in the atmosphere.

The main focus of climate change is on the rising atmospheric concentration of CO_2. This gas was first isolated by the burning of charcoal in an enclosed vessel and the observation that the resulting ashes were less dense than the original charcoal, whereas the resulting air was denser. Starting in 1958, Charles David Keeling was the first to begin measuring CO_2 in the baseline (non-polluted) air at the top of Mauna Loa, Hawaii. The basis of all techniques used to measure CO_2 is infrared (IR) spectroscopy.

IR spectroscopy is the technique used to probe the IR absorption of molecules from which information about their concentration and vibrational/rotational energy levels can be obtained. In a general IR spectroscopy experiment, a beam of IR light is split into two. One half of the beam passes directly through to a detector; the other half passes through a gas sample (such as CO_2). Scanning or Fourier transform techniques can be used to obtain information at a range of wavelengths. The concentration of the analyte is related to the absorption of light by the Beer-Lambert law:

$$A = \alpha \cdot c \cdot l,$$
$$\text{Where } A = \log (I/I_0),$$
$$\alpha = (4 \cdot \pi \cdot k) / \lambda,$$

and c is the concentration of the compound, l is equal to the path length of light through the sample, I is the intensity of radiation having passed through the sample, I_0 is the intensity of radiation in the reference beam, k is a constant for a given substance called the extinction coefficient, and λ is the wavelength. Ultraviolet spectroscopy works on the same principle as IR spectroscopy, but with UV light, which excites electronic, not vibrational energy levels. UV spectroscopy is useful for quantification of compounds that do not have an IR signal, such as ozone.

Many of the elements utilized by life have more than one stable isotope. Because isotopes decay at a fixed rate and some physical, chemical, or biological processes favor one isotope over the other, this often offers the ability to use these isotopes to give paleontological information. Two of the most important techniques from a climate change perspective are ^{14}C dating and ^{18}O temperature records.

The ratio of $^{12}CO_2$ to $^{14}CO_2$ in the air is maintained at a constant ratio, with $^{14}CO_2$ making up less than one part per million of the total. However, when the carbon from the CO_2 is trapped away from the atmosphere, either physically in ice or chemically in biology, the ^{14}C decays at a fixed rate (the half-life at around 6,000 years). Thus, for any sample of carbon that has been locked away from the atmosphere, the time it has been locked away can be calculated based on the amount of remaining ^{14}C. The ratio of ^{18}O to ^{16}O in the atmosphere varies as a function of temperature. When the O_2 is fixed into ice or biological systems, the ratio is determined only by the decay of ^{18}O. Thus, if the time since the oxygen was fixed is known, then the temperature at the time the oxygen was fixed can be calculated.

When air is trapped in ice cores, these two techniques can be combined to determine how long ago the air was trapped, and what the local temperature was when the air was trapped. When the amount of CO_2 in the air is quantified by IR and the dust in the air is collected a record of temperature, CO_2, and dust going back hundreds of thousands of years can be constructed. This record has been central to the global warming debate.

When faced with the task of measuring atmospheric components such as chlorofluorocarbons (CFCs), which have very low atmospheric mixing ratios, one approach is to first attempt to separate the air into its constituent components. Russian scientist Mikhail Tswett invented this technique in the early 20th century. Tswett ground up plant leaves in petroleum ether, and passed the resulting liquid though a glass tube filled with powdered chalk. Tswett observed that as the liquid passed down the tube, a range of colored bands were formed; thus demonstrating that leaves contain a range of different pigments. More important, however, he had invented a new separation technique, this technique he named *chromatography* (meaning literally "color writing").

In a general chromatography experiment, analytes in a mobile phase are passed though a stationary phase and are separated depending on their affinity for the stationary phase. A century after its discovery, there are now a great number of different chromatographic techniques allowing the separation of a wide variety of analytes. The technique of most relevance is gas chromatography, which separates a mixture of gases by passing them through a long column. The column is packed or lined with material that traps different components with a greater or lesser affinity; this ensures that each component arrives to the end of the column at a different time. Once separated, the analytes are detected by a number of techniques. The most popular one for CFCs is called Energy Citations Database (ECD), which measures the dip in current across a small gap that occurs when the CFC molecules pass.

Svante Arrhenius, considered the father of climate change science, was also a founder of the field of physical chemistry.

THE GREENHOUSE EFFECT AND GLOBAL WARMING

The greenhouse effect was discovered by Joseph Fourier in 1824, and was first investigated quantitatively by Svante Arrhenius in 1896. Radiation from the Sun, when measured at the top of the Earth's atmosphere, can be seen to cover a wide spectrum. This spectrum is consistent with the blackbody radiation associated with the temperature of the Sun's surface (5250 K). The spectrum observed from the Earth's surface is consistent with this once the adsorption of atmospheric species has been accounted for. The peak intensity of the solar radiation is around 500 nm., or in the UV-Visible region.

The Earth absorbs this radiation and reradiates at a lower wavelength, again consistent with a blackbody radiation at its temperature. The peak radiation emitted by the Earth is around 1,000 nm., which corresponds to infrared. Different atmospheric gases absorb infrared radiation, and are collectively referred to as greenhouse gases. This absorption traps the outgoing radiation, maintaining the planet at habitable temperatures.

Greenhouse gases absorb IR radiation at characteristic frequencies that correspond to the normal modes of vibration of the molecule. Greenhouse gases of notable importance include water (H_2O), which causes about 36–70 percent of the greenhouse effect (not including clouds); CO_2, which causes 9–26 percent; methane (CH_4), which causes 4–9 percent; and ozone, which causes 3–7 percent, according to Kiehl et al. These gases all absorb radiation, as they have a vibrational mode that results in a change in dipole of the molecule. These vibrational modes are normally investigated using IR spectroscopy. The IR spectrum of CO_2 reveals that it absorbs at two characteristic frequencies; the Bending mode at 14 μm, and the Asymmetric Stretch at four μm.

Greenhouse gases are rated with a greenhouse potential, which ranks their ability to absorb the Earth's radiation relative to CO_2 and gives some idea of the relative contributions of each component. Although water is a powerful greenhouse gas, the contribution of additional water is hard to quantify, as its concentration varies greatly throughout the atmosphere. In many areas of the globe, the water vapor concentration is such that all IR radiation of the relevant wavelength is absorbed. This highlights the importance of CO_2 as a greenhouse gas, which absorbs wavelengths that water does not.

The amount of time a chemical persists in the atmosphere clearly has great importance for many compounds such as CO_2, whereas the fastest loss of CO_2 is to the oceans, the main chemical sink in the atmosphere is oxidation. Oxidants are present in the atmosphere as a result of the evolution of photosynthetic organisms around 2–3 billion years ago. The primary oxidants present include oxygen (O_2), ozone (O_3), and the hydoxy radical (OH).

Global warming is proposed to occur because of growing atmospheric concentration of the greenhouse gases; these can be increased by a variety of human processes. The concentration of CO_2 in the atmosphere has risen from less than 250 ppm (parts per million) to over 380 ppm since pre-industrial times. This is as a consequence of the burning of fossil fuels such as coal, oil, and gas. Thus carbon that was stored in the ground is released in the form of CO_2.

An aerosol is a colloidal suspension of either liquid or solid particles in the gas phase. Aerosols are created in the atmosphere by the action of the winds suspending dust, sea salt, and organic matter, and from biogenic sources such as plant pollen, as well as from anthropogenic sources such as fossil fuel burning. Aerosols are of interest, as one of the key areas of uncertainty in climate change predictions involves the role of aerosols.

GREEN CHEMISTRY

There are many ways in which chemistry has helped to reduce CO_2 emissions and helped adaptation to a changing climate. Iron fertilization experiments aim to reduce the concentration of atmospheric CO_2 by promoting the growth of phytoplankton in oligotrophic regions of the ocean, where primary production is supposedly limited by the iron supply, such as in the Southern Ocean. Some paleontology researchers have shown a link between large quantities of iron in the air and the onset of ice ages. On first discovering of this, according to J.H. Martin and S.E. Fitzwater, the lead oceanographer in the project commented on the strong link between iron and planetary temperature saying, "Give me a half a tanker of iron and I'll give you the next ice age."

Paul Crutzen, a British atmospheric chemist and head of the group who initially discovered the stratospheric ozone hole, has suggested a radical proposal to mitigate global warming. Crutzen proposes to control the climate with the use of sulphate aerosol injected directly into the stratosphere. These aerosols would reflect sunlight, thereby cooling the planet significantly, but he predicts the effect will be short-lived (about one week). Crutzen suggests that regular planeloads of sulphate dispersed in the stratosphere would be a safe and cost effective way regulate the Earth's climate.

Photovoltaic describes the use of semiconductors to convert the sun's radiation into electrical energy. The cost of producing photovoltaic energy is high, as the chemicals need to be extremely pure. However, the technology has the potential to provide large amounts of energy with low CO_2 emissions. Green chemistry is an emerging discipline that looks at ways to produce chemical products with reduced impact on the environment. Its importance was recognized in 2005, when the Nobel Prize for chemistry was awarded to Yves Chauvin, Robert H. Grubbs, and Richard R. Schrock for their work in this field.

Chile

LOCATED ALONG THE Pacific seaboard of South America, the Republic of Chile has a land area of 292,183 sq. mi. (756,950 sq. km.), with a population of 16,598,074 (2007 est.), and a population density of 57 people per sq. mi. (22 people per sq. km.). With 5 percent of the land arable, 21 percent of Chile is forested, with 1.15 million hectares of plantation forests, most of which is pine. In spite of a heavy reliance on mining, Chile has a relatively low level of carbon dioxide emissions—2.7 metric tons per person in 1990, rising to 4.1 metric tons in 1999, and then falling to 3.7 metric tons in 2003. Most of the carbon dioxide emissions come from liquid fuels (56 percent). Twenty-eight percent of emissions come from transportation, largely through heavy use of cars. The public transport system is very good in some parts of the country, such as in the capital, Santiago, and the area around it including Valparaiso, but many people rely on the use of cars, leading to considerable urban congestion in Santiago.

Some 30 percent of Chile's carbon dioxide emissions come from the use of solid fuels, largely made up from heavy use of coal for electricity generation, with 51.2 percent of electricity coming from fossil fuels, and 46.6 percent from hydropower. Chile has operated hydroelectric power plants since 1897, when the Chivilingo Hydroelectric Plant was built, only the second to operate in South America. Since then, the Chilean energy company Empresa Nacional de Electricidad S.A. (ENDESA) has built a number of other hydroelectric plants such as the Colbún Hydroelectric Plant, located in the Maule region; the Pangue and Penuenche Hydroelectric Plants, situated on the upper Bío-Bío River; the Pullinque Hydroelectric Plant using water from the Pullinque Lake; and the Ralco Hydroelectric Plant.

Chile faces serious problems resulting from climate change and global warming. The El Niño effect has caused some damage to the Chilean wine industry, with less rainfall likely to lead to a decline in grape yields. There has been a steady increase in the annual average temperature since 1939, with the rate of warming doubling in the last 40 years, and more than tripling in the last 25 years; this has also been noticed in the Andes Mountains and in other parts of the country. This has had a major effect on the southern parts of Chile, where there has been glacial melting; the rising water levels in Chilean Patagonia are expected to flood some of the small islands off the country's southern coast.

The ozone hole also is expected to lead to a rise in the prevalence of skin cancer over the next decades. Global warming and climate change has caused much damage to Chilean Antarctica, which the Chilean government, unlike the other nations that have territory in Antarctica, regards as an integral part of the country.

The Chilean government of Patricio Aylwin Azócar ratified the Vienna Convention soon after he became president in 1992, and Chile took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May of the same year. The government of Azócar's successor, Eduardo Frei, signed the Kyoto Protocol to the UN Framework Convention on Climate Change on June 17, 1998; it was ratified on August 26, 2002, and took effect on February 16, 2005.

China

THE RISE OF the Tibetan Plateau in western China caused a major worldwide climate shift. As the highest region on Earth, this area became the world's third major weather-maker, after the polar regions, and gave rise to the South Asia Monsoon about 8 million years ago. The growth of the plateau also set the stage for the ice ages that began approximately 2.5 million years ago. Glacial deposits, lake strand-lines, paleo-biologic studies, and ice core records now available from the Tibetan Plateau are filling a critical gap in comparing the Asian mid-latitude climate record with the more extensive records from other continents and the polar regions.

During historic times, China has undergone significant climate shifts, some natural, others most likely anthropogenic. Although desertification has been ongoing in China for perhaps 3,000 years, at least some of this has been attributed to human activities. The recent rapid retreat of China's glaciers appears to be linked to global warming. Although the Chinese government places its highest priority on economic growth, it also appears to be taking anthropogenic climate change very seriously.

IMPACT OF THE TIBETAN PLATEAU

Rapid uplift during the late Cenozoic has shaped the landscape of the Tibetan Plateau and has drastically changed China's climate. Regional differences in geomorphology and local precipitation can result in different timing of glacial advances around the world. Currently, the Pacific Ocean monsoon dominates east China, while both the South Asia Monsoon and the mid-latitude Westerlies control the weather of the Himalaya and western China. The South Asia Monsoon dominates the southern part of Tibet, while the mid-latitude Westerlies dominate the northern part. These different climatic regimes have had important influences on the Quaternary glaciations.

The rise of the Himalayan Mountains and plateaus significantly increased worldwide erosion rates. Silicate weathering provides one of the major natural processes that remove CO_2 from the atmosphere, in the process forming carbonates. Hence, the rise of the Himalaya and Tibetan Plateau could have contributed to the onset of Pleistocene glaciation by depleting atmospheric CO_2, the most abundant greenhouse gas.

The Tibetan Plateau contains the largest ice mass on the Earth outside the polar regions. The Tibetan Plateau holds almost 37,000 catalogued glaciers, with a combined area of nearly 50,000 km^2. These glaciers owe their existence to the rise of the Tibetan Plateau. They extend north into the arid and desert regions, feeding the Yellow and Yangtze rivers, which provide the main water resource for arid central Asia, and northeastern China. They also extend south into the warmer, wetter forests and concentrate around the Brahmaputra, Mekong, and Salween rivers, which provide needed water to both local residents and much of southeast Asia.

Coastal areas of China could suffer from sea-level rise due to melting of polar ice caps. On the Tibetan Plateau, however, the immediate response to the accelerating glacial retreat could be villages displaced as a consequence of lake expansion and disasters related to glacial lake outbursts and other floods. Severe water shortages may follow once the reservoir of glacial ice is depleted.

PALEOCLIMATE RECORDS

Until recently, researchers have found it difficult to compare the relative ages of China's Quaternary glaciations with each other, let alone with global ice ages. However, absolute numerical dating now allows China's glaciations to be placed into the pre-existing worldwide framework. Based on these new dating results, Yi Chaolu and others have determined that most Asian Quaternary glaciations in the last 100,000 years were synchronous with global glacial events. One glacial advance between 44,000 and 54,000 years ago in southeastern Tibet was not synchronous with global cooling, and might have been caused by greater precipitation during a locally colder period. Chinese researchers have identified more Quaternary glacial periods before the Wisconsin Glaciation than have been identified in other regions of the world. The uplift of Tibet during the Cenozoic could be responsible for these differences.

As one of the thickest ice caps in central Asia, the Guliya Ice Cap, on the crest of the Kun Lun Mountains, provides valuable information for this critical region about the past climatic and environmental changes. Yang Meixue and others report that the Guliya ice core demonstrates periodic oscillations of the temperature and precipitation over the past 1,700 years. The results show various oscillations in the ice core records, with multiple timescales (200, 150, 70, 40, and 20 years). Their amplitude, phase, and frequency vary with time. Temperatures recorded since 1700 C.E. show that precipitation correlates well with temperature in this region.

Yao Tandong and others used data from an ice core from the Puruogangri Icefield on the central Tibetan Plateau to construct a temperature history for the region based on the temperature proxy, $\delta^{18}O$. Reconstructing temperatures back to 1000 C.E. shows changes on the plateau generally similar to those in other parts of the Northern Hemisphere on a multidecadal timescale. These data indicate that the 20th century warming in China was abrupt and exceptional, and that the 20th century was warmer than any time during the past 1,000 years.

Unlike much of the Northern Hemisphere, temperatures throughout the Tibetan Plateau showed no widespread cooling trend from 1000 C.E. to the late 19th century. They show, instead, slightly increasing temperatures. For the northern portion of the plateau, however, temperatures exhibited a very slight cooling trend from 1000 C.E. to the late 19th century. This reconstruction confirms the existence of the Medieval Warm Period and the Little Ice Age in China. However, the Little Ice Age was not as relatively cold as in other regions of the Northern Hemisphere.

The impressive Tibetan Plateau contains the largest ice mass on Earth outside the polar regions, with almost 37,000 catalogued glaciers that have a combined area of nearly 50,000 km^2.

RECENT CLIMATE CHANGE

China is experiencing a well-documented, widespread warming. The glaciers on the Tibetan Plateau are retreating rapidly, and permafrost is melting. This rate has accelerated in the early 21st century under the impact of an intensified South Asia Monsoon, which is likely a consequence of global warming.

Yao Tandong and others trace the glacial retreat in China to the termination of the Little Ice Age, around the beginning of the 20th century. Since then, the glacial retreat can be divided into several stages. The first half of the 20th century was characterized by shifting from glacial advances to retreats. Between the 1950s and the 1960s, the glaciers began extensive retreat, with over half of the studied glaciers retreating, about 30 percent advancing, and the others stable. In a short period from the late 1960s to the late 1970s, advancing glaciers increased again and the percentage of retreating glaciers decreased to less than half. Starting in the 1980s, glacier retreat intensified again, with 90 percent of the studied glaciers retreating. Since the 1990s, glacial retreat has been accelerating, with 95 percent of the studied glaciers now retreating.

The magnitude of glacial retreat is less on the northern Tibetan Plateau, and more at the margins; the greatest retreats are on the southeast plateau. The rate of glacial retreat reached 213 ft. (65 m.) per year on the southeast plateau, where the South Asia Monsoon prevails. The smallest glacial retreat appears on the central plateau, where a continental climate dominates.

Monsoons and the Westerlies affect the dominant patterns of glacial retreat on the Tibetan Plateau. The monsoon water vapor flows through the lower reaches of the Brahmaputra River valley toward the interior of the plateau, which results in the development of the largest glaciers. With global warming, the Southeast Asia Monsoon is intensifying, which causes more precipitation on the southeastern plateau. The increased precipitation there comes mostly as rainfall, as opposed to the situation in the mountains influenced by the Westerlies, where increased precipitation on high elevation glaciers falls mostly as snow. Trends showed strong increases for spring and winter precipitation from 1961 to 2001.

Over the last decade, many lakes in highly glaciated regions have expanded. Yao Tandong and others assessed size changes of lakes greater than 3.7 sq. mi. (10 sq. km.) and discovered that over 70 percent of the lakes evaluated expanded by at least 12 percent, since the 1990s. Glaciological observations in the region suggest that intensified glacial melting in response to the current warming is the principal driver, not precipitation patterns over the plateau.

Lake expansion will most likely modify the hydrologic cycle over the Tibetan Plateau. Grassland destruction and resultant reduction of livestock grazing is now occurring near Lhasa. (Higher CO_2 concentrations also favor woody plants over grasslands.) Furthermore, the potential for glacial lake outburst flooding is also increasing, which could cause serious damage in south Asian countries such as India, Nepal, and Bhutan.

The southern limits of China's permafrost appear to be moving northward at over .93 mi. (1.5 km.) per year. The area of permafrost is expected to decline by 30–50 percent during this century. Permafrost collapse tends to cause slumping of the soil surface and flooding, followed by a complete change in vegetation, soil structure, and many other important aspects of these ecosystems. Melting permafrost causes concern, because frozen ground stores huge quantities of carbon as methane and CO_2.

Recent studies show that initial flooding caused by melting boosts plant productivity, sequestering more carbon from the atmosphere in plant biomass. Hence, permafrost degradation may initially increase soil carbon sequestration, rather than release large amounts of carbon into the atmosphere, as originally predicted. But over time, the greenhouse effect of high methane emissions will outweigh the reduction of carbon in the atmosphere.

Chinese scientists conclude that human activities have accelerated the desertification process and have driven the north China deserts southward by approximately 186 mi. (300 km.) over the past 3,000 years. A growing population, intensive agricultural activities, excessive tree-cutting, and frequent warfare have damaged the natural vegetation, caused soil erosion, and intensified desertification. Reforestation projects and greater rainfall from changes in the East Asia Monsoon patterns currently affecting the semi-arid to arid areas in this region are likely to help prevent and reverse desertification. However, water shortages will persist, due to lack of glacier storage and the current heavy mining of ground water.

Most recently, both the International Energy Agency and the Netherlands Assessment Agency say that China became the world's leading source of greenhouse gas emissions in 2007. According to the World Bank, Chinese industry uses 4–10 times more water per unit of production than the average in industrialized nations. China ratified the Kyoto Protocol in 2002, but as a developing nation was not held to specific emissions targets. China's emissions of sulfur dioxide and particulates that act contrary to greenhouse gases (decreasing radiative heating in the lower atmosphere) are increasing even faster than China's economic growth. Their control may exacerbate the warming.

The *China Daily* recently reported that over 400 sq. mi. (644 sq. km.) of land in southern China would be flooded by 2050 as sea levels rise due to global warming. The Pearl River Delta area, a leading manufacturing hub, will be hard hit by climate change in the coming decades. The cities of Guangzhou, Zhuhai, and Foshan are expected to be the worst hit as sea levels rise by at least 11.8 in. (30 cm.) by 2050. Climate change will thus likely depress economic development of this province, which is currently one of the biggest consumers of energy and producers of greenhouse gases.

CLIMATE CHANGE POLICY

Although China's leaders recognize that they must deal with emissions of climate and health-related pollutants, economic growth remains the country's highest priority. The state is a partner in most energy, and many industrial, enterprises, as well as the regulator of environmental issues. As a result, environmental controls are weak, and enforcement of standards and laws lacks uniformity. China's central Energy Bureau has only 100 full-time staff (compared to the U.S. Department of Energy's 110,000). Another result of the economic system has been to allow low-efficiency energy use with little, if any, economic penalty.

China depends heavily (about 70 percent) on coal for its energy. With energy demands rising, more coal production is planned at least until 2020. China produces about 35 percent of the world's steel, 50 percent of the world's cement and flat glass, and about 33 percent of the world's aluminum—all very energy-intensive industries. In 2007, China was the second largest producer of cars (passing Japan), next to the United States. On average, China uses 20 percent more energy per ton of steel and 45 percent more per unit of cement than the international averages. Because of the international nature of their market, China's leaders argue that pollution originating from these global industries should not be attributed strictly to China, but that end users are partners in degrading the environment.

The Chinese leadership has issued numerous statements recognizing the need for a change in course. Recent actions include the passage of the Renewable Energy Law (endorsing expanded use of renewables), the phasing out of export subsides for polluting industries, and the closing of illegal coal mines and some heavily polluting factories. Targets for energy efficiency have been established, but have so far gone unmet. The government has been unwilling to use significant financial tools to implement climate-related goals. The government controls the rates for commodities such as electricity, fuel oil, gasoline, and water, which all remain relatively inexpensive. Officials have rejected proposals to introduce surcharges on electricity and coal to reflect the true cost to the environment. China has also declined to institute other tax policies or market-based incentives or to accept mandatory limits on its CO_2 emissions.

The per capita use of energy in China still falls far below that of most of the industrialized world; only about 15 percent of that in the United States. As citizens of China achieve the level of affluence of the industrialized world, they will invariably desire more amenities. Private cars, for instance, are increasingly common. To achieve parity in standard of living without greatly increasing their energy use and greenhouse gas emissions will be a daunting challenge.

Clean Air Act, U.S.

THE U.S. CLEAN Air Act (CAA) was passed by the U.S. Congress in 1963 and strengthened with amendments passed in 1970, 1977, and 1990. The U.S. Environmental Protection Agency (EPA) is responsible for implementation and regulation of the CAA, although much of the work falls to state and local governments. EPA regulates many pollutants (such as particulate matter) that play an important role in the Earth's radiation balance, but CAA has not been used to regulate greenhouse gases (GHGs), the pollutants most responsible for global warming. A 2007 U.S. Supreme Court decision ruled that GHGs fall within the jurisdiction of the EPA and the CAA, forcing the EPA to re-examine its ruling on this matter.

The first U.S. federal legislation dealing with air pollution was the Air Pollution Control Act of 1955, which recognized air pollution as a national hazard and encouraged research on the issue. In 1963, the original version of the CAA was passed, which called for the study of air quality issues and set emissions standards for stationary sources. The 1970 CAA was a major overhaul of the original version, making it a comprehensive federal law regulating stationary and mobile sources of air pollution.

The 1970 amendments further established a federal regulatory roll that had previously been lacking. Along with these amendments, Congress created the EPA in 1970 and charged it with carrying out the CAA. The EPA set National Ambient Air Quality Standards for six "criteria" pollutants, and set the target year at 1975 for locations across the United States to meet these standards. Many parts of the country did not meet this deadline, however, and the CAA amendments of 1977 were passed mainly to set new goals and deadlines.

A larger revision occurred with the CAA amendments of 1990. Most significantly, a new market-based cap-and-trade system was implemented as an approach for meeting air quality goals. The 1990 amendments included new standards for hazardous air pollutants and new requirements for EPA regulation and reporting. The 1990 amendments also included provisions to deal with the pressing air quality issues of the time, such as stronger regulation of ground-level ozone, particulate matter, and carbon monoxide; provisions to protect the stratospheric ozone layer; and measures to reduce the pollutants contributing to acid rain. Despite existing knowledge of global warming, however, the amendments did not include any measures to deal with GHGs or climate change.

GHGs, such as carbon dioxide (CO_2), have not been included in either of the groups that the EPA regulates, which are comprised of the six "criteria" pollutants and a group of hazardous air pollutants. In 1999, a group of private organizations petitioned the EPA to begin regulating four GHGs, including CO_2. The EPA denied the petition by responding that CO_2 is not a pollutant under the CAA, that the EPA did not have the authority to regulate against climate change, and that even if it did, it would choose not to regulate due to uncertainty in establishing a causal link between global warming and GHGs. Led by Massachusetts, 12 states, four local governments, and 13 private organizations then filed suit against the EPA (joined by 10 states and six trade associations), challenging that decision.

In the case's Supreme Court hearing, the judges did not rule directly on the issue of global warming. Rather, they had to decide if the states had legal standing to sue; that is, if they had demonstrated there was imminent harm and that regulation would have a significant impact on reducing that harm. The majority of the court agreed that there was a well-recognized threat of harm from climate change, particularly the threat of sea-level rise to Massachusetts's coasts, and that the EPA's refusal to regulate was contributing to the threat of injury. In addition, the court rejected the EPA's argument that CO_2 was not an air pollutant under the definitions of the CAA. Although the EPA now has the authority to regulate CO_2, the agency must still decide if and how GHGs will actually be regulated.

Clean Development Mechanism

THE KYOTO PROTOCOL establishes three innovative mechanisms known as joint implementation, the clean development mechanism (CDM), and emissions trading to reduce greenhouse gas emissions. These are designed to help Annex I Parties cut the cost of meeting their emissions targets by taking advantage of opportunities to reduce emissions (or increase greenhouse gas removals) that cost less in other countries.

The CDM was established under Article 12 of the Kyoto Protocol to achieve two goals: to promote sustainable development in the developing nations, and to allow developed (industrialized) nations to earn emission credits by investing in emission-reducing projects in developing nations. To get credits under this mechanism, the project proponent has to prove that the greenhouse gas emission reductions are real, measurable, and that these reductions are in addition to what would have occurred in the absence of the project. These credits can then be used by the nations to meet their targets under the Kyoto Protocol. However, there is a limit on how many an Annex I party can use toward their target (it is restricted up to one percent of the party's emissions in its base year, for each of the five years of the commitment period).

Current modalities of the CDM include activities that focus on greenhouse gas reductions through several activities, such as afforestation and reforestation (often known as sinks), solar electrification, recovery of energy (biogas) from waste, installation of more energy-efficient boilers, and introduction of cleaner transportation methods. The countries are expected to refrain from building nuclear facilities to generate credits for CDM. It is generally believed that the CDM will generate investment in developing nations and promote the transfer of environmentally friendly or cleaner technologies to developing nations. This would be in addition to the financial and technology transfer commitments under the convention and Kyoto Protocol.

A number of domestic and international governance structures have been set up to oversee the CDM projects. Three key institutions validate the CDM projects: Designated National Authorities (DNAs are usually housed in some government agency or ministry, but in some cases can be outsourced to a private agency), Designated Operational Entities (usually private sector entities, so far about 12 such companies have been accredited), and the CDM Executive Board (EB) that operates under a Member of the Party (MOP) and consists of 10 members and 10 alternates of the EB drawn from all the constituencies of the parties. As of January 2006, about 68 projects were registered with the CDM EB, and, if implemented, could reduce up to 30 million tons of greenhouse gas emissions on an annual basis.

The project cycle of the CDM as described by the United Nations Framework Convention on Climate Change consists of six phases: project activity design, proposal of a new baseline and/or monitoring methodology, use of an approved methodology, validation of the CDM project activity, registration of the CDM project activity, and certification/verification of the CDM project activity. Under the project activity design phase, project participants (or the parties) submit the proposed CDM project activity information using the project design document developed by the EB.

The DNA is the first institution to review a project design document. Assuming everything is in order, the DNA will write a letter of approval saying that all participants are voluntary and that the sustainable development criteria have been met. The next phase in the cycle involves submission of the new baseline methodology (in addition to the description of the project with a list of participants) to the EB for review before the project activity can be registered.

If the project is not using a pre-approved methodology in the project activity, the next phase involves submitting the details of the methodology to the EB for review and approval of the methodology/technology. If the project is using the already approved methodology, the next phase involves validation of the CDM project activity. Under the validation phase, an independent evaluation of the project activity is carried out by a designated operational entity against the requirements of the CDM as defined under the protocol.

To validate a project, the designated operational entity will review the project design document (PDD) to determine if the project's methodology is in line with approved methodologies, that the claimed emissions reductions and baseline scenarios are accurate, and that the project is "additional." In making its determination, the designated operational entity will also post the PDD on the internet for a 30-day public comment period. After validation, the project is registered, which means that EB has formally accepted the project, a prerequisite for the verification, certification, and issuance of credits related to the project activity.

There is also a final 30-day public comment period while the project is at the EB/CDM. Verification involves periodic review by the designated operational entity of the monitored reductions in anthropogenic emissions of greenhouse gases by sources that have occurred due to the registered CDM project activity. Certification is the written assurance provided by the designated operational entity that the registered CDM project activity has achieved the reductions in anthropogenic emissions of greenhouse gases by sources as verified. After the full cycle has been completed, the credits are granted to the parties involved. Because this is a long process, many parties/nations are discouraged. Emphasis by the EB on the additional reductions due to the CDM project activity, high costs associated with the approval process, and administrative delays hinder the development of many small-scale, community-based CDM projects.

Although this mechanism provides for the transfer of cleaner technologies to developing countries and gives credits to developed countries, there are a few problems. One of the most controversial aspects of Article 12 is that it requires projects to show "reductions in emissions that are additional to any that would occur in the absence of the certified project activity." This requirement has become known as "additionality" and is intended to ensure there is a net emissions reduction. This is an important clause, but it is not always easy to establish.

Another controversial aspect of the CDM is the requirement that projects must also help developing countries in "achieving sustainable development." However, under this mechanism, a universal definition of sustainable development was not developed (which could have ensured accountability of the authorities overseeing project approval); instead, individual countries have been allowed to set their own definition of sustainable development and judge whether a project meets these criteria.

Although it was perceived that the CDM projects would help developing countries by transfer of technology and finances, it has been observed that the CDM projects are not that global in scope. This market is heavily concentrated in large, middle-income countries led by India, China, and Brazil, which is consistent with the current direction of Foreign Direct Investment. On the other hand, some of the poorest countries, especially in Africa, have almost entirely been left behind, with only two countries—South Africa and Morocco—to have validated a CDM project (as of September 2006). According to the Prototype Carbon Fund's report "Carbon Market Trends 2005," published by the World Bank Group, "This under-representation of Africa raises deep concerns about the overall equity of the distribution of the CDM market, as the vast majority of African countries have not, for the moment, been able to pick up even one first deal."

These facts do not support the notion that the CDM would help remove poverty and move the poorest countries to a cleaner path of development.

CLIMAP Project

THE CLIMAP PROJECT (Climate: Long range Investigation, Mapping, and Prediction), run by the World Data Center for Paleoclimatology, first published its oceanic map in 1981. Although nominally meant to map ocean conditions, the project gave insight into global warming, due to the fact that oceanic conditions in a region distant from the ice sheets were largely dependent on greenhouse gases. Therefore, a model of the conditions thousands of years ago compared to current conditions could provide evidence for human-caused global warming.

Although CLIMAP is frequently cited as a useful resource for mapping oceanic conditions during the last glacial maximum, several of its claims are controversial and, perhaps, misestimates. Unfortunately, collecting sediment core samples from the Pacific Ocean is quite expensive; therefore, re-collecting the data or obtaining more samples is difficult and unlikely.

The World Data Center for Paleoclimatology is based in Boulder, Colorado, and operated by the National Climatic Data Center (NCDC) in Asheville, North Carolina, along with the National Data Center for Meteorology. The NCDC is part of the National Environmental Satellite, Data, and Information Service (NESDIS), a part of the National Oceanic and Atmospheric Administration within the U.S. Department of Commerce. Its mission is to: "provide access and stewardship to the nation's resource of global climate and weather related data and information, and assess and monitor climate variation and change," and is self-proclaimed the "world's largest archive of climate data."

Within the NCDC, there are six branches for data: Land-Based; Marine; Paleoclimatology; Satellite; Upper Air; and Weather/Climate, Events, Information & Assessments. The Paleoclimatology branch manages the World Data Center for Climatology and the Applied Research Center for Climatology; it also deals with CLIMAP. Paleoclimatology is the study of climates before the current era, when accurate, high technology instrumentation was not available. Therefore, paleoclimatologists reconstruct models of climates from such data sources as corals, ice cores, ocean and lake sediments, and tree rings; these data sources are called natural proxy sources.

CLIMAP was based on research during the 1970s (the International Decade of Ocean Exploration) and 1980s, focusing on mapping the Earth's climate during the period of the last glacial maximum (approximately 18,000 years ago). Researchers for the CLIMAP Project collected numerous sediment core samples, and generated detailed maps of the climate 18,000 years ago, with information such as glacial patterns and vegetation zones. The core samples were from anywhere between 24,000 and 14,000 years ago; during this period, the climate was assumed to be relatively constant and stable.

After thorough analysis, the CLIMAP scientists predicted that the sea surface temperatures (SST) in the tropics were only three or fewer degrees C cooler than they are today; this estimate is considered by most Earth scientists to be inaccurate. Many scientists instead support the theory that the tropical SSTs have since dropped closer to 5–6 degrees C. How this discrepancy arose is unknown.

Climate

CLIMATE AND WEATHER are not synonymous. Weather is the condition that prevails at a given moment and may change within days or even hours. At moments of meteorological fluidity, weather can change in minutes. Weather is variable, whereas climate is constant under ordinary circumstances. This is so because climate is the average of weather over long durations. Climate may change rapidly, as it did at the end of the Cretaceous era, but the circumstances that change climate rapidly are unusual. When climate changes rapidly Earth is in crisis. At the end of the Cretaceous, for example, a gigantic meteor impacted Earth, ejecting a huge cloud of debris and dust and touching off widespread forest fires. The debris, dust, and ash from this catastrophe blocked out sunlight, cooling Earth. These are not ordinary circumstances and most of the time, climate holds steady.

Climate arises from the interaction of several factors: latitude, proximity to oceans or mountains, altitude, radiation from the Sun, ocean currents, wind, continental drift, the greenhouse effect, volcanic activity, radioactivity of Earth's core, photosynthesis, transpiration, eccentricity of Earth's orbit around the sun, the tilt of Earth's axis, rainfall, and the reflection of sunlight from clouds, snow, and ice. Earth has many climates, ranging from desert to lush rainforest. Temperature and rainfall vary widely by locale. Near the equator, the range of temperatures is small and rainfall abundant. Away from the equator, temperatures and rainfall vary considerably. Humans have adapted to many climates. In contrast, many other animals are adapted to a single climate, and change threatens them.

The factors that shape climate begin with the Sun, for without it, Earth would be a dark, frozen, lifeless rock. The Sun's radiation, which Earth absorbs as heat, is 2.5 times greater at the equator than at the poles. Equatorial waters play a crucial role as a vast reservoir of heat. Near the equator, the ocean absorbs as much as 98 percent of the sun's rays, reflecting only 2 percent back into space. Warm equatorial waters flow toward the poles. The Gulf Stream, for example, carries equatorial water and warm air into the North Atlantic Ocean before cooling near the North Pole. In the past, equatorial currents have been warm enough to melt the ice caps, heating the climate.

Earth's tilt on its axis magnifies the effect of the sun's radiation. An Earth that did not tilt on its axis would not have seasons, because each latitude would receive a constant amount of sunlight and therefore a constant amount of heat year round. Earth is, however, tilted 23.5 degrees on its axis, causing it to receive varying amounts of sunlight and imparting seasons to the planet. When the Northern Hemisphere is tilted toward the Sun, this portion of Earth experiences summer, and the Southern Hemisphere, receiving less Sun that the north, experiences winter. When the Southern Hemisphere is tilted toward the Sun, the reverse is true.

THE GREENHOUSE EFFECT

The greenhouse effect likewise amplifies the effect of the Sun's radiation. Greenhouse gases—carbon dioxide (CO_2), methane, and water vapor are examples—trap sunlight in the atmosphere. Without any greenhouse gases, sunlight would pass through the atmosphere and strike Earth, which would absorb a portion of the sunlight. (Land absorbs less sunlight than water.) The rest would rebound from Earth as infrared radiation, passing out of the atmosphere and into space. Greenhouse gases do not, however, permit infrared radiation to pass into space, but rather absorb it as heat, in turn heating the atmosphere. Of the greenhouse gases, methane breaks down in the atmosphere after a few decades. CO_2, however, may linger centuries in the atmosphere.

Earth produces CO_2 through volcanic eruptions, spewing large quantities of it into the atmosphere. Since the Industrial Revolution, humans have increased the concentration of CO_2 by burning fossil fuels. Humans are adding CO_2 to the atmosphere faster than natural processes can reduce its concentration. As the concentration of CO_2 in the atmosphere increases, so does temperature.

Counterbalancing the effect of volcanoes in increasing CO_2 in the atmosphere, three factors reduce CO_2 and so cool Earth. First, CO_2 dissolves in rainwater to form carbonic acid, taking a portion of the gas out of the atmosphere. Second, the ocean absorbs CO_2. Microorganisms in the ocean convert CO_2 into carbonates, taking the gas out of circulation. Third, photosynthetic algae and plants consume CO_2 during photosynthesis, converting it into sugars. Plants also affect the climate through transpiration, a process that adds water vapor to the atmosphere.

Water vapor traps more heat than either methane or CO_2. Like methane, water vapor does not persist in the atmosphere, but rather falls to the ground as rain. The clouds that carry water vapor reflect sunlight back into space without letting it penetrate to Earth. Water vapor, therefore, has a complex effect on the climate. Water vapor is a greenhouse gas that warms Earth, but the clouds that carry water vapor cool the planet by blocking out sunlight. Clouds cover half the planet, reflecting 30 percent of sunlight, thereby cooling Earth.

Rain affects climate in several ways. It is abundant at the equator and at 30 degrees latitude, where it drenches Earth in monsoons. Rain is also plentiful at the windward side of mountains. As they rise to cross a mountain, clouds cool and release water vapor as rain. On the leeward side of mountains, clouds have little water vapor left to discharge as rain, and so the climate is arid. The climate is likewise arid between 15 and 30 degrees latitude, where air at low pressure prevents clouds from rising, cooling, and releasing their water vapor as rain. Rain sustains the growth of plants. Rapidly growing rainforests consume large amounts of CO_2, though humans are chopping them down at an unsustainable rate.

Heat from Earth's core augments the heat supplied by the sun. Radioactive elements in the core decay over time, converting mass into energy, just as the sun and nuclear reactors do. This energy is in the form of heat and pressure. Pressure forces heat, in the form of molten rock, toward Earth's surface. Volcanic eruptions, in addition to spewing huge amounts of CO_2 into the atmosphere, transfer molten rock from inside Earth to the surface, where molten rock liberates its heat.

A cold climate reinforces itself with the accumulation of snow and ice, which reflect sunlight back into space.

Despite the fact that volcanoes liberate heat and release CO_2, their effect on the climate is not always in the direction of higher temperatures. Volcanoes also spew debris, dust, and ash into the atmosphere. These particles block out the Sun and so may cool Earth. The eruption of Mount Tambora, in 1815, ejected huge clouds of debris into the atmosphere. Feeling the full effects of the eruption, 1816 was so cold that it is remembered as the year that had no summer.

Wind affects climate by carrying warm or cool air across the land. Warm air originates at the equator and follows ocean currents to higher latitudes. Cool air, originating at the poles, blows to lower latitudes. When warm and cool air meet, warm air rises and cool air sinks. As warm air rises, it cools, and sheds its water vapor as rain. The areas along contrasting weather fronts are, therefore, places of abundant rainfall.

In their restlessness, the continents affect climate. Earth is not a static entity as was once believed. Rather, the continents wander across Earth, changing their position and their orientation toward one another. When continents have moved toward the poles, their climates have cooled. Only when Antarctica, for example, moved to the South Pole did it acquire glaciers. In contrast, when continents gather near the equator, as Pangea did, the climate becomes balmy. Plants grew in abundance and herbivores became large, setting the conditions for the evolution of the dinosaurs.

Nor is Earth's orbit constant. In the 17th century, German astronomer Johannes Kepler demonstrated that Earth's orbit, as is true of the orbits of all the planets, is an ellipse. At one extreme, the ellipse is pronounced, and Earth is nearest the Sun at the closest approach of the ellipse and furthest from the sun at the greatest distance of the ellipse. The climate in these instances alternates between warmth when Earth is near the sun, and cold when Earth is far from the Sun. At the other extreme, Earth's orbit, though still an ellipse, is nearly circular. Earth, being roughly the same distance from the Sun at every point in its orbit, receives roughly the same amount of sunlight year round, and so has a uniformly warm climate.

A cold climate reinforces itself through the accumulation of snow and ice, both of which reflect sunlight back into space. By this mechanism, Earth, covered with snow and ice, cools because it reflects, rather than absorbs, heat in the form of sunlight. At the culmination of this feedback loop is an ice age, with Earth covered in glaciers. However, a warm climate can also reinforce itself through the accumulation of CO_2 in the atmosphere. At the culmination of this feedback loop CO_2 accumulates until all snow and ice have melted. The succession of climates, with varying temperatures, makes clear that climate is not static, but changes over time. The current climate is a warm interlude at the end of the Pleistocene ice age. Whether the climate will stay warm or descend into another ice age remains open to question.

THE CLIMATES OF AFRICA

The climate is not uniform, but rather varies by locale. From this, it follows that the continents have a multiplicity of climates. Africa, the cradle of humanity, has a Mediterranean climate in its coastland along the Mediterranean Sea. The sea imparts its heat to North Africa. But, the sea breeze does not penetrate far into Africa, making only a thin strip of coastline Mediterranean in climate. The sea absorbs heat in summer and retains this heat into autumn, radiating it to Mediterranean Africa and making it hotter in summer and autumn than in spring and winter.

The coast of Algeria and Tunisia records temperatures above 80 degrees F (26 degrees C) in August, and around 50 degrees F (10 degrees C) in January. January in North Africa is warmer than January in many other regions of the world. The Atlantic coast of Morocco is cooler, with July temperatures recorded below 70 degrees F (21 degrees C). The Canaries Current, which bathes the Atlantic coast of North Africa, is cooler than the Mediterranean Sea, and accounts for the lower temperatures along the west coast of Morocco.

Most of North Africa has temperatures above 70 degrees F (21 degrees C) during at least nine months of the year. Between May and September, the air is clear, sunshine is abundant, and rainfall is scant. Temperatures rise going east along the Mediterranean coast. Mediterranean Libya and Egypt record summer temperatures as high as 105 degrees F (41 degrees C). In the interior of Egypt, away from the moderating effect of the sea, temperatures rise still higher. Merowe, Egypt has recorded 111 degrees F (44 degrees C) in June, and Wadi Halfa, 127 degrees F (53 degrees C) in April.

In Mediterranean Africa, rain falls in winter rather than in summer. October marks the onset of the winter rains. The coast of Algeria and Tunisia average more than 20 in. (51 cm.) of rain per year. Geryville, Algeria averages a bit less, between 10–20 in. (25–51 cm.) of rain per year. Tripoli, Libya receives 16 in. (41 cm.) of rain per year, Alexandria, Egypt 7 in. (18 cm.), but Cairo only 1 in. (2.5 cm.). Inland and away from the influence of the sea, Cairo and its surrounding lands resemble the Sahara more than the Mediterranean. Winters are mild in Mediterranean Africa. Libya and Egypt average 57 degrees F (14 degrees C) in January, although Algeria has recorded temperatures below freezing.

South of Mediterranean Africa is the Sahara desert, an arid region that receives less than 2 in. (5 cm.) of rain per year. Rainfall is variable. Some years, the Sahara receives no rain, whereas in other years it has between 2–5 in. (5–13 cm.). Temperatures are torrid, sometimes exceeding 170 degrees F (77 degrees C). Between May and September, temperatures regularly surpass 110 degrees F (43 degrees C). Yet January is mild, with record temperatures around 50 degrees F (10 degrees C) on the northern fringe of the desert, and 70 degrees F (21 degrees C) on the southern fringe.

West of the Sahara lie the countries of West Africa. The climate is moderate along the Atlantic coast, but varies inland. West Africa has extremes of temperature. In April and May, temperatures exceed 100 degrees F (38 degrees C), though August has recorded temperatures as low as 71 degrees F (22 degrees C). At the wettest locales, rainfall exceeds 175 in. (444 cm.) of rain per year. The rainy season stretches from April to November and peaks in June. Less rain falls between December and March, though no part of West Africa has a period without rain. The volume of rain diminishes moving east to Niger and Nigeria. Niger averages 40 in. (102 cm.) of rain a year, and Nigeria 60 in. (152 cm.). Most rain falls between June and September. Temperatures peak between April and June, exceeding 90 degrees F(32 degrees C) in Niger and Nigeria. Temperatures cool to 70 degrees F (31 degrees C)between December and February.

South of Egypt lies Sudan, an arid region and further south are Ethiopia and Somalia, both of them wetter than Sudan. Somalia receives between 10–20 in. (25–51 cm.) of rain per year; the upper bound holds for northern Ethiopia, though the southwest has more than 75 in. (190 cm.) of rain a year. Rainfall peaks in February and March and, again, between June and September. The Indian Ocean cools Somalia, whose temperature hovers around 60 degrees F (16 degrees C) in January and 75 degrees F (24 degrees C) in July. The heights of Ethiopia are, likewise, cool. Addis Ababa, Ethiopia has recorded 60 degrees F (16 degrees C) in April. In winter, temperatures fall to freezing.

Cameroon is one of the wettest countries in Africa. In one year, Debundja recorded 374 in. (950 cm.) of rain. The heaviest rains fall between July and September. Year-round, the air is hot and humid. To the east lie Congo and the Democratic Republic of Congo. Their location on the equator holds the temperature nearly constant. The mean is 78 degrees F (25 degrees C), with a variance of only 3 degrees. March and April are the hottest months and July and August the coolest. As is true of other equatorial regions, rainfall is heavy, totaling 100 in. (254 cm.) per year. These countries have two rainy seasons, one between March and June, and the other between September and November.

East of the Democratic Republic of Congo lie Kenya, Tanzania, and Uganda, whose hottest months, January and February, are dry. Daytime heat gives way to nighttime temperatures as cool as 55 degrees F (13 degrees C). Rains fall between March and May, with northern Kenya subsisting on less than than 10 in. (25 cm.) per year. The highlands of Kenya and the whole of Uganda get 40–50 in. (102–127 cm.) of rain per year. South of the Democratic Republic of Congo, the Indian Ocean moderates the climate. Whereas temperatures in January hover in the 80s degrees F (high 50s degrees C), they fall in July into the 50s and 60s degrees F (10–15 degrees C). In contrast to Mediterranean Africa, spring is warmer than autumn in southern Africa. Most of this region receives less than 25 in. (64 cm.) of rain per year, with the most arid lands getting only 5 in (13 cm.). Despite the dearth of rain in these lands, other regions, visited by clouds from the Indian Ocean, receive 100 in. (254 cm.) of rain per year.

THE CLIMATES OF ASIA

Northeast of Africa stretches Asia, a continent of contrasts. The deserts of Central Asia give way to rainforest in Southeast Asia. India and Sri Lanka host rainforests that are fed by the monsoons. Monsoons originate in the South Indian Ocean and dump their rain over large tracts of land between June and September. India and Sri Lanka derive 85 percent of their rainfall from monsoons. The west coast of India and Malaysia receive more than 75 in. (191 cm.) of rain per year. The coast of Burma and Thailand and most of Sri Lanka are drenched by 350 in. (889 cm.) of rain per year. In the north, however, small regions of India and Pakistan receive as little as 3 in. (8 cm.) of rain per year.

The Indian Ocean moderates the climate of Sri Lanka, whose temperatures seldom fall below 70 degrees F (21 degrees C) or exceed 85 degrees F (29 degrees C). In southern India, temperatures in April and May hover between 82–85 degrees F (28–29 degrees C). In central India, temperatures in April exceed 85 degrees F (29 degrees C), and in May, 95 degrees F (35 degrees C). At their warmest, temperatures exceed 105 degrees F (41 degrees C).

Large and distanced from the equator, China has a variable climate. Heaviest in the south, rainfall decreases moving north. Hong Kong gets 85 in. (216 cm.) of rain per year, the lands between Hangchow Bay and the Gulf of Tonkin receive 40 in. (102 cm.), and northern China makes do with 20–25 in. (51–64 cm.). Mongolia subsists on fewer than 10 in. (26 cm.) of rain per year. In the middle of the Yangtze River valley, the heaviest rains fall in May and June. South of the river, the rains begin in June. Temperatures are warm in southern, central, and parts of northern China. Hankow, a town along the Yangtze River, averages 40 degrees F (4 degrees C) in January and 86 degrees F (30 degrees C) in July. The middle and lower Yangtze valley averages above freezing in January and above 80 degrees F (26 degrees C) in July and August. Further north, Beijing has recorded 110 degrees F (43 degrees C) in July. The region north of the Russian port of Vladivostock is cold in winter. Temperatures have fallen to minus 30 degrees F (minus 34 degrees C). Temperatures in Mongolia have fallen below zero degrees F (minus 18 degrees C) in January.

Off the coast of China lies Japan. The Pacific Ocean warms Tokyo, whose temperature in January exceeds 40 degrees F (4 degrees C). July temperatures peak at 87 degrees F (31 degrees C). January is the coldest month and July and August the warmest. In winter, precipitation falls as snow. Between November and April, temperatures are cold enough for snow to linger on the ground in drifts as high as 10 ft. (3 m.). The heaviest rains fall in June and July. Southernmost Japan and the mountains of the northeast receive 80 in. (203 cm.) of rain per year. The island of Honshu receives between 40–60 in. (102–152 cm.) of rain per year. Hokkaido in the north receives only 20–30 in. (51–76 cm.) of rain per year.

South of China is Southeast Asia and the islands of Indonesia, the Philippines, and New Guinea. Indonesia has an equatorial climate with little variation in temperature. With a range of only a few degrees, the monthly mean varies between 78–81 degrees F (25–27 degrees C). Jakarta, Indonesia, with temperatures of 78–79 degrees F (25–26 degrees C), has a range of only 1 degree. The air is hot and moist and rainfall heavy. Indonesia and New Guinea total more than 100 in. (254 cm.) of rain per year. The heaviest rains fall between September and December. The Philippines can exceed 120 in. (305 cm.) of rain per year, and the mountains of Indonesia and New Guinea tally 150 in. (381 cm.). Cambodia receives more than 200 in. (508 cm.) of rain per year with the heaviest rains in autumn.

West of China stretches the vast tract of Central Asia. Much of the land is arid, receiving fewer than 2 in. (5 cm.) of rain per year. Some areas total as little as .5 in. (1 cm.) of rain per year. Parts of southwest Asia are likewise dry. The deserts of Syria and Arabia tally less than 2 in. (5 cm.) of rain per year. Jerusalem, Israel fares better with 16 in. (41 cm.) of rain per year. Haifa, Israel totals 24 in. (61 cm.) and Beirut, Lebanon receives 35 in. (89 cm.). The interior of Turkey receives only around 15 in. (38 cm.) of rain per year, but the Mediterranean coast totals between 25–45 in. (64–114 cm.). The heaviest rains fall in April and May. In the Levant, the rains fall between October and April, with the heaviest rains in January. Little rain falls between May and September. Away from the coast, temperatures vary widely. Ankara, Turkey has recorded temperatures as low as minus 13 degrees F (minus 25 degrees C) in January, and as high as 100 degrees F (38 degrees C) in July. In Sivas, Turkey temperatures have fallen to minus 30 degrees F (minus 34 degrees C) in January, and in Beirut and Jerusalem temperatures have soared to 107 degrees F (42 degrees C) in July.

Arabia, Mesopotamia, and Persia lie southeast of Turkey. Saudi Arabia, inland from the Indian Ocean, totals less than 2 in. (5 cm.) of rain per year, whereas Oman and Yemen, benefiting from the moist air of the Indian Ocean, receive 15–20 in. (38–51 cm.) and 20–30 in. (51-75 cm.) of rain per year, respectively. Iraq and Iran tally fewer than 10 in. (25 cm.) of rain per year. The rains fall between November and April, though they are not steady. Little rain falls between May and October. These lands have only a brief spring. In April, temperatures rise rapidly to their summer highs. Baghdad, Iraq, reaches 110 degrees F (43 degrees C) in July; Tehran, Iran, 109 (42 degrees C) ; and Basra, Iraq, 105 (40 degrees C) .

North of Mongolia stretches the vast expanse of Russia, whose winters are among the coldest on Earth. In Siberia, temperatures stay below 0 degrees F (minus 18 degrees C) in January. Verkhoyansk, Russia averages minus 58 degrees F (minus 50 degrees C) in January and has recorded minus 94 (minus 70 degrees C) . January temperatures have fallen to minus 90 degrees F (degrees C) in Oymyakon, to minus 44 (minus 68 degrees C) in Moscow and to minus 35 (minus 37 degrees C) in St. Petersburg. Ice and snow cover the ground in Siberia more than 200 days per year. The port of Vladivostock remains frozen between December and April. Blanketed by snow, the ground is warmer than the air. The Crimea, benefiting from the warm waters of the Baltic Sea, averages nearly 40 degrees F (4 degrees C) in January. In summer, rain totals more than 20 in. (38 cm.) throughout Russia. As is true of the Mediterranean basin, autumn is warmer than spring in Russia.

THE CLIMATES OF EUROPE

West of Russia is Europe, a peninsula of Asia. The Gulf Stream originates near the Equator and, as it flows north, it warms the Atlantic coast of Europe, including Great Britain. Western Europe is warmer than comparable latitudes. Most of Western Europe has winter temperatures above freezing. As far north as Norway, the ocean is above 40 degrees F (4 degrees C) in winter, warmer than the ocean at comparable latitudes elsewhere. In January, Britain and France post temperatures above 40 degrees F (4 degrees C) , and Spain averages 50 (10 degrees C) .

Clouds and rain characterize the climate of northwestern Europe in winter. The region is among the cloudiest on Earth. As in Mediterranean lands, autumn is warmer than spring in Europe. Along the Atlantic coast, summer is cooler than it is in the interior of the continent. Portugal averages only 70 degrees F (21 degrees C) in July, and Norway only 50 (10 degrees C) . As rain falls in the winter, January is the wettest month in Western Europe and Britain and June the driest.

Central Europe, bereft of the warm Gulf Stream, is colder than Western Europe. Sveg, Sweden is as cold as minus 56 degrees F (13 degrees C) in winter. Rainfall is moderate, averaging 20 to 25 in. in much of Central Europe. The Po valley, having a continental rather than a Mediterranean climate, averages 30 in., and the wettest regions receive 40 to 50 in. Clouds hover in the sky much of the year. In winter, clouds drift into the valleys of the Alps. The mountain summits are clear and sunny.

In summer, the pattern reverses, with clouds above the summits and the valleys bathed in sunlight. South of the Alps stretches Mediterranean Europe. Its climate mirrors that of Mediterranean Africa. In some parts of the Mediterranean, temperatures average 50 degrees F (10 degrees C) in the coldest months. Temperatures year round are warmer in the south and east than near the Atlantic. Clear and sunny, summer is dry. Rainfall peaks in April and May and again in October. Rainfall tends to be heavy, with drizzle infrequent.

THE CLIMATE OF THE AMERICAS

Like Western Europe, the Atlantic coast of North America benefits from the warmth of the Gulf Stream. The American southeast has hot and humid summers and warm winters. South Florida records temperatures above 80 degrees F (27 degrees C) even in winter. The temperature never falls below freezing in Key West, Florida. Key West, Galveston, and San Antonio, Texas, and Vicksburg, Mississippi average more than 80 degrees F (27 degrees C) in July. The Gulf Stream brings rain to the American southeast. The Gulf Coast between New Orleans, Louisiana and Mobile, Alabama averages more than 60 in. (162 cm.) of rain per year.

At the other end of North America, the California Current cools the Pacific Coast. San Diego averages 67 degrees F (19 degrees C) in July, whereas Savannah, Georgia, at comparable latitude, averages 80 (27 degrees C) in July. The Pacific coast receives the most rain in North America. Wynoochee Oxbow, Washington averages 146 in. (371 cm.) of rain per year. Away from the moist Pacific air, the interior of North America receives less rain. The Colorado basin averages fewer than 3 in. (8 cm.) of rain per year. The Great Plains are prone to drought, with disastrous results in the 1870s and 1930s.

The Pacific Ocean warms British Columbia, Canada. Victoria and Vancouver, British Columbia average 39 degrees F (4 degrees C) in January. Away from the warmth of the Pacific and the Gulf Stream, northern latitudes are cold. The coldest winters occur between the Hudson Bay and Alaska. Fort Good Hope, near the Arctic Circle, has recorded minus 79 degrees F (minus 62 degrees C). Fort Vermillon, Canada has recorded minus 78 (minus 61 degrees C) and Churchill, Manitoba minus 57 (minus 49 degrees C) in January.

Storing the heat from the summer sun, the Great Lakes warm adjoining lands year round. The effect of the Great Lakes is mild, but measurable in winter. Toledo, Ohio, near Lake Erie, has recorded minus 16 degrees F (minus 9 degrees C) , whereas Columbus, Ohio, 100 mi. (161 km.) south and thus outside the moderating effect of Lake Erie, has recorded minus 20. Snowfall is heavy in the Great Lakes; clouds absorb moisture from the lakes, returning it to the region as snow. As in the Mediterranean, autumn is warmer than spring in North America. In autumn, temperatures reminiscent of summer often follow a cold spell. Americans know this time as Indian summer.

South of the United States stretch Mexico, Central America, South America, and the Caribbean islands. Moving south through Mexico, rainfall increases. The warmth of the Pacific Ocean makes the western coast of Mexico among the hottest lands in the Americas. The coasts of Central America are hot and rainy. The mountains of the interior are comparatively cool, though rainfall is abundant. Most of Central America receives more than 100 in. (254 cm.) of rain per year. Warmed by tropical waters on both coasts, Central America displays a uniform temperature. Panama averages roughly 80 degrees F (27 degrees C) year round.

South America narrows moving south. The decreasing width of the continent amplifies the effect of ocean currents on the southernmost lands. The east coast of South America, warmed by the Atlantic Ocean, is 10

Climate is so important that it has shaped human affairs—drought may have extinguished the Mayan civilization.

degrees F (6 degrees C) warmer than the western coast at comparable latitudes. Tropical South America is cooler than tropical Africa because the former has thicker clouds, heavier rains, and denser forests than the latter. As far south as the Tropic of Capricorn, South America averages more than 70 degrees F (21 degrees C) year round. South America is warmer in winter and cooler in summer than comparable latitudes in North America.

The heaviest rains fall east of the Andes Mountains, summer being the rainy season. Moist equatorial air, flows east to west across South America. The Amazon River valley receives more than 80 in. (203 cm.) of rain per year, with some locales tallying 100 in (254 cm.). The continent receives rain at least 250 days per year.

The Caribbean Sea and the Gulf of Mexico, with temperatures above 80 degrees F (27 degrees C) year round, warm the Caribbean islands. The climate is hot and humid. Rain is heaviest in June and again in October, with less rain falling in July and August. Moore Town, Jamaica averages 222 in. (564 cm.) of rain per year, and Port Antonio, Jamaica averages 137 in. (348 cm.). Kingston, Jamaica, on the leeward side of the mountains, averages only 31 in. (79 cm.) of rain per year. The moderating effect of the Caribbean Sea and the Gulf of Mexico holds temperatures constant. Only four degrees separate January and July mean temperatures in Barbados. The Caribbean, Florida, and the Gulf Coast are vulnerable to hurricanes.

THE CLIMATES OF AUSTRALIA, NEW ZEALAND, AND ANTARCTICA

In the South Pacific lies Australia, among the driest continents on Earth. Nearly half of the continent receives fewer than 10 in. (25 cm.) of rain per year. Less than 10 percent of Australia receives more than 40 in. (108 cm.). The South Equatorial Current warms the north and west coasts of Australia. Because of this ocean current, northwestern Australia is hottest. Marble Bar, Australia has recorded 121 degrees F (49 degrees C) and 161 consecutive days of at least 100 degrees F (38 degrees C). Roebourne, Australia has reached 117 degrees F (47 degrees C) in January and 220 days of at least 90 degrees F (32 degrees C) . The north of Australia receives its rain in summer, whereas the south receives its rain in winter. Paradoxically, the rainy season is less humid than the dry season.

Off the southeast coast of Australia lies New Zealand. At about the latitude of Italy in the Northern Hemisphere, New Zealand, bereft of the warmth of the Mediterranean Sea, is 10 degrees F (6 degrees C) cooler than Italy in summer. In winter, New Zealand, benefiting from warm Pacific currents, is warmer than Italy. New Zealand summers are sunny. Much of New Zealand receives fewer than 40 in. (102 cm.) of rain per year. The rains fall between October and January, with the heaviest rain in October.

South of the habitable continents is Antarctica, a land of unremitting snow and ice. The climate is too cold for the continent to host permanent settlements of humans. December averages minus 8 degrees F (minus 22 degrees C) and in January, minus 18 (minus 28 degrees C) . Precipitation, in the form of snow, falls in winter. Summer has clear skies and sunshine, but the sun is not warm enough at this latitude to melt the snow and ice. Instead, snow falls upon already existing piles of snow, compacting it into ice.

So important is climate that it shapes human affairs. The drying of the climate about five million years ago changed East Africa from forest to grassland and forced human ancestors out of the trees and onto the grasslands as bipeds. Drought may have extinguished the Akkadian and Mayan civilizations. The Little Ice Age nearly froze George Washington's Continental Army at Valley Forge. Humans are very much creatures of their climate.

Climate Action Network

THE CLIMATE ACTION NETWORK (CAN) is an international network of over 365 nongovernmental organizations working toward the building of collaborative and individual actions and programs designed to combat and minimize human-induced impacts leading to climate change. Established in March 1989, the network has seven regional offices located in Africa, Europe, Latin America, North America, South Asia, and Southeast Asia.

The vision of the network is to "protect the atmosphere while allowing for sustainable and equitable development worldwide." Based on the Intergovernmental Panel for Climate Change (IPCC) reports, the network has developed a comprehensive agenda for achieving change. The network is trying to keep global average temperatures as far below a two-degree rise as possible. The network calls on governments to commit to a global objective to maintain global temperatures at this level. While advocating this action, the network is also researching how to achieve this goal without compromising development needs. The network has developed a three-track approach to addressing the issue of climate change. The Kyoto track targets developed countries, the greening track targets developing countries, while the adaptation track targets the countries most vulnerable to climate change.

The Kyoto track uses the legally binding instruments of the United Nations Framework Convention on Climate Change and the Kyoto Protocol to drive greenhouse gas emissions reductions. The Kyoto Protocol contains mandatory provisions for the reduction of greenhouse gases by Annex I (industrialized) countries. Obligatory, dated targets, emissions-trading programs, and compliance mechanisms are vital components of the protocol.

In accordance with principles of historical responsibility and equity, only industrialized countries will be subject to these commitments. However, as developing countries industrialize, they will come under the purview of the protocol's mandatory provisions. The Kyoto track will spur the rapid development of sustainable technologies by industrialized countries, which will then be transferred to developing countries in the greening track.

The greening (decarbonization) track involves the rapid introduction of clean, sustainable technologies to developing countries in order that they may reduce their current emissions and follow a low-carbon path to development. The ability of these countries to develop in a sustainable way is largely dependent on the provision of technical and other assistance from industrialized countries. The greening track applies to all developing countries, except the least-developed countries, whose emissions are negligible, though they are provided incentives to participate, if they so desire. The emissions reduction and clean development goals vary according to the capacity of individual developing countries.

The adaptation track is designed to assist the most vulnerable counties (for example, small island states) in anticipating and limiting the effects of climate change. Industrialized countries bear the responsibility of providing assistance to these countries and, in the case that some consequences of climate change cannot be mitigated, the responsibility for compensation. Countries that receive assistance in the adaptation track may also participate in the other tracks, if circumstances permit.

The network has adopted this three-track system because it is committed to the principle of historical responsibility. This system calls on governments and countries that have historically contributed the most greenhouse gases to take responsibility for their actions.

While all countries have equal access to the atmospheric commons, different countries suffer disproportionately from the effects of global warming and climate change. This is particularly the case for developing countries. This three-track system is also based on the intergenerational principle, calling on nations to think about future generations and their right to have equal access to, and to live within, the atmospheric commons.

Climate Change, Effects

CLIMATE CHANGE IS commonly used to describe any systematic alteration or statistically significant variation in either the average state of the climate elements such as precipitation, temperature, winds, or pressure; or in its variability, sustained over a finite time period (decades or longer). It can be referred to as the long-term change in global weather patterns, associated especially with increases in temperature, precipitation, and storm activity.

These inconsistencies in climate systems are a potential consequence of the greenhouse effect by greenhouse gases (GHGs). Examples of greenhouse gases include: carbon dioxide (CO_2), methane (CH_4), dinitrogen monoxide or nitrous oxide (N_2O), halocarbon gases such as trichlorofluorocarbon ($CFCl_3$) and dichloroflurocarbon (CF_2Cl_2), water (H_2O), perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6). The atmospheric concentrations of these gases have been increasing, due to anthropogenic activities.

Climate change is attributed directly or indirectly to anthropogenic activities that impact the natural composition of the global climate elements. It may also be a result of natural external forcing, such as changes in Earth's orbital variables, or solar emission, and other natural internal processes of the Earth's climate system. The relative influences of external anthropogenic and natural factors on climate can be broadly compared, using the concept of radiative forcing. Radiative forcing simply refers to the process that disrupts the infrared radiation balance between incoming solar radiation from the Sun and the outgoing radiation from the Earth. A positive radiative forcing primarily results in the relative warming of the Earth's surface and is due to increasing levels of GHGs. A negative radiative forcing, which can arise from an increase in some types of aerosols, tends to bring about the cooling of the Earth's surface.

Changes in orbital variables, solar output, or explosive volcanic activity, are natural external factors that can also cause radiative forcing. The systematic account of these climate-forcing agents and their differences over a timescale is required to understand past climate changes in the context of natural variations, and to predict the nature of future climate changes.

The effects of climate change include variations in biospheric ambient temperature, which could lead to heat stress, change in rainfall patterns, sea-level rise, saltwater intrusion, loss of biodiversity, drought, habitat loss, and freshwater depletion and pollution. In most cases, climate change has been used interchangeably with global warming, and the greenhouse effect. However, in recent accepted usage, climate change only connotes any change or changes in modern climate systems, whether due to natural variability or as a result of human-caused activity, including an increase over a period of time of the average temperature of the Earth's atmosphere and oceans, known as global warming.

The United Nations Framework Convention on Climate Change (UNFCCC) has adopted the phrase *climate variability* for non-human mediated changes in climate elements. Climate variability is usually natural in origin, resulting primarily from slight variations in the complex processes that drive the movement of heat and mass between the atmosphere, the marine aquatic ecosystems, and the land surfaces. For example, the El Niño–Southern Oscillation (ENSO) is caused by weakening trade winds in the southern part of the Pacific Ocean, and has consistently affected regional variations of precipitation and temperature over much of the tropics, subtropics, and some mid-latitude areas, leading to warmer episodes in these areas. Trade winds carry warmer air west, which leads to rising sea temperatures and increased precipitation.

According to reports by the Intergovernmental Panel on Climate Change (IPCC), human beings are altering the Earth's natural climate system. Evidence indicates that human-induced climate change, if allowed to continue unabated, could have profound consequences for the economy and the quality of life of future generations. Fossil fuel consumption, which has been steadily increasing since the pre-industrial period, is causing an overall increase in concentrations of atmospheric GHGs, especially CO_2.

Current research indicates that radiative forcing driven by greenhouse gases is the primary cause of global warming. According to these studies, GHGs traps the Sun's heat energy and compels a redistribution of the trapped radiation available near the Earth's surface, thus regulating the Earth's temperature. GHGs, especially CO_2, are the major non-climate factors driving climate change. The continuous build-up of these gases is expected to cause significant changes in climatic conditions over the next century.

WATER RESOURCES AND TEMPERATURE RISE

Researchers around the globe have found that climate change is likely to impact water resources depletion and pollution significantly. There have been observed changes in surface temperature, rainfall, evaporation, and extreme events since the beginning of the 20th century. The atmospheric concentration of CO_2 has increased from about 280 parts per million by volume (ppmv) to about 369 ppmv, and the global temperature of the Earth has increased by about 0.6 degrees C. The present CO_2 concentration has not been exceeded during the past 420,000 years and likely not during the past 20 million years. The current rate of atmospheric CO_2 level increase is unprecedented during at least the past 20,000 years. About 75 percent of the anthropogenic emissions of CO_2 to the atmosphere during the past 20 years is attributed to fossil fuel burning. The rest is predominantly due to land-use change, especially deforestation.

The globally averaged surface temperature is projected to increase by 1.4 to 5.8 degrees C 1990–2100. The global mean sea level has risen by 4–8 in. (10–20 cm.). The average global surface temperature is projected to increase by 1.4–3.0 degrees C 1990–2100 for low-emission scenarios, and 2.5–5.8 degrees C for higher emission scenarios of greenhouse gases in the atmosphere. Over the same period, associated rise in global mean sea level is projected between 1.3–13.6 sq. in. (9–88 sq. cm.).

A number of researchers have reported the impact of climate-change scenarios on hydrology of various basins and regions; they project that increasing temperature and decline in rainfall may reduce net recharge and affect freshwater resources. Human-caused influences are expected to follow a steady growth trend in the future; climate modifications caused by anthropogenic radiative forcing are considered to be more permanent than those caused by natural variability factors.

According to the Intergovernmental Panel on Climate Change (IPCC), since the Industrial Revolution began in the mid-16th century, CO_2 levels in the atmosphere have increased by 35 percent and the atmospheric concentration of CH_4 has increased by 1060 parts per billion (151 percent) and will continue to increase. The present CH_4 concentration has not been exceeded during the past 420,000 years. The inter-annual growth in CH_4 level slowed and became significantly variable in the 1990s, compared with the 1980s. It has been suggested that a significant ratio of the current CH_4 emissions are anthropogenic rather than natural. The anthropogenic sources of methane include the consumption of fossil fuels, cattle, paddy rice fields, and landfills. Recent studies have indicted carbon monoxide (CO) emissions as a cause of increasing atmospheric CH_4 concentration.

In addition, the emissions of persistent GHGs such as CO_2, N_2O, PFCs, and SF_6 could continue to have long-term impacts on atmospheric composition, radiative forcing, and climate elements. This could imply that anthropogenic climate change may persist for a long time to come. The enhanced atmospheric concentrations of GHGs are implicated as the primary cause of global warming.

Recent findings by the IPCC indicate that the atmospheric concentration of CO_2 in 2005 was 375 ppm compared to the pre-industrial levels of 280 ppm. This has contributed to the increase in the Earth's surface temperature by 0.6 degrees C (one degree F). Worldwide measurements of sea level have demonstrated a rise of about 0.56 ft. (0.17 m.) during the 20th century. The world's glaciers have, over time, receded steadily and Arctic sea ice extent has steadily shrunk by 2.7 percent per decade since 1978.

Glaciers are an intriguing part of the Earth's natural environment and have been identified as one of the significant and sensitive indicators of climate change. Their size, lifespan, and timescale information of accumulation and ablation, or growth and collapse (glacier retreat) are primarily attributed to change in climate elements such as temperature, precipitation, wind speed, humidity, and solar radiation.

Increased surface temperatures of the Earth are causing glaciers to melt faster than winter snows can replenish them. Melting sea ice may eventually lead to global changes in water resources and circulation, and melting ice could speed up warming of the Arctic because water absorbs much more heat than ice. Extreme and ongoing declines in the thickness and extent of Arctic sea ice will pose enormous consequences for the Arctic population, their ecosystems, and coastal evolution. As the glaciers shrink, a greater portion of the Earth's water will enter the liquid phase and becomes available to the oceans and the atmosphere. This will ultimately result in a increased volume of water in the oceans, which could lead to a significant rise in sea level.

IMPACTS OF SEA-LEVEL RISE

During the 20th century, the sea level rose by 4–8 in. (10–20 cm.) primarily as a result of melting glacier ice and thermal expansion of warmer ocean water. It has been predicted that sea level rise will be even greater as the oceans warm along with the rest of the Earth. This is due to the fact that water expands as its temperature increases. Climate change models have predicted that a global mean sea level rise as much as 33 in. (85 cm.) is expected during the 21st century. Accelerated global sea-level rise is expected to have far-reaching and dramatic impacts in vulnerable regions of the Earth where subsidence and erosion challenges already exist. Rising seawaters are already submerging, for example, coastal wetlands and mangroves in southern Florida, and approximately one million acres of Louisiana wetlands have become open water since the mid 20th century.

Sea-level rise has the potential of causing increases in the intrusion of saltwater into coastal aquifers. Shallow islands, and coastal aquifers supporting human use (such as those in Long Island, New York, and central California) could be at greatest risk. Rising sea level has also contributed to increased mortality of trees in coastal areas of Louisiana and southern Florida, where saltwater has already intruded into the groundwater on which trees depend.

Other impacts associated with sea-level rise include changes in salinity distribution in estuaries, altered coastal circulation patterns, destruction of transportation infrastructure in low-lying areas, and increased pressure on coastal levee systems. Atlantic and Gulf Coast shorelines will be especially vulnerable to long-term sea-level rise, as well as any increase in the frequency of storm surges or hurricanes. Most erosion events on these coasts are the results of storms, and the slope of these areas is so vulnerable and gentle that a small rise in sea level may produce a large inland shift of the shoreline. This increases the threats to coastal development, transportation, freshwater aquifers, infrastructure, and fisheries. These impacts can adversely affect the quality of water resources. Moreover, the potential negative implications of climate change for water quality include reductions in stream flows, increased storm surges, and higher water temperatures. An increase in the number of intense precipitation days could lead to increases in the variety of agricultural and municipal polluting substances being washed into rivers, estuaries, streams, and lakes, and sea-level rise would contribute to saltwater intrusion into rivers, estuaries, and coastal aquifers.

FRESHWATER SUPPLY ISSUES

Global climate change will have major impacts on freshwater ecosystems. This will affect availability, as well as quality, distribution, and form. In certain regions, where stream flow and precipitation increase, flooding could threaten the structure and functions of aquatic systems, leading to increased pollution of freshwater ecosystems, especially in areas where human-mediated activities might have altered the landscape. The impacts of climate change on the Earth's freshwater resources have the potential of affecting international relations, especially at continental or country borders, where shared wetlands can generate local and international political and geographical disputes.

Impacts of climate change on water resources will have a wide range of consequences for coastal ecosystems. The health of the Earth's ecosystems will be affected by changes in the quality and quantity of freshwater runoff into coastal wetlands, higher water temperatures, extreme runoff rates or altered timing, and the ability of watersheds to assimilate pollutants and wastes.

Global climatic changes could pose a serious demand on the water supply. In most regions of the world where there are observed and projected declines in per capita average of annual freshwater availability, coupled with attendant population growth, the possibility of increased demand for water will likely lead to increased withdrawal of water, which will invariably reduce the recharging time of the water tables. These changes may influence a wide range of water-system components, including reservoir operations, water quality, hydroelectric generation, and navigation. In some regions, where large volumes of water are channeled for non-consumptive purposes such as agriculture demand, particularly for irrigation, water supply will be particularly sensitive to climate conditions;

Predicted mean sea-level rise of as much as 33 in. in the 21st century threatens fragile shorelines such as this one in Florida.

demand for irrigation water tends to increase as conditions become hotter and drier. A possible change in field-level climate may result in altering the timing of, and need for, irrigation.

In-stream water uses such as hydroelectric power generation, navigation, recreation, and ecosystem maintenance are also sensitive to changes in the quantity, quality, and timing of runoff stemming from greenhouse warming. Potential negative implications of climate change include reductions in dilution flows, increased storm surges, and higher water temperatures. Low flows in many rivers will lead to increases in salinity levels to downstream water users.

On the other hand, higher flows could help reduce some water quality concerns. Warmer water could threaten aquatic life directly, as cool-water habitats disappear, and indirectly, as dissolved oxygen levels decline with higher temperatures. An increase in days with more intense precipitation could increase the agricultural and urban pollutants washed into streams and lakes, further reducing oxygen levels. Heavy rainfall is primarily responsible for soil erosion, leaching of agricultural chemicals, and runoff of urban and livestock wastes and nutrients into water bodies.

CHANGING ECOSYSTEMS AND WEATHER

Another possible effect associated with climate change is the potential danger it holds for marine ecosystems. As the sea-level rises, coupled with increased warming of the ocean waters, marine biodiversity will be further threatened by the myriad impacts on all marine ecosystems, from tropical coral reefs (especially in the Maldives), to polar ecosystems. Coral reefs are already under severe stress from human activities, and have experienced unprecedented increases in the extent of coral bleaching, emergent coral diseases, and widespread die-offs. Damages to coral reefs lead to depletion of important habitat for fish food.

Changes in ocean temperatures, currents, and net productivity will affect the distribution, abundance, assemblages, and productivity of marine populations, with unpredictable consequences to marine ecosystems and fisheries. As the Earth's surface temperature warms, species may either migrate to a cooler, more suitable habitat, or die. Species that are particularly vulnerable to climate change effects include polar animals, such as seals, penguins, and polar bears, coral reefs, and many other endangered animal and plant species.

Climate change has the potential to alter the hydrologic cycle. In many regions of the world, global climate change will have significant effects on precipitation and evapotranspiration. Heavier rainfall could lead to flooding in many regions as warmer temperatures speed up the hydrologic cycle. Flood frequencies in some areas are likely to change. In northern latitudes and snowmelt-driven basins, floods may become more frequent, although the increase in flooding for any given climate scenario is uncertain and impacts will vary among basins.

Over the past century, it is estimated that there has been a 5–10 percent increase in precipitation. Climate-induced changes in hydrology will affect the magnitude, frequency, and cost of extreme events, which have the greatest economic and social impact on humans. Flooding, the most costly and destructive natural disaster, is becoming a common and extreme event as a result of climate-induced variations. Severe weather events are becoming more common and extreme, as well.

Climate change researchers have indicated that the number and strength of anthropogenic-induced climate extreme events such as storms, hurricanes, typhoons, floods, and tornadoes have increased over the past 10–20 years. For example, a record breaking 28 tropical storms hit the United States in 2005, alone. All these phenomena are traceable to variations in radiative forcing brought about by anthropogenic GHGs in the atmosphere. Increases in precipitation and runoff are likely to intensify the stresses on streams, lakes, bays, estuaries, and rivers in some regions of the world by strengthening the transport of nutrients and contaminants loading to coastal ecosystems. Higher latitudes are more likely to receive increased precipitation and runoff, while lower latitudes are more likely to experience decreased runoff.

Regions with snowfall, such as the Rocky Mountains and Sierra Nevada, California, will experience seasonal shifts in runoff, with increases in winter and early spring runoff, decreases in late spring and summer runoff, and possible increased flood intensities. The frequency and severity of droughts could increase in some areas as a result of a decrease in total rainfall, more frequent dry spells, and greater evapotranspiration.

HEALTH ISSUES

Several health challenges can be linked to global climate change. According to IPCC scientists, a climate-induced warmer world could lead to a number of health problems. These health challenges include increased global distribution of tropical diseases, such as malaria and dengue, heat stress, hunger-related ailments, and injuries and drowning associated with increased storm frequency and intensity.

Africa, for example, is expected to be at risk from increased incidence of vectorborne diseases. A warmer Africa has the potential of opening up new areas for malaria, and altered temperature and rainfall patterns in the continent could lead to increased incidence of yellow fever, dengue fever, onchocerciasis, and trypanosomiasis. In the Middle East and Asia, heat stress, which will affect human comfort levels, and the possible spread of vectorborne diseases will likely result from climate-induced changes. In general, decreases in freshwater availability would lead to indirect impacts on human health.

Climate Change Knowledge Network

THE CLIMATE CHANGE Knowledge Network (CCKN) was established in 1998, to enhance cooperation between developed and developing countries on research related to climate change. The network aims to make knowledge about climate change available to all countries of the world. The collaborative efforts encouraged by the network strive to disseminate knowledge on climate change and to make such knowledge relevant for the international policy process. The network includes 12 core member institutions in Senegal, Zimbabwe, the United States, Canada, Brazil, Argentina, China, India, Norway, the Netherlands, and Sweden. The governments of Canada, the United States, and Norway support its activities.

The aims of the network are to promote more sustainable and equitable climate change management through research and communication on issues such as the Kyoto Protocol, to develop a dialogue between developed and developing countries for a better understanding of the global effects of climate change, and to help each member institution to increase its capacity to propose regional policies about climate change. The network promotes international negotiations that make explicit connections between development and climate change. The network also enables members to take part in various projects, to share their results with other members, and to bridge the gap between development and climate change. The CCKN is pledged to equity among its members and is based on mutual learning. Members take part in activities that involve the whole network and also in partnerships with other members.

The CCKN has its headquarters at the International Institute for Sustainable Development, in Canada, which also helps the members to disseminate their work and projects via the internet. The network's core members are institutions selected from developing and developed countries. They participate in decision-making processes, research projects, and fundraising activities. The network also has associate members, who are either former core members, or organizations with interests in climate change that share the same aims as those of the network. Network members usually meet in person, once a year, at the annual meeting the Conference of the Parties to the United Nations Framework Convention on Climate Change.

Through individual and joint projects, member organizations identify relevant research areas and work collaboratively to shape the international climate change process, as well as regional and local processes. An ongoing interest of the knowledge network is the assessment of the socioeconomic and environmental impacts to implement the UN Framework Convention on Climate Change and the Kyoto Protocol.

The CCKN is committed to the training of negotiators from developing countries so that they can effectively take part in international negotiating processes. As part of its activities, the network has devised an online resource to provide an overview of the key topics and actors in climate negotiations. This is an important tool for developing countries that are the most affected by climate change, but whose negotiating capabilities are often challenged. The network recognizes that developing and least-developed countries are the most vulnerable to the impacts of climate change, so it has undertaken research on the long-term policy measures to be adopted. The CCKN was able to bring together the International Institute for Sustainable Development, the Center for International Climate and Environmental Research, and the Tata Energy Research Institute to explore the impacts of economic changes and climate change for India's agricultural sector.

The most significant project of the CCKN is the Clean Development Mechanism (CDM), a multiphase assessment of the role of decentralized renewable energy in sustainable development, poverty relief, and greenhouse gas mitigation through the Kyoto Protocol. As the first stage of the CDM, the network commissioned a series of short scoping studies completed by its partners in developing countries. These studies assessed the national state of decentralized renewable energy in China, India, Senegal, Zimbabwe, and Chile and were completed in early 2002. The second stage of the project involves ways to encourage the use of decentralized renewable energy systems.

Climate Cycles

THERE ARE IDENTIFIABLE cycles in the weather patterns of the Earth. There are four seasons every year in the temperate zones. In the polar regions, there are seasons of light and dark, and in the tropical regions, there are seasons of wet monsoons and dry periods. These identifiable annual cycles are like the cycles of the climate of the Earth over vast eons of the geologic eras.

Geologists estimate the age of the Earth at about 4 billion years old. For much of that time, it was a ball of gas, then the scene of enormous volcanic activity, and then weather activity dominated the whole of the Archaic or Pre-Cambrian eras of Earth's history. During that time, repetitions of climate patterns may have occurred, but there were also dramatic changes. There was a time when oxygen came to be a major part of the atmosphere, when it was not as abundant as now. These point to cycles in the climate, or the long-term average of the weather on Earth.

The last ice age ended around 12,000 years ago. However, it was not the first ice age on Earth, nor the last. It was only the end of the most recent ice age. There were at least three others in the recent history of the Earth. These ice ages, between interglacial periods, are identifiable cycles of climate in the history of the Earth.

One possible cause of cyclical changes in Earth's climate is its orbiting of the Sun (the Milankovich cycle). The solar calendar is keyed to the annual journey of the Earth around the Sun. It is a journey that occurs every year and causes seasonal change. Although there are the same seasons every year, they are never exactly alike. Astronomers and others have observed that there is a cycle that some set at roughly 24,000, or 48,000, or even 72,000 years. The cycle is believed to be responsible for climate changes because the Earth wobbles a bit as it orbits the Sun due to the variations in the gravitational pull of other planets and of the Sun itself. The slight changes in orbit and the tilt of the Earth in relationship to the Sun's rays means more or less sunlight hitting the Earth, increasing or reducing the amount of energy available to warm the Earth and its atmosphere.

Some scientists believe that ice ages may be caused by the variations in sunlight hitting the Earth during its solar journeys. However, the amount of sunlight during the solar journey has to be combined with solar variations. The sun goes through cycles of activity in which varying levels of energy are emitted. The solar energy variations are related to the presence and absence of sunspots. Increases in these are likely to also bring about an increase in aurora lights, in both the Northern and Southern Hemispheres. The aurora lights are connected to the magnetic field of the Earth. Researchers studying the sun's magnetic activity over 100,000-year cycles have proposed the theory that the climate of the Earth is affected by this solar activity cycle. Waldo S. Glock attempted to show a relationship between the weather as a part of a climate pattern and variations in periodic solar activity.

The pattern that paleoclimatologists have discovered is one that describes significant climatic changes with relatively small changes in the Earth's solar orbit. The variations in sunlight have been compared to variations in weather on Earth. Instruments have been developed to measure the amount of solar energy striking the Earth. Cycles have been detected using data from weather records. Weather records have also been compared statistically with wheat prices. The higher the price of wheat in historically available data, the poorer the weather likely was. Other plant information that has been available to study climate cycles is found in the rings of trees. Dendrochronology is the study of tree rings over time. Trees grow faster in wet warm years than in dry years or in cooler times.

The discovery of climate cycles that has been verified by a variety of sources points to the current phenomenon of global warming. However, it was preceded by an ice age in which there was global cooling. Consequently, the Earth has experienced both global cooling and global warming in its 4-billion-year-old history. Opposed to theories of climatic cycles is the fact that the climate of the Earth also changes in non-cyclical ways when charted on a variety of timescales.

There are shorter cycles, such as the El Niño Southern Oscillation, the Pacific decadal Oscillation, the Arctic Oscillation, and the North Atlantic Oscillation, the 1,500-year cycle from ice core samples, and the sunspot cycle (the Hale cycle). All of these cycles can be hypothesized from climate records. They are being used in debates over global warming to argue that either the cause is anthropogenic, or that global warming is part of a natural cycle that is only apparently anthropogenic.

Climate Feedback

CLIMATE FEEDBACK (CF) is a direct or indirect partial response (sensitivity) of any component of the climate system (for example, clouds, atmospheric chemical composition, or atmospheric water vapor) back on the Earth's near-surface temperature (NST) that was initially offset by an external to the climate system forcing. An initial disturbance of the NST comes from a change in the physical properties of the surface (for example, due to human agricultural activities) or atmosphere (for example, an industrial increase of greenhouse gases), or occurs due to the presence of an external to the system's heat source (such as urban heat islands). When the NST is initially forced, a feedback either amplifies (positive feedback) or damps/controls/scales (negative feedback) the effect of the disturbance back on the NST.

CF should be differentiated from radiative feedbacks (RF), which represent a response of the NST back to the radiative balance at the top of the atmosphere (TOA), which was initially offset by an external forcing. The radiative balance (RB) at the TOA is the difference between the incoming into the Earth's solar radiation, and the outgoing terrestrial radiation. Both CF and RF are components of a climate feedback loop's network. The system's net feedback loops effect (netFLE) accounts for all possible influences of the climate variables on each other and is compounded with direct and indirect feedback loops.

There are many CFs that are recognized in the Earth's climate system of interactions. Among them are water vapor feedback, lapse-rate feedback, ice/snow albedo feedback, carbon cycle feedback, biogeochemical cycles feedback, dynamical feedback, ocean circulation and marine life feedbacks, and cloud feedbacks. In most cases, feedbacks can be expanded further to a set of other feedbacks in accordance with the physical properties of a climate variable in relation to the NST. Thus, a cloud feedback is expandable to changes in cloud cover, cloud top temperature and/or height, cloud optical thickness, or cloud droplet size. It is recognized that, for the climate system, the most important CF is water vapor feedback, which is closely coupled to lapse-rate and cloud feedbacks.

There are direct (one-to-one relationships between temperature and a climate variable) and induced (via other variables) CFs. Another term for induced feedback is *indirect feedback*. Due to the atmospheric, oceanic, and land processes interactions, most of which depend on temperature, the direct CFs compete with, and are enriched by, the induced ones. Sometimes, it is possible to find a scale in time (such as annual or decadal) and space (such as regional or global) where a separation of the climate variables into fast and slow varying ones is possible, and the climate system can be simplified to understand and predict its evolutionary paths. Slow varying variables define slow feedbacks. Fast feedbacks, acting along a chain of interactions, cancel each other, affecting the tendencies of the climate system evolution. An example of a fast negative CF is a lapse-rate feedback (sometimes termed *atmospheric temperature profile feedback*), which establishes the atmospheric temperature profile and the magnitude of the near-surface temperature in response to surface heating in a matter of hours. An example of a slow positive CF is a global ice-albedo feedback, which is active over many centuries and brought the Earth to the ice ages and back.

Strength of the feedbacks is defined by climate system composition (for example, how many elements of the climate system are under consideration), an initial state (for example, the recent climate, or an ice age), and the nature of the relationship among climate variables spanned over spatial and time domains. For example, an atmospheric feedback initiated by surface warming due to an increase in carbon dioxide is different in dry and moist atmospheres: the presence of water vapor in the atmosphere increases the strength of the dry atmosphere positive feedback on the surface temperature. Feedbacks initiated in a cloudy and/or polluted atmosphere are different from ones initiated in a clear (no clouds) and clean (no aerosols) atmosphere. Feedbacks resulting from a volcano confined to the polar vortex region (or just to one hemisphere) will be different from the feedbacks resulting from a tropical volcano eruption.

A general measure of CFs is the climate sensitivity (CS), or its reciprocal, a climate feedback parameter (CFP). The CS depends on a netFLE and where climate forcing is in place. The CS and CFP are easily estimated from the numerical models as they represent a closed description of the model climate state's evolution and they allow for executing "sensitivity" experiments with a model. Differences in the model

CS estimations are explained by implementation of a slightly different set of feedbacks (such as that related to clouds) that amplify or dampen the initial perturbation. It is difficult to infer CS from the observations, as they do not supply a complete and continuous mirror of the real world, and each observational climate state carries footprints of numerous non-attributed forcings from the present and past. Without a model, it is difficult to recognize a single feedback or a single feedback loop, or to validate an estimated model feedback with observations. However, observations are the only source to validate model parameterizations, which are approximations of the climate system feedbacks.

Climate Forcing

CLIMATE FORCING OCCURS when the global energy balance of the Earth is changed. There are a number of mechanisms that can force climate change. The Earth's global climate is a dynamic system that is in equilibrium. On a planetary scale, it is steered by the amount of energy available in the system for use by its various ecosystems. If the amount of energy stored or received in the climate system changes, then climate changes occur as well. The global climate is affected by the Sun, which provides much of the energy in the global energy balance. If the energy from the Sun increases or decreases, climatic changes will likely occur. On the other hand, if the amount of energy kept by the Earth from sunlight increases, then climate changes will also occur.

The flows of energy occurring in the planetary climate system are important to the global climate system. The global climate system includes the heated core of the Earth and the parts of the Earth that receive the Sun's energy. The parts of the Earth's climate system include the atmosphere, the oceans, the cryosphere (ice caps at the poles and the alpine glaciers), the geosphere (for example, the reflective desert sands), the dense foliage of the tropics, the vast forests of the temperate and boreal zones, and other parts of the biosphere. All of these play a role in the convection system on the planet that transfers heat around the globe.

The atmosphere is central to the Earth's climate, which is a mixture of gases and aerosols (suspended liquids and solid articles). Commonly known as the air, the atmosphere is mostly nitrogen and oxygen. These two gases are available in amounts of about 78 percent nitrogen, 21 percent oxygen. They total about 99 percent of the air that surrounds the planet. The remaining gases and aerosols are present in only trace amounts; however, the greenhouse gases (such as carbon dioxide, methane, and nitrous oxide) play an extremely important part in the energy dynamics of the planet's global climate.

Greenhouse gases regulate the amount of heat that is present in the lower atmosphere. The gases capture radiant infrared energy and bounce it back to Earth. The gases act as a thin thermal blanket and have a natural greenhouse effect. As a result of greenhouse gases, the temperature of the Earth is 33 degrees C warmer than it would be otherwise. However, since the Industrial Revolution began about 200 years ago, the volume of human-made greenhouse gas emissions has increased enough to affect the greenhouse gas effect and to cause global warming.

Convection is the mechanism through which many energy transfers in the system are exchanged. The oceans are heated by the energy of sunlight. The sunlight is a system input that dynamically affects the global climate on a planetary scale. The output in the system is that most of the Earth's sunlight warming occurs in the tropics on either side of the equator. The warm seawater evaporates and rises, forming a lower pressure over the oceans and seas of the tropics and the land, as well. The rising warmer air is replaced by cooler, denser air flowing in from the polar regions. Movements in the atmosphere are also heat transfers. The atmosphere also stores energy. About 70 percent of the Earth's surface is covered by water. The oceans are energy storage centers that contain, in their top 656 ft. (200 m.) of ocean water, 30 times the amount of energy that is stored by the atmosphere.

The continental and alpine glaciers of the high mountains contain most of the Earth's cryosphere. Filled with ice and snow, and frozen by subzero temperatures for much of the year, the white surfaces reflect vast quantities of energy that would otherwise be absorbed by the Earth. The global climate system would then have a major energy source that would affect the dynamics of the interrelated parts of the system, and thereby invoke major changes in its output.

The plant portion of the Earth's biosphere (all living organisms, including humans) uses carbon dioxide and sunlight to photosynthesize food for growth. The oceans play an important role in this process because plankton, while microscopic, consume vast quantities of carbon dioxide. The gas is locked away in carbonate shells, which sink to the ocean depths. In the planetary climate system, this portion of the biological part of the system reduces the amount of carbon dioxide in the atmosphere and thereby weakens the greenhouse gas effect. Both the sunlight reflection of the cryosphere and the biosphere reduce the energy in the global climate system, thereby cooling the Earth. Clouds and the upper levels of the atmosphere also play a role in the global climate system. Clouds reflect vast volumes of sunlight into outer space. Energy in the form of x-rays, gamma rays, or ultraviolet energy is also reflected back into outer space.

The global energy balance can be affected by changes on Earth, such as an increase in volcanism. Active volcanoes send huge clouds of gases and ash into the atmosphere. If the volume is sufficiently large, the input of gases and ash to the system can affect the planetary climate system by blocking the amount of the available energy and temporarily forcing cooling of the planet. The major question is whether rising levels of anthropogenic carbon dioxide are forcing global warming.

Climate Impacts LINK Project

THE CLIMATE IMPACTS LINK Project (LINK) provides climate model data harvested at the Met Office Hadley Centre (MOHC) for use by researchers, institutions, companies, and political organizations. These users are located both in the United Kingdom and abroad; the data from LINK impact many fields such as marine biology, aviation, civil engineering, public policy, economics, and atmospheric sciences.

LINK is supported financially by the United Kingdom's Department of the Environment, Food, and Rural Affairs (DEFRA), based in London, England. DEFRA, in fact, established LINK in 1991, and assigned the Climate Research Unit (CRU) at the University of East Anglia (UAE) to handle the data. The task became too large for the computer systems at the UAE Climate Research Unit and the contract was sublet to the United Kingdom's British Atmospheric Data Centre (BADC). The CRU maintained the ancillary data responsibilities until the year 2006 when those, too, were taken over by the BADC. Subsequently, the duties were subcontracted to the MOHC by the BADC, though still overseen by the BADC.

The BADC, overseen by the United Kingdom National Environment Research Council (NERC), acts as the chief data center for Atmospheric Sciences and reports to the NERC. It was established in 1994 to take over the responsibilities of the former Geophysical Data Facility. At the time, it was funded by NERC's predecessor, the Science and Engineering Research Council (SERC) and generally supported research concerned with the atmosphere within approximately 6–249 m. (10–400 km.) above the Earth's surface. Today, the broader NERC supports all atmospheric science.

DEFRA works to reduce greenhouse gas emissions both domestically and internationally. Its other chief goal of the Department is to foster a clean, healthy environment for people to live and work in. To achieve this second goal, DEFRA is a strong proponent for sustainable development. It works to achieve this in rural settings, urban communities, within the European Union, and beyond.

LINK uses several models to analyze the data at the MOHC. These models include the HadCM2 (Hadley Centre Coupled Model versions 2) and HadCM2 (for global datasets), HadRM2 and HadRM3 (high resolution regional atmospheric models), and HadGEM1 (an integrated model for both types of data). The HadCM2 and HadCM3 (Hadley Centre Coupled Model versions 3) models were used for the International Panel on Climate Change (IPCC) Second and Third Assessment Reports to the United Nations, respectively. The newer HadGEM1 along with the HadCM3 models were both used for the Fourth Assessment Report. The regional HadRM2 and HadRM3 models cover European climates and the latter contributed data to the United Kingdom Climate Impacts Programme 2002 Scientific Report on Climate Change Scenarios for the United Kingdom (UKCIP02). The 2008 report (UKCIP08) will also use data from the HadRM3 model.

Climate Models

CLIMATE MODELS ARE quantitative representations of the earth, its atmosphere, and the ways in which they interact to influence the climate. Models range from the comparatively simple to the extremely complex and their range, complexity, and predictive power have increased significantly in the 21st century as computational power has increased. The ability of scientists to create sophisticated climate models is of several magnitudes of order beyond what was possible even a few years ago.

Scientists use mathematical formulae, combined with the modeling ability of computers and available data sources, to create an understanding of how climate and weather effects work in different parts of the atmosphere. The purpose of the models is not just to understand atmospheric interactions, however, but to predict how they will work in the future. Predicting the weather will be of great benefit in helping people prepare for adverse phenomena such as hurricanes and typhoons, as well as the longer-term effects of drought or floods.

Further, as evidence has begun to accumulate that increased release of carbon dioxide and other gases is having a significant effect on the warming of the atmosphere, climate models have acquired the additional role of predicting the future of the world's climate and the effect of constant warming of the atmosphere.

This has led to some controversy because there are powerful economic and political incentives for some to try to demonstrate that atmospheric warming, and hence, global climate change, is not a long-term, persistent phenomenon or, if it is, that it is the result of human actions. Climate scientists have found themselves, their motives, and their methodologies questioned, much more fiercely than before and not every scientist has been comfortable with this development.

Academic discourse and the scientific method require knowledge to be accumulated in a systematic method subject to peer review, which means that most scientists are, quite properly, hesitant about giving simple, unequivocal answers to questions that require 'yes' or 'no' answers. The entire academic process is not transparent to outsiders and it is difficult to refute criticism.

THE SCIENTIFIC BASIS

The fundamental climate change equation concerns the exchange of heat in the atmosphere. Heat is transmitted to the atmosphere from radiation from the Sun. Some of the heat energy is absorbed and some reflected. The amount of energy reflected depends on the albedo of the surface and can be affected by variables such as color, elevation, and shape. If more energy is retained than reflected, then the atmosphere will increase in temperature, but temperatures will decrease if the opposite is true. This equation is affected by the composition of the atmosphere, among many other factors. While the equation appears navigable, in fact the complexity of the atmosphere is such that it is extremely difficult to write accurately.

Scientists in the 19th century attempted to create the equation using the mathematical and analytical tools available. At that time, the number of atmospheric observations and the extent of their coverage were very limited. As observations improved in quality and quantity, the ability to model the equation improved. Scientists realized that the wind system was not consistent acround the world and, consequently, what happened in one part of the world was different from another part of the world, even with similar initial conditions. Consequently, it became a logical step to divide the surface of the world into smaller subsections on a grid basis and attempt to solve the equations and, hence, predict the weather, for each grid square.

However, these efforts failed as it became clear that solutions required contemporaneous computational power. It was practically impossible to predict the weather by solving equations for grid squares more quickly than weather elapsed in real time. Consequently, new forms of modeling were considered.

Serendipitously, World War II provided a significant boost to climate modeling because, for military purposes, the extent and range of atmospheric observations increased enormously. As the war gave way to the Cold War, that level of observation continued and, in some ways, intensified. The launching of satellites and attendant technology was also beneficial in this respect. These observations helped to reveal the global patterns of wind and wave circulation and helped to identify variations across the globe and the reasons for them.

Scientists had abandoned the idea of using a single equation (no matter how complex) to represent the whole atmosphere on practical grounds; now there was further proof that such an approach was flawed on scientific grounds. In the years since then, scientists have approached the problem by treating the relevant individual variables with increasing sophistication. For example, the first generation of models included as a variable the Earth's surface, which was posited to have properties that were an amalgam of both land and water. While this approach would give an approximate result at the global level, at lower levels the results would vary from real life conditions.

Subsequent iterations of models have increased the sophistication of the treatment of the surface by dividing land and sea areas, with different types of elevation and of albedo, as these clearly have an impact on the circulation of the atmosphere. In the third generation of models, land is now treated as having up to three levels: the base level of the ground itself, a possible layer of snow or ice overlaying the ground, and a possible third layer of vegetation. Because these conditions can change quite rapidly, it is clear that constant surveillance of both the atmosphere and the Earth's land cover are required. Areas such as the Amazon rainforest, for example, are being rapidly deforested; this can have a significant impact on how models should be constructed, since it has an impact upon the circulation of the atmosphere. For example, stubble burning in Indonesia annually produces a heavy pall of smoke over much of island Southeast Asia, affecting the atmosphere to the extent that it should be considered in climate models. Volcanic activity is less predictable, but can also have a strong impact upon the atmosphere.

COMPUTATIONAL POWER

Clearly, the need to deal with these variations requires an enormous amount of computational power. This power has not been available until recent years. In 1965, the computer scientist Gordon E. Moore predicted that, because of the increasing sophistication with which transistors could be placed upon a circuit board, computational power was doubling approximately every two years. Moore's Law has continued to hold true until the first decade of the 21st century, although it is through different technologies that the improvements are made. The result is that modeling of the atmosphere with multiple, rapidly changing variables has become possible for the first time.

When a single computer is insufficient for computations required or the amount of data and observations collected, it is also now possible to use distributed networks of computers that use spare computing power to contribute to analyses over a comparatively lengthy period of time. Owing to the very high level of penetration of personal computers in Western societies, as well as cheap and reliable internet access, it is possible to use spare capacity on machines belonging to members of the public who are willing to subscribe to the scheme. This shows, among a number of other changes, that personal computers are now hugely more powerful devices than were available to even the most advanced scientific researchers just a few years ago.

ADVANCED CLIMATE MODELS

Climate models have now reached a third generation of variants. They have, in the more than one century of iterations that have taken place, added a considerable level of sophistication to the original approaches. Models now attempt customarily to explain the entire global system instead of regional or partial attempts, owing to the greater level of understanding of the heterogeneity of interactions around the world.

Nevertheless, the basic approach remains the same, in that the atmosphere is divided both vertically and horizontally into sections. This entails dividing the surface of the earth into a series of two-dimensional squares that are then provided with a three-dimensional element of height. Early models posited a homogeneous surface cover that was a composite of land and water. Subsequently, grid squares have been accurately divided into those areas which are land and which are sea, together with possible layers of ice with an additional variable concerning land cover. Degrees of salinity and the exchange of salt between land and sea ice have also been integrated, as have up to several dozen vertical layers of the atmosphere. The models themselves are divided into three principal component areas; the land, the sea (and the ice), and the atmosphere. To make improvements more feasible, researchers will tend to work on one of these component areas individually, although this is not required.

Climate modelers create their own individual models, which are similar in basic approach but vary in the forcings, or weighting given to specific variables within the model. The different weightings, like variations within the initial conditions ascribed to the model, will produce often significant changes in predictions, especially over the long-term if variations become magnified with regular, perhaps annual, increases in the relevant variables concerned. Consequently, it is prudent to run a series of simulations with marginally different initial conditions and forcings to consider possible outlying results.

DATA

The ability of climate modelers to integrate the increasing number of variables into their models and add more sophisticated techniques for modeling the interactions between them relies to a considerable extent on the greatly enhanced number of data observations and their accuracy. Generations of weather balloons and their successors, for example, have been instrumental in the enormous increase in volume and scope of observations that are now available. Expansion of satellite coverage of the world, often driven by military objectives, has also increased the amount of data.

However, few data observations are of the depth required for sophisticated new models. To supplement actual observations, therefore, it has been necessary (and very helpful) to consider the evidence from past records, such as ice cores and tree-ring growth, which provide a considerable amount of useful information dating, in some cases, back many thousands of years. In other cases, proxy variables are used, especially for those variables which it is not possible or practical to measure directly, no matter how advanced the measuring technology may be.

The use of proxy variables and the comparatively narrow temporal range of some crucial observations means there is some equivocation in results and this, again, means it is prudent to take a broad view of results and simulations from models used around the world, which use a variety of initial conditions and weightings. Many scientific institutions make their data freely available for just this purpose.

Climate Sensitivity and Feedbacks

CLIMATE SENSITIVITY IS generally defined as the global mean surface temperature change that is followed by the doubling of carbon dioxide (CO_2) in the atmosphere. Put simply, climate sensitivity is the amount that temperatures rise or fall in response to alterations in climate.

Since 1990, official estimates of climate sensitivity have ranged between 2.7–8.1 degrees F (1.5–4.5 degrees C). In the summer of 2004, at the Workshop on Climate Sensitivity, researchers generally agreed that temperatures have warmed by 0.6 degrees C over the last 100 years. Feedbacks are mechanisms that amplify or diminish climate change. Examples include water vapor, land ice-cover, vegetation cover, and ocean heat transport. Feedbacks may be affected by physical processes such as wind, snow, and seasonal variations.

Climatologists have identified three major ways in which climate sensitivity and feedbacks may be studied using computer models. The first method uses a three-dimensional global climate model according to a specified formula based on CO_2 doubling. The second uses CLIMAP climate boundary conditions to produce an analysis based on the cooling of the last ice age, which occurred approximately 18,000 years ago. Finally, climatologists analyze climate sensitivity by estimating the changes in global temperature, in conjunction with the presence of greenhouse gases, to estimate empirical climate sensitivity. In computer models designed to estimate climate change, feedbacks are used to determine the magnitude of predicted climate changes, as well as the time span in which the changes are likely to occur. Results vary among climate sensitivity models, because of the differences in the ways in which climate feedbacks are handled in the particular model used.

As early as 1984, a study of climate sensitivity and feedbacks conducted by James Hensen, et al., determined that increased levels of greenhouse gases in the atmosphere were indicative of eventual global mean warming of approximately 1 degree C, a reading that was comparable to the Altithermal, a dry postglacial interval that is believed to be the warmest period on earth over the last 100,000 years. Beginning in the late 20th century, the Intergovernmental Panel on Climate Change (IPCC), established by the United Nations Environment Programme (UNEP) and the United Nations World Meteorological Organization (WMO), began issuing assessments of the scientific and socioeconomic data that were available on climate change. These assessment reports have greatly contributed to the understanding of global warming and climate change, although they have continued to generate considerable controversy.

STEADY TEMPERATURE RISE

The Third Assessment Report (TAR) was released in 2001, predicting that average surface temperatures of the Earth would increase steadily between 1990 and 2100, with estimates ranging from 2.5–10 degrees F (1.4–5.8 degrees C). At the same time, IPCC researchers predicted that sea levels would continue to rise steadily. Despite these pessimistic predictions, IPCC scientists generally believe that human behaviors, which are considered contributory factors in global warming and climate change, may alter predictions if humans begin to engage in more environmentally responsible behavior. Examples of possible responsible actions include making drastic reductions in CO_2

emissions and eliminating use of aerosols and some pesticides.

TAR findings have consistently been used to support the notion that a consensus exists among scientists concerning global warming. The Third Report acknowledges that considerable confidence exists in the ability of climate sensitivity and feedback models to predict future climate changes, but notes that many such models fail to account for all elements of climate change. A fourth IPCC report, released on April 27, 2007, employed tens of thousands of data series on climate sensitivity and feedbacks to more fully assess current conditions and make more accurate predictions on the future of global warming and climate change.

CONTROVERSY AND IMPROVEMENTS

A number of scientists continue to take issue with the position taken by IPCC scientists. Some find fault with the entire concept of climate sensitivity. The debate about climate sensitivity modeling is so great that it is sometimes called SWAG (a "scientific wild-ass guess").

Some researchers find fault with measurement techniques, while others insist that global warming and climate change are responses to geophysical occurrences rather than irresponsible human behaviors. A good deal of the controversy about climate sensitivity modeling results from disagreements on the best ways to characterize feedbacks, because variations in the ways that feedbacks are employed in various models produces vastly different results.

The uncertainty of climate change predictions based on cloud feedback are arguably the most frequently-cited evidence that climate sensitivity models are inaccurate predictors of future climate patterns. In most models, cloud feedback is perceived as a positive indicator of global warming. In others, cloud feedback is viewed as a neutral mechanism. Many researchers insist that some uncertainty in predicting global warming through climate sensitivity modeling is inevitable.

Reasons given for this inherent uncertainty include gaps in the understanding of the physical processes that contribute to feedbacks, the fact that interactions among the various processes are likely to be complex, and the dynamic nature of climate. Ongoing attempts to make the use of feedbacks in climate sensitivity predictions more accurate have led to the use of supplementary observational studies, such as those that include data gathered from satellites. Another way in which scientists are trying to make climate modeling more accurate is through the use of Climate Process Teams (CPT), in which groups of scientists work together to improve the prediction process. The National Center for Atmospheric Research (NCAR) and the Geophysical Fluid Dynamics Laboratory (GFDL) have developed two models that are widely used by American researchers in predicting global warming and climate change.

Using low-latitude cloud feedbacks, team members have arrived at vastly different predictions. The NCAR team first used the Community Climate Model (CCM), which they developed in 1983 for use by the global research community. In 1994, NCAR introduced an improved model, the Climate System Model (CSM), which uses atmosphere, land surface, global ocean, and sea ice feedbacks. Research at GFDL combines computer modeling with specialized observations based on the atmosphere and oceans, and on chemistry and biology, to make predictions on climate change.

Climate Thresholds

CLIMATE CHANGE IS not always a gradual process. Just as the weather includes both the ordinary passage of seasons and unpredictable, extraordinary events, such as devastating hurricanes and droughts, so, too, does climate change entail both gradual processes and the sudden, sharp changes called climate thresholds. These thresholds are hypothetical—that is, they have not been observed directly, though it is believed that they have happened in the past.

Methane is often implicated in climate threshold theories. A powerful greenhouse gas, methane is contained on the Earth in a number of forms that could be unlocked all at once by sufficiently warm temperatures. For instance, in western Siberia, permafrost peat bogs that have remained frozen since the end of the last ice age are beginning to thaw; if they continue to do so, they will release large amounts of dissolved methane in a sharp spike rather than the gradual increase seen in the past. The clathrate gun hypothesis focuses on an even larger supply of methane: the methane clathrate (ice containing methane) found in enormous amounts on the cold ocean floor. Sufficient warming would melt the ice, releasing enough methane over a short period of time to severely accelerate global warming.

The most severe mass extinction, much greater than the extinction of the dinosaurs, is the Permian-Triassic Extinction. The event caused the extinction of over 90 percent of sea life and two-thirds of terrestrial vertebrates, about 250 million years ago (before the birth of the dinosaurs). This was also the only known mass extinction of insects, at a time when they enjoyed their greatest diversity and largest size. The sudden emptying of so many niches in the ecosystem likely accounts for the success of fungi, and of bivalves such as oysters, both of which were rare before the extinction but which survived and thrived after it.

There is evidence of an extraordinary release of methane at about this time. The only known possible cause of such a release would be the melting of oceanic methane clathrate, which could explain why the Permian sea life was affected much more than land-dwelling life forms. Seen in this light, catastrophic scenarios for global warming no longer seem unprecedented.

Any positive feedback to the greenhouse effect can force a climate threshold. Such an occurrence is called a runaway greenhouse effect. Most positive feedbacks, even strong ones, are obviously not runaway effects; it must be a self-perpetuating feedback, such that the effects are stronger every time it "loops" back around. Runaway greenhouse effects not only cause a rapid rise in temperature, they are fed by rising temperatures until something changes the system sufficiently to reduce the effect or achieve equilibrium. The planet Venus certainly resembles the aftermath of a runaway greenhouse effect, whether or not that is how it developed.

Climate Zones

FROM THE POLAR regions to the temperate zones to the tropics, there are different climate zones that create different habitats. Within the tropics, the temperate regions, and the polar areas, there are varying amounts of sunlight, water, temperatures, and soil conditions that are the product of proximity to large bodies of water, to lack of rainfall, and to the elevations in specific areas. Like the Alpine region of Europe, each of these regions is found in different climate zones.

Climate is the long-term weather pattern (for at least 30 years) in an area. The climate includes general patterns and extremes of drought, rains, storms, and freezing temperatures. Air temperature and precipitation are two of the most important factors affecting the climate of a region. The world's biomes are regulated by their respectively localized climates. It is climate that determines what plants grow in a locality and the animals that can inhabit it.

THE KÖPPEN CLIMATE CLASSIFICATION SYSTEM

In 1900, the Russian-German climatologist Vladimir Köppen presented the scientific community with a system for classifying the world's climates. Today, it is called the Köppen Climate Classification System. It divides the Earth's surface into climatic regions that generally coincide with world patterns of vegetation and soils. The system has five major climate types. These are based on averages of annual rainfall and temperatures. The annual averages are combined with the monthly rain and temperature statistics. The Köppen System gives each zone a letter name. A is for Moist Tropical Climates, where the temperature is warm all year long, but usually within a narrow range. In addition, there dry seasons followed by wet seasons, which are often the result of monsoon winds.

Zone B is for Dry Climates, which have little rain and a wide daily temperature range, hot in the day and cold at night as radiant heat is returned to outer space. This zone has two subgroups: the semi-arid or steppe regions (S) and arid or desert (W) areas. The C zone is the Humid Middle Latitude Climate, where the land and water differences are the determining factors. These are zones that have warm dry summers and wet, cool winters. D zones have Continental Climates. These climates are in the interior of large landmasses such as central Asia or central North America. The total precipitation can range from low to above moderate. The seasonal temperatures range widely. Zone E climates are the Cold Climates. These are the regions of permanent ice and tundra. Summer temperatures are above freezing, but not enough to melt most of the accumulated ice and snow, or the permafrost.

The Köppen Climate Classification System divides the major five zones into sub-zones. These are assigned a lowercase letter to distinguish specific seasonal characteristics of temperature and precipitation. A lowercase "f" designates zones that are moist year-round. In these zones there is no dry season, with precipitation usually every week or so. The lowercase "f" is usually assigned to zone A, C, and D climates. Lowercase "m" is used to designate rainforest climates. This sub-zone has a short dry season that is monsoon in character, but the rain is enough to create a forest that feeds on a nearly constant rainfall. The lower case "m" sub-zone is assigned to A zone climates. The lowercase "s" stands for the places that have dry season in the summer. This letter applies to summer in both the Northern and Southern Hemispheres. In contrast, lower case "w" is used for localities that have a dry season in the winter. The letter is applied to winter in both the Northern and Southern Hemispheres.

The Köppen Climate Classification System has been refined to account for subtler variations in climates. A third letter is applied to denote these sub-zones. The lowercase letter "a" is used to indicate hot summers where the summertime temperatures are above 72 degrees F (22 degrees C) in the warmest month. Zones C and D are climates where these conditions prevail. The lowercase letter "b" is used to indicate areas where there are warm summers with the warmest month below 72 degrees F (22 degrees C). Again, these conditions are found in Zone C and D climates. Lowercase "c" is used to indicate areas with cool, short summers. In these areas, the summertime lasts less than four months. The temperatures reach over 50 degrees F (10 degrees C). Zone C and D climates have areas with these conditions. Areas with a "d" designation have very cold winters, with the coldest month having temperatures that reach below minus 36 degrees F (minus 38 degrees C). Areas with these conditions are found in the D climate only.

An "h" designation means the area is dry-hot with an average temperature that reaches to above 64 degrees F (18 degrees C). These conditions are found in B climates only. Areas with a lowercase "k" designation have dry-cold climates. These are areas with annual weather conditions where the average temperature does not get above 64 degrees F (18 degrees C). These conditions are found in B climates only.

The climate zones can also be described as Low-Latitude, Tropical Rainforests, Tropical Savanna, Middle-Latitude, Marine West Coast, Humid Continental, Humid Subtropical, Mediterranean, Continental Steppe, High-Latitude, Sub-arctic, Tundra, Polar Ice, Dry Climate, Desert and Highland Climates. All of these zones are related to their location relative to the poles, the temperate zones, the tropics and the equator, in combination with factors of altitude, proximity to the sea, and wind directions. In each one, plants and animals have adapted to the environmental conditions of that zone. The environmental conditions are products of latitude, temperatures, precipitation, elevation, sun exposure, humidity, and the direction of the winds that traverse the region.

HARDINESS ZONES

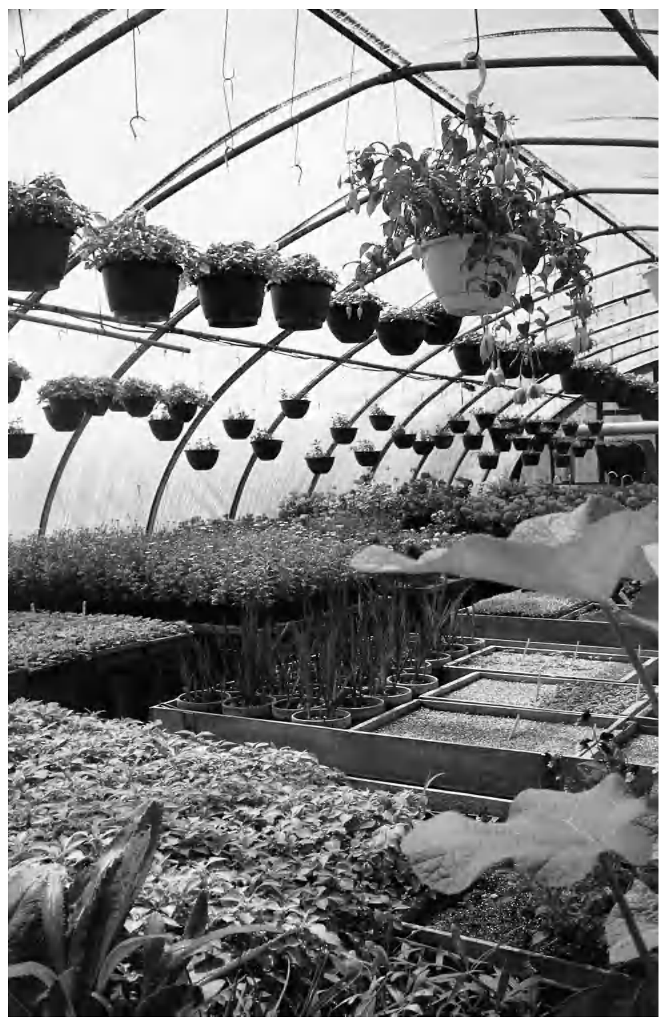
An important system of climate zones used for gardeners is that developed and maintained by the U.S. Department of Agriculture (USDA). The zones have been developed in cooperation with the National Weather Service (NWS). These zones have been called hardiness zones as well as climate zones. They are based upon 60 years of accumulated weather data recording wintertime temperatures. The hardiness zones are bands that straddle the North American continent including both the United States and Canada.

Maps of the hardiness zones are found on most packages of flower or vegetable seeds sold by professional growers in the United States. They are also put onto the tags that are tied to trees and shrubs or other plants sold by gardening centers or by professional nurseries. Similar standards have been applied in Europe and on other continents. When gardeners, landscapers, farmers, and others know their hardiness zones, they are able to choose more wisely plants that will flourish in that zone.

EFFECTS OF GLOBAL WARMING

Some scientists have issued warnings that the current climate zones may disappear. There will always be zones, as long as there is an atmosphere covering the Earth. However, the changes wrought by global warming are creating new, previously unknown climate zones with some warmer, others drier, others colder, and others still changing. Climate models that are global in scope are forecasting that several existing climate zones in a number of places around the world may completely disappear. The threatened zones include tropical highlands, regions near the poles, vast areas of the tropics, and the subtropics.

Among the areas most severely affected are the southeastern United States, southeastern Asia, parts of Africa, the Amazonian rain forest, and the African and South American mountain ranges. The shifting zones will develop new ecological systems, with the loss of many species from the area. In general, the climate zone models show changes will shift some zones to higher latitudes and to higher elevations. Species of flora and fauna that now flourish in current conditions at high altitudes will either adapt to the advances of lower elevations, or perish because they have no place higher to go. Shifting wind and rain patterns with warmer temperatures will affect ecological



The hardiness zone information on potted plants is based on 60 years of weather data and is related to climate zones.

systems. Because most species cannot migrate, there will probably be enormous losses in biodiversity.

Climatic Data, Atmospheric Observations

ATMOSPHERIC OBSERVATIONS FORM the basis for weather prediction and analysis, for monitoring climate and climate change, and for atmospheric and climate research. Observations are carried out routinely and in a well-coordinated manner by weather services and individuals using a variety of platforms and instruments. The range of intentions behind observing the atmosphere leads to different types of data products. For climate trend applications, a number of errors need to be carefully addressed. Climate variables have been measured for centuries, but it has only been possible to construct a consistent global picture of climate trends from these data since the late 1900s.

Atmospheric observations are partial descriptions of the state of the atmosphere, the statistics of which determine the state of the climate system. If these observations are carried out over long time periods, changes in the climate system can be addressed. Most of the observations are measurements, for example, a property of the atmosphere is quantified using instruments.

The most important examples of atmospheric measurement are air temperature, pressure, humidity, wind speed and direction, radiation, and the composition of the atmosphere. However, visual observations of cloud type and fraction, precipitation type, or weather type are also important.

Atmospheric observations require a variety of instruments. In-situ instruments measure the physical or chemical properties of the surrounding air. Remote sensing systems indirectly derive these properties from perturbations of electromagnetic signals passing through the air. Platforms used for atmospheric observations include ground-based stations, ships, buoys, weather balloons, aircraft, or satellites. Sometimes the atmosphere is sampled a posteriori, for example, air samples in glass flasks are analyzed chemically in a laboratory, or the composition of air in bubbles trapped millennia ago in ice are analyzed.

Systematic atmospheric observations require a high degree of coordination, and can be of vital strategic interest. Therefore, they are mostly performed by large, national organizations such as weather services. Global cooperation is achieved through the World Meteorological Organization (WMO), which issues standards and recommendations concerning instruments, calibrations, measurement practices, reporting, and quality control/quality assurance. The WMO also regulates data exchange. Observations are also performed within large research programs.

Atmospheric observations are performed with different intentions. The most common ones are meteorological and climatological applications. Important considerations for meteorological applications are real-time availability, precision, and spatial resolution. These data are typically used for weather forecasting and analysis. Important considerations for climate data are accuracy, representativeness, and long-term stability. These data are used for climate research, planning and risk assessment, or similar applications.

THE UNCERTAINTIES OF CLIMATIC DATA

Long time-series of climatic data are subject to several types of uncertainties. Systematic or random errors in the measurement instruments make up only part of the total uncertainty. Changes in instrumentation, measurement practices, reporting, location, and station environments also contribute to the total uncertainty and inevitably lead to heterogeneous data sets. In order to assess long-term climate trends reliably, systematic errors must be corrected to make different parts of a series comparable, which is termed *homogenization*. For this process, sufficient background information on the measurements (often termed *metadata*) is necessary. Mostly, data are homogenized with respect to a time average such as monthly means. Additional efforts are necessary to address changes in climate extremes. With daily climate data, for instance, it is necessary to homogenize the shape of the distribution function, as negative extremes might be affected differently by an inhomogeneity (such as change in location) than positive extremes.

Another type of uncertainty relates to the changing representativeness of the measurement location over time. Meteorological stations erected a century ago at the outskirts of a city are now often in the city center, and, therefore, represent a more local climate that is subject to urban effects. Depending on the application, this bias is undesired and must be accounted for (for example, when calculating long-term global climate trends).

THE HISTORY OF CLIMATE OBSERVATIONS

Climate observations were performed during the classical epoch. However, instrumental measurements started only in the 17th century with the advent of the Enlightenment. The longest continuous temperature time series is the Central England temperature, which reaches back to 1659. Early meteorological measurements were disseminated through scientific journals and private correspondence, and were studied by the scientists of the Enlightenment.

Around the 1850s, the number and spatial distribution of meteorological stations became such that a global view became possible. Many of the widely-used global climate data sets for the Earth's surface reach back to the second half of the 19th century, comprising surface air temperature, pressure, precipitation, and other variables. There are, however, changes within these data sets that affect the quality of the analyses. National meteorological networks, the Brussels Maritime Conference of 1853 and, after 1873, the International (now World) Meteorological Organization established standards for weather observations. The data quality and coverage over both the terrestrial and marine domains have increased.

Climate and weather data near the Earth's surface only provide a very limited view of the large-scale atmospheric circulation. Upper-air measurements started in the late 19th century, but were rather experimental in the beginning. In many countries, operational upper-air networks using aircraft, kites, and pilot balloons (free-flying balloons tracked from the ground to derive wind profiles) were gradually established during the 1900s to 1920s, while radiosonde networks (weather balloons measuring temperature, pressure, and humidity and transmitting the data to a receiver at the ground) began in the late 1930s and 1940s. The quality of atmospheric observations and international coordination was strongly improved during the International Geophysical Year (IGY) 1957–58. The IGY led to the establishment of meteorological stations in Antarctica, improved networks of weather balloon soundings, atmospheric ozone observations, and to measurements of carbon dioxide (CO_2) in the atmosphere.

Another important step in the history of climate observations was the onset of space-borne Earth observation in the 1970s. Satellites provide a near-global coverage of numerous climate variables, such as sea ice or snow coverage, cloud cover, and the vertical temperature structure, though radiosonde data still form the backbone of the upper-air network. In particular, satellites provide detailed information on the concentration of trace gases and on the amount and properties of aerosols. At least as important as for surface data, quality remains a fundamental issue for satellite data. In particular, the overlap between different sensors is often too short to obtain reliable transfer functions.

CONTEMPORARY METHODS

A huge amount of meteorological data is measured each day and is processed to produce meteorological analyses and weather forecasts. Although observations are irregular in time and space (with large gaps), these applications require three-dimensional data sets on a regular space-time grid. Such data sets are produced from all atmospheric observations (from the Earth's surface, ships, aircraft, balloons, and satellites) using a filtering and interpolation scheme combined with a numerical weather prediction model. The procedure is termed data assimilation, or analysis, and essentially consists of short-term forecasts that are corrected according to the incoming observations, providing new initial fields for the next forecasting time step, and so on.

In large reanalysis projects, this procedure is applied to past observations, thus providing global gridded meteorological data sets for the past approximately 50 years. Only a subset of the global meteorological network is needed for climate observations, but with particular requirements concerning quality and long-term stability. Ensuring the existence of suitable networks is the task of the Global Climate Observing System (GCOS), an institution that is co-sponsored by the WMO and other intergovernmental organizations. Climate data are used for climate monitoring, but also for climate research, such as detection and attribution of climate change or the validation of climate models.

Climatic Data, Cave Records

CAVES HAVE PROVIDED climate researchers with several useful ways to learn about past climates. In caves that are connected to the surface, plant (particularly pollen) and animal remains allow scientists to study floral and faunal successions over time, which often reflect concurrent climate shifts. Cave deposits, collectively called *speleothems* (for example, stalagmites and stalagtites) provide interesting information that, though geochemical techniques are still being refined, promises a detailed and well-constrained record of past climate variability.

Caves are commonly found in limestone (calcium carbonate, $CaCO_3$) bedrock settings. When precipitation moves through a soil horizon, it picks up dissolved carbon dioxide (CO_2) produced in organic decomposition, thereby becoming mildly acidic. The acidic groundwater then slowly dissolves $CaCO_3$ bedrock, forming caves over time. Speleothems form when dissolved $CaCO_3$ precipitates from groundwater upon interaction with cave air. As groundwater carrying dissolved CO_2 and $CaCO_3$ reaches the cave interior, CO_2 degasses as a result of the large difference in partial pressure of CO_2 between the soil and the cave air. The water is then supersaturated with respect to $CaCO_3$, causing mineral crystal precipitation on cave surfaces.

Speleothems are ideal terrestrial climate records because they can be accurately dated using uranium series dating, which circumvents problems in carbon dating that complicate other terrestrial records, and because they exist in relatively stable cave environments that experience little or no erosion and may therefore grow continuously, often for hundreds of thousands of years. They can also be found all over the world, at high and low latitudes and elevations, and, therefore, have the potential to provide a wide range of terrestrial climate records.

Climate records are interpreted from speleothems by examining growth rate, stable isotopic composition, organic matter inclusions, trace and minor element composition, and variations in banding or crystal structure.

A cross-section of a stalagmite, for instance, reveals a very thin banding pattern. Uranium series dating indicates that these bands are often annual, especially in areas with a strong rainy season signal (as in monsoon areas). The relative thickness of these bands represents changing growth rates and can provide information about relative amounts of rainfall from year to year, or even variations in biological activity at the surface.

Speleothems, such as these formations in Carlsbad Caverns National Park, may hold valuable climatic data.

Increased biological activity adds more CO_2 to the soil, making the groundwater more acidic and better able to dissolve $CaCO_3$, leading to increased mineral precipitation inside caves. Bands of sediment or sandy material indicate complete cessation of speleothem deposition, which is usually interpreted as severe drought, or severe cold, as in glacial times when there is less meltwater available and groundwater may be completely frozen. Sea-level changes can also be inferred from cave shapes, and mineral or organic growth layers on speleothems in seaside caves.

Stable isotopes of oxygen and carbon, and trace element concentrations are analyzed within the carbonate or in pockets of trapped water called "fluid inclusions." Minor or trace elements can be included in speleothem structure, either via groundwater or airborne dust particles, and can represent changes in temperature or air circulation, or geologic occurrences such as nearby volcanic eruptions. In-cave processes such as mineral recrystallization, evaporative processes (especially in caves near the surface), and whether or not the $CaCO_3$ was deposited in isotopic equilibrium with groundwater, may influence isotopic composition.

If these variations can be discounted, isotopic shifts can be cautiously interpreted. In most carbonate proxy records, shifts in oxygen isotopes reflect changing temperature. In caves, however, temperatures are fairly stable throughout the year, so oxygen isotope variations must reflect a different climate signal. Large variations over hundreds of thousands of years reflect changes in meteoritic water composition related to glacial/interglacial transitions. Smaller-scale changes have been interpreted as variations in surface temperature, residence time of the groundwater in bedrock reservoirs, or changes in moisture source and pathway of precipitation. Carbon isotopes are influenced by a complex suite of factors on the surface, such as biological activity (including variations in C_4 or C_3 type plant abundances), rainfall, and bedrock composition. As with other proxy records, it is often difficult to separate the actual climate signal from "noise" in the record. Comparison of cave data with other nearby climate records such as ice cores or sediment cores helps to identify real climate signals.

Climatic Data, Historical Records

HISTORICAL RECORDS OF climate data include the instrumental record and proxy climate data from human recorded history. Proxy records are a substitute for direct measurements by meteorological instruments. The principal sources of historical proxy records are written, archaeological, and iconographic evidence.

Accurate reconstruction of past climate relies on information from instruments that measure air pressure, wind speed, wind direction, precipitation, air temperature, and humidity made at weather or climate stations around the globe. But looking further back in time, the record declines, both in terms of the area of the world covered and the number of variables measured. By the late 1700s, it includes only a handful of places, mainly in Europe.

The time period covered is not the only consideration. The data must also be quality controlled. This requires the availability of so-called metadata concerning the type of instruments used, measurement practices and observation routines, information on the position and exposure of instruments, and facts on the setting in which the instruments are located (for example, urban or rural).

MEETING CRITERIA

Only a few records come close to meeting these criteria, and most of them suffer from multiple deficiencies, usually because the instruments were shifted to nearby, but different sites. Thus, most records are, in fact, composite series, containing data from a number of sites in one area. One notable exception is the record of the Armagh Observatory in Northern Ireland 1796–2002. The resulting historical climate record is the longest for any single site in the United Kingdom and Ireland (although a gap 1825–33 was filled by data from two stations in Dublin). Only two other European stations have records as long at the Armagh series: Stockholm and Uppsala, both in Sweden.

The central England time-series of air temperature is the longest instrumental record in the world. It puts together data from a number of climate stations in England, namely, Ringway, Malvern, Squires Gate, and Rothampsted, for 1772–present. It was not until 1840 that the first official national archive of climate data was set up, housed at the Royal Greenwich Observatory near London.

A formal system of weather observations did not begin in the United States until 1818. However, climate data have been gleaned from private sources for several years prior to this. Of note is the reconstruction by R.D. Erhardt for the southern United States, using data from the private journals of Winthrop Sargent and William Dunbar. Measurements were taken near Natchez, Mississippi, commencing in 1798 and 1799, respectively. The Dunbar record includes daily measurements of air temperature, barometric pressure, wind direction, precipitation, and state of the sky for the hours of 0600, 1500, and 2100 local time 1799–1818. It is regarded as one of the best early instrumental records in the United States.

H.E. Landsberg and others assembled a composite temperature series from 1795 for the eastern United States. The main sources of climate data 1820–70 are archived by the Smithsonian Institute and the U.S. Army Medical Corp. Data. Records became plentiful following the establishment of the U.S. Signal Service in 1870 and the U.S. Weather Service in 1891. L.J. Darter has assembled a comprehensive listing of archived U.S. data.

Globally, the total number of climate stations with records of daily air temperature grew steadily from about 100 in 1880, to a peak of approximately 1,500 in 1970. A decline set in after that, with a sudden loss of over half the stations around 1990, leaving a total of just over 5,000 in 2000. The loss in stations varied around the world. The biggest losses occurred in China, the former Soviet Union, Africa, and South America.

The number of stations used as the global historical climate network for calculation of mean global temperature is reduced by about two-thirds to remove records with insufficient continuity or quality control. The maximum number of acceptable station records over land regions of the globe was just over 3,000 1951–90. Prior to the 1940s, there are problems of accuracy and lack of standardization in the way climate variables are measured, making it difficult to reliably compare measurements made in different places. For marine regions, sea-surface temperature measurements taken on board ships are used. As most of them are made voluntarily, coverage is mainly along main shipping lanes and is sparse in the southern oceans. There has been increased reliance on highly-accurate satellite measurements of global temperature since measurements began in 1979.

It is common to use proxy data to extend the historical record of actual measurements. A common source of proxy data are written records, such as diaries, chronicles, and ships' logs, or accounts of things such as floods, droughts, lake levels, grape harvests, and wheat prices from which climate conditions can be inferred. Some of these records are quite long. For example, there are records of the variation of the level of Lake Victoria in equatorial Africa since 1860, wheat prices in Europe since 1200, the occurrence of sea ice off Iceland since 860 C.E., date of first bloom of cherry tress in Kyoto, Japan, since 812 C.E., and water level in the Nile at Cairo, since 622 C.E. Iconographic proxy data is assembled from old paintings and carvings that depict the type of vegetation and the position of glaciers and frozen rivers and lakes that give an indication of climate of the time.

Archaeological remains can provide proxy climate data and evidence of past migrations linked to climatic change. For example, from about 900 C.E., Vikings settled in southern Greenland and farmed soil, that by 1200 C.E., became too cold for agriculture. The remnants of these settlements provide evidence of what agricultural activities took place during this time, known as the Medieval Warm Period, which was brought to an end by the onset of a cold period known as the Little Ice Age.

Tree rings of long-lived trees also provide useful proxy data for extending the historical climate record. Tree rings are wider in wet years for trees growing in semi-arid climates, and wider in warm years for trees growing in cold climates. Reconstruction of past climates prior to the historical record requires the use of the paleoclimatic proxy data from the geological past based on investigations of fossils, sedimentary rocks, and ice and sea cores.

Climatic Data, Ice Observations

SEASONAL CHANGES IN snow and ice cover on the Earth's surface result largely from the Earth's position relative to the sun. However, because ice systems also respond to climate on longer timescales, they are considered good indicators of the Earth's climate as a whole. In addition to being good climatic indicators, glaciers and ice sheets influence the Earth's climate in two important ways. The first is their potential impact on sea-level rise and global water resources under declining ice regimes. Glaciers and ice sheets account for two-thirds of the Earth's freshwater and would contribute approximately 229 ft. (70 m.) to sea-level rise if they were to melt completely.

The majority of this ice is located in the Earth's polar regions, largely in the Greenland and Antarctic ice sheets, which combined account for approximately 97.5 percent of potential sea-level rise. Alternatively, glaciers located outside of the polar regions, commonly referred to as alpine glaciers, play a relatively small role in their overall contribution to global ice volume and, thus, sea-level rise. However, they are perhaps the most critical ice volumes when considering their locations with respect to populated areas. Alpine glaciers are found at the headwaters of river systems throughout the globe and, thus, are an important water source for many regions. These glaciers are also more susceptible to melt owing to their smaller size; as a result these systems have experienced the most visible decreases in ice volume.

Second, decreases in global ice and snow cover are considered particularly important to the Earth's climate system because such changes are considered to be part of a positive feedback loop, commonly referred to as the snow-ice albedo feedback. Under this scenario, as temperatures increase, the extent of snow and ice decreases, and the highly reflective snow or ice surface is replaced with the darker (more absorptive) ocean or land surface underlying it. The increased absorption of energy completes the feedback loop, as more solar radiation is absorbed by the Earth's surface, leading to an overall increase in air and sea surface temperatures, and further decreases in ice and snow volume.

Global air temperatures have increased in the past century. Climate observations indicate that increases in temperature over this timeframe have accelerated in recent decades, and are unlikely to slow under current climatic conditions. One key example of the positive feedback associated with the loss of ice mass is the increased rate of warming observed in the Arctic, which has warmed at nearly twice the global average. Global temperature increases are strongly correlated with decreases in global ice mass, which have been in a relatively constant state of decline throughout the last century. As global temperature rates increase, global ice volumes have experienced the largest rates of decline in recent decades.

Observations of global ice masses are a critical component of climate change research. They give scientists insight into how ice masses are changing over time, how quickly changes are taking place, and allow climate scientists to make informed predictions of how these ice masses are likely to change in the future. Improvements in technology have changed the way in which climate scientists make observations of glaciers, ice sheets, and sea ice. New techniques now include the use of satellite and remote-sensing data as a means of monitoring these systems.

Prior to the 19th century, records of weather and climate were rare. As a result, climate scientists use proxy records (such as ice cores, lake and ocean sediments, and ocean coral) to make inferences about how the Earth's climate and ice masses have changed in the past. The current understanding of changes to the Earth's cryosphere (snow and ice) is comprised, therefore, of a combination of data derived from proxy records (indirect observations) and from direct ice observations. Combined, direct and indirect observations provide insight into how global ice masses are changing over time and provide a context in which to view current changes in global ice masses.

INDIRECT ICE OBSERVATIONS

Proxy records are commonly used to reconstruct the Earth's climate beyond the period of direct scientific observation. Some commonly used proxy records include ice cores, tree rings, ocean sediments, and coral records. Consistent results in the historical climatic data derived from these proxy records indicate the reliability of these records as accurate means of reconstructing past climates.

Increased access to polar regions in the 20th century helped bring glaciers and ice sheets to the forefront of science.

These records indicate large-scale changes in the Earth's climate in the past, including periods of complete global glaciation (Snowball Earth) and contrasting ice-free periods. During the past 900,000 years, the Earth has fallen into a pattern of glacial-interglacial cycles operating on 100,000-year timescales. Glaciations are long periods of cold temperatures, resulting in the growth of large land and sea ice masses extending outward from the poles. These glaciations tend to come to an abrupt end with rapid warming and consequent ice recession.

The last glaciation, the Wisconsin glaciation, ended approximately 10,000 to 11,000 years ago. During this glaciation, ice caps in the Northern Hemisphere extended to latitudes of approximately 45 degrees N, and were 1.8–2.5 mi. (3–4 km.) thick. Since the end of the Wisconsin glaciation, the Earth's climate has been in a period of relative climatic stability, a period commonly referred to as the Holocene (the past 10,000 years).

Synthesis of proxy records for the past 1,000 years in the Northern Hemisphere shows a gradual cooling for 900 years, culminating in the Little Ice Age (1400–1850). During the Little Ice Age, sea ice throughout the Arctic increased, and alpine glaciers across Europe expanded down valleys, covering farmland and destroying agriculture. Since the end of the Little Ice Age, the world has been in a state of declining ice extent.

Proxy records from the Southern Hemisphere are not as unanimous in their observations of 20th century warming. Some regions in the Southern Hemisphere, including Australia, New Zealand, and South America indicate the 20th century as a period of unprecedented warmth in the last millennium. However, ice core records from Antarctica do not indicate this same 20th-century warming. The data derived from both proxy records, and direct observation, indicate that climate does not always operate on a global scale, rather, changes occur on a more regional scale.

DIRECT ICE OBSERVATIONS

While indigenous people have populated the Arctic for thousands of years, exploration of the Arctic by European explorers did not begin until the 16th century. While these voyages were initially motivated by the search for the Northwest Passage, they also provided the first real records of Arctic sea ice conditions. However, it was not until numerous expeditions to the Arctic and several attempts for the North Pole had been made that the distribution of sea ice in the Arctic became well understood.

While early theories speculated the existence of a large southern continent, Antarctica eluded explorers for several centuries, until it was first sighted by Captain James Cook in 1773, after which many voyages were made to the area for both sealing and exploration. Similar to the Arctic, by the mid-1800s, there were rough models of sea, ocean currents, and winds for the Antarctic region.

The first scientific literature discussing Arctic, sea ice properties and extent were published in the 1870s, but it was the organization of the First International Polar Year (IPY) in 1882–83 that spurred scientific exploration to both the globe's polar regions. From 1900–06, a major scientific expedition to the Arctic Ocean was undertaken by Fridtjof Nansen, aboard the *Fram,* to determine ocean currents and sea-ice extent. In the Southern Hemisphere, expeditions by Robert Falcon Scott, Erich von Dryglaski, and Ernest Shackleton to Antarctica marked the transition from early exploration to modern scientific expeditions.

MODERN ICE OBSERVATIONS IN THE POLAR REGIONS

In the 1950s, international scientific campaigns were undertaken on both the Greenland and Antarctic ice sheets. The scientific advances made during these research campaigns were unprecedented, and resulted in deep ice cores retrieved from both the Northern and Southern Hemispheres, as well as the establishment of long-term scientific monitoring sites. The information gained during these campaigns now form the foundations for the current understanding of ice volumes and ice-sheet dynamics in these regions, as well as providing high-resolution proxies of past climatic conditions. Insight into past glacial dynamics provides a context in which to view the current ice-sheet behavior.

Continued technological advances in transportation, computing, and communications have increased accessibility to the polar regions, and increased the number of scientists investigating glacial dynamics in these regions. In the late 1960s, an improved understanding of the potential environmental impacts associated with decreasing global ice volumes brought the study of glaciers and ice sheets to the forefront of scientific research. The current understanding of global ice volumes to serve a bellwethers of global climate change is largely the result of research done in the 1960s; it was during this time that glaciologists and climate scientists began expressing concern over 20th-century climate change.

In 1972, the Landsat 1 satellite was launched and provided the next major scientific advance in ice monitoring. The development of remote-sensing techniques has opened a whole new world for scientists studying sea ice, ice sheets, and glaciers. These techniques allow scientists to make observations of ice extents and changing surface heights, without having to make expensive and time-consuming visits to these remote regions.

ICE OBSERVATIONS OF ALPINE GLACIERS

While alpine glaciers compose a relatively small component of the Earth's cryospheric system, a large proportion of the world's population relies on the melted water from these systems for drinking water and hydroelectric power. Understanding how alpine glaciers are likely to respond to future climatic changes is, therefore, a crucial component of sustainable planning and development. Direct ice observations from alpine glaciers and ice fields have a longer history than those in the more remote polar regions, largely because they are situated closer to population centers.

The longest records of glacial dynamics come from Europe, where records extend over 150 years. These records include glacial mass balance measurements (measurements of snow accumulation and melt), ice extent, and thickness. The large number of alpine glaciers existing on the mountain ranges of Africa, North America, South America, Europe, and Asia mean that individual monitoring of all glaciers is not feasible. As a result, the same advances in remote-sensing technology that have improved monitoring of polar ice masses have also been an asset to the collection of information about alpine glaciers and ice fields.

Climatic Data, Instrumental Records

DETECTION OF CURRENT global temperature and reconstruction of past trends rely on data from four sources: surface temperature from weather or climate stations, weather balloons, satellite mounted remote sensors, and proxy sources. Data from the first three categories are known as the instrumental record.

Until recently, measurements of global air-temperature change were based entirely on measurements taken on the ground at weather stations. Three authorities that have taken responsibility for the combined surface record are the Climate Research Unit (CRU) of the University of East Anglia (UEA), the National Aeronautics and Space Administration's (NASA's) Goddard Institute for Space Studies (GISS), and the Global Historical Climate Network (GHCN) run by the U.S. National Oceanographic and Atmospheric Administration (NOAA).

Given that the data come from weather stations unevenly distributed over the Earth's surface, mostly in the Northern Hemisphere, mainly on land, close to towns and cities, the question arises as to the extent to which these temperatures can be taken as representative of the atmosphere as a whole.

Modification of the surface by human activity can have a significant effect on local climate near the ground. The best-documented example is the urban heat island effect, in which localized warming due to asphalt and concrete replacing grass and trees can influence data from urban stations. This can make an urban area several degrees C warmer than its rural surroundings.

Several researchers have demonstrated that only very small changes in population are enough to induce a statistically significant local warming effect. Many weather stations are located at airports, which originally were located in rural areas on the outskirts of urban areas. But with rapid population growth, airports have made a transition from rural to heat island and it is difficult for the national agencies responsible for archiving climate data to take these influences into account. The problem has been made worse by the fact that two-thirds of the weather stations operating around 1975, mainly rural, have been closed down. For example, the GHCN network showed a peak of about 15,000 stations around 1970, which declined to 5,000 as stations deemed non-essential for operational purposes were closed down. The loss was mainly of rural stations.

Over 70 percent of the Earth's surface is covered by water. Because of this, land-based surface temperature data are supplemented by measurements taken at sea, usually by ships. Scientists have assumed that there is a link between the surface layer temperature of seawater and that of the air above it. Sea surface temperatures are estimated from the temperature of seawater as it is taken aboard as an engine coolant. Sometimes, a bucket tethered to a rope thrown overboard serves the purpose. The bucket is then hauled aboard, and the water temperature is measured with a thermometer. Other sea surface data are taken by combining data from several rather different sources, such as buoys, satellite infrared data, nighttime marine air temperatures measured aboard ships, and measurements made at small island stations.

Each method has problems that result in errors or differences among the data sets. The mean global surface temperature of the Earth shows a warming of 0.3–0.7 degrees C over the past century; this is an increase statistically of about 0.003 to 0.007 degrees C per year, a rate not far from the standard error for the data. The data sets from the various sources (CRU, GISS and GHCN) show slightly dissimilar trends as the data are processed in different ways.

WEATHER BALLOON DATA

Weather balloon data originate from a package of instruments called a radiosonde attached to a balloon that sends pressure, humidity, temperature, and wind data by radio transmitter to a ground-based receiving station as the balloon ascends. NOAA and the U.S. National Climate Data Center have assembled data on temperatures through the lower atmosphere (troposphere) based on radiosondes since 1958, and have assembled it into the Radiosonde Atmospheric Temperature Products for Assessing Climate (RATPAC) data set.

RATPAC consists of station and spatially averaged monthly mean temperature from 1958 to present derived from radiosonde observations taken at 87 weather stations across the globe. The data set consists of a timed series for 13 pressure levels from the surface to 30 mbar pressure level in the atmosphere and a seasonal time series for three layers of the atmosphere (850–300, 300–100, and 100–50 mbar). Although more limited in time and space, these data are free of the ground-based contamination that affect the surface temperature record. RATPAC data shows a global temperature increase of 0.17±0.05 degrees C per decade between 1979 and 2004 compared with the GHCN of 0.16±0.04 degrees C, GISS of 0.16±0.04 degrees C and CRU of 0.17±0.04 degrees C per decade for the same period.

SATELLITE DATA

NOAA polar-orbiting Tiros-N satellites have made temperature measurements of the atmosphere (troposphere and stratosphere) since 1979, using microwave radiometry called Microwave Sounding Units (MSU).

MSU instruments measure the microwave emissions of oxygen molecules, which are related to air temperature. By monitoring microwave emissions at different frequencies, it is possible to identify temperature changes in various layers of the atmosphere. Initial analyses of the MSU data were conducted by scientists at the University of Alabama, Huntsville (UAH), and later by scientists at the Remote Sensing Systems (RSS) facility in Santa Rosa, California.

TRULY GLOBAL

The MSU temperature data set is the only one that is truly global, highly accurate, and uses a completely homogeneous measurement over the entire planet. It also measures the part of the atmosphere that, according to the climate models, should be experiencing the greatest warming due to the enhanced greenhouse effect. The accuracy of the MSU measurements is 0.1 degrees C, which is considerably better than the accuracy of surface data.

Both the MSU UAH, and MSU RSS estimates indicate the middle part of the lower atmosphere (mid-troposphere) has warmed since 1979, but the RSS estimate at 0.18 degrees C per decade is higher than that of the UAH estimate at 0.14 degrees C per decade, both for the period extending from January 1979 to June 2006.

Climatic Data, Lake Records

SEDIMENTS THAT ACCUMULATE in lakes and ponds are composed of many kinds of materials. Some, such as windborne dust, pollen, and soot, fall into lakes from the atmosphere. Others, such as clay, silt, sand, gravel, and large organic debris, such as charcoal and leaves, are washed into lakes by running water.

A third group of materials originates in lakes: the remains of aquatic organisms, most importantly the silica-based shells of diatoms (algae) and the calcium-based shells of zooplankton and some invertebrate animals. Core samples extracted with hollow drills from lakebeds show that sediment composition varies over time, suggesting that the materials accumulated under different environmental conditions. Sometimes, even seasonal variations are significant enough to produce annual layers, called varves. By extrapolating from modern observations of events and conditions that produce different kinds of sediments, and by determining the relative amounts of different chemical compounds present in different sediment layers, paleolimnologists have assembled local records that help show how climates have changed worldwide.

The presence of a particular material in a lake sediment sample represents a proxy, or stand-in, for some event that helped precipitate its deposition. Dating lake sediments usually involves analyzing and comparing several materials to produce a multi-proxy account. Relative dating, or chronostratigraphy, is a straightforward process, because younger sediments almost always overlie older ones. However, the action of waves, currents, and lake bottom springs can locally mix material from different strata. Even without such confounding effects, each type of material poses a different set of analytical challenges.

AEOLIAN SEDIMENTS

Windborne or aeolian materials that fall into a lake may have been blown overland for considerable distances. Fine, inorganic particles like dust and sand carried by winds are difficult to distinguish from similar, waterborne materials unless they are chemically or geologically unique, representing particular outcroppings exposed at a lower elevation than the lake, or otherwise outside its watershed. Abundant aeolian sediments can indicate drying climates, because they are more likely to be mobilized by winds when soils are dry and plant cover is sparse. Soot is deposited during fires, which are more common under drying conditions.

Pollen grains are often distinct enough that plant families, genera, and even species can be identified from pollens preserved in lake sediments. An abundance of particular pollens at any given sediment level can be taken as a proxy for climatic conditions favoring the plant species that produced them. However, not all pollens become windborne (particularly those adapted for insect borne dispersal), and those that are windborne are not equally durable, so sediment pollen records are always incomplete. Finally, unusual short-term weather patterns and major storms can produce unusual aeolian deposits, resulting in inaccurate or imprecise interpretations.

FLUVIAL AND FOSSIL SEDIMENTS

Waterborne or fluvial sediments include fine materials resembling aeolian deposits, but also larger particles such as gravel, pebbles, cobbles, and organic debris too dense or massive to be entrained by winds. Materials drop out of the water column in order of density; the denser the object, the more quickly it is deposited. As one result, the densest fluvial sediments accumulate closest to the point where the river or stream that carries them enters a lake, producing horizontal sorting patterns called facies.

As another result, larger and smaller particles that arrive together will not settle out at the same rates. In regions where runoff is seasonal, a pattern of alternating bands of coarse, dense materials and finer, lighter ones will develop. Once their seasonality is understood, such varved sediments provide a year-by-year account of relative precipitation on a particular watershed.

Some sediments accumulate in lakes because small, short-lived organisms reproduce and die off in large numbers. For paleolimnologists, some of the most useful organic sediments include the persistent shells and scales of diatoms, chrysophytes (golden-brown algae), mollusks, arthropods, and foraminifera. Diatoms are algae that develop hard, silicon structures called frustules, which can be used to identify different species. The presence of different diatom species in different sediments has been used as a proxy for variations in pH (acidity), temperature, salinity, nutrient concentration, and even the annual period of ice cover. Many invertebrate animals and smaller foraminifera secrete calcium carbonate- ($CaCO_3$) based shells.

In addition to species-based ecological proxies similar to those provided by diatoms, the carbon (C) content of these shells allows sediments up to about 60,000 years old to be dated using the radiocarbon (^{14}C) technique familiar to archaeologists. However, diatom frustules and foraminiferan shells are small enough to become windborne, and their presence in lake sediments must be interpreted with caution.

Leaves and other common plant remains composed of cellulose can also be dated with radioactive decay analysis of the unstable isotopes $\delta^{13}C$ and $\delta^{18}O$ (oxygen). Plant remains may also be blown or washed into lakes, so materials from identifiable species provide more precise proxies for climate effects. But, even the presence of pigments such as chlorophyll and carotenoids in sediments can provide a general proxy, indicating the growth of plants. Finally, any identifiable fossil remains of insects, fish, and other animals can provide further clues to the sorts of environments that existed at any particular time.

CHEMICAL PROXIES

Both organic and mineral lake sediments undergo reactions that vary depending on their chemical compositions, and on environmental factors such as temperature, and the light and nutrients available to organisms. Compounds containing arsenic (As) carbon (C), chlorine (Cl), iron (Fe), mercury (Hg), nitrogen (N), phosphorus (P), silicon (Si), Sodium (Na), and sulfur (S) are among those that have been used as proxies for the climate conditions prevailing at the time sediments were deposited. Iron-bearing compounds align themselves with the Earth's magnetic field; changing alignments in different strata track changes in the field itself. As some minerals form, they can even trap samples of lake water in microscopic spaces. Many different combinations of particle size, composition, and chemical interaction are possible, making it necessary to understand and account for many different processes in order to use lake sediments as effective proxies for the climatic conditions in the past.

Climatic Data, Nature of the Data

CLIMATE MODELING IS the process of trying to create mathematical models that represent to the highest possible level of accuracy the circulation of wind in the atmosphere and the exchange of heat into and out of it. Since efforts at modeling began in the 19th century, those efforts have become increasingly complex and sophisticated, particularly in recent decades. Two factors have contributed to that increasing sophistication: first, the dramatic improvement in computational power; second, the huge increases in the range and coverage of data that may be used in data sets for analysis in models. As new data become available, they enable researchers to propose modifications to existing models, while proposals to extend models prompt efforts to find ways to obtain the data necessary to determine the success of the proposal.

Climate models have now reached a third generation or series of iterations, which represents a high level of sophistication compared to the past. Land components of models take account of such variables as vegetation cover, elevation, albedo and salt circulation between land, sea and sea-ice. The same degree of sophistication is evident with respect to the ice and atmospheric components of models. The Goddard Institute of Space Studies (GISS) in New York manages a series of climate models in conjunction with the National Aeronautics and Space Administration (NASA). GISS models employ data collected since the 1850s, which are available on a grid basis for either annual or monthly average readings.

Accurate data only became available for most parts of the earth in recent decades, owing to the amount of resources required to make observations and because the perceived need for global observations has only comparatively recently emerged.

World War II provided the equipment and capability for collecting data, while it was the failure to complete satisfactory models on a regional or geographically-limited basis that did not properly integrate global effects that stimulated the increase in the scope of data collection. Nevertheless, GISS models provide datasets in the following categories: temperature; radiation; vertical heat fluxes; salt; water; pressure; height; velocity and horizontal mass fluxes.

Temperature is measured at data points in vertical and horizontal dimensions. Sophisticated climate models employ many layers within the atmosphere and data must be collected from each of these levels for models to be correctly computed. Meteorological equipment, such as weather balloons, which have become an advanced technology in their own right, is employed to collect temperature and other readings in the atmosphere.

In addition to raw temperature recordings, models are also able to use daily minimum and maximum temperatures and the variance between them (other periods may also be computed as required), as well as a composite ground temperature and the temperature of the ocean.

Radiation is a crucial data element because the heat exchange of the atmosphere determines global warming and, hence, climate change to a large extent. Data are collected on the amount of solar energy reflected nd absorbed by the surface of the Earth. The nature and extent of cloud cover is monitored, as is the extent of energy rebounding off that cloud cover. Aggregate and grid-specific releases of energy data are collected; one measure of atmospheric clarity that is employed is Boucher's Sulfate Burden, measured in milligrams per square meter.

This Sulfate Burden is one of the variables employed to examine various forcings in the model—that is, the weight given to different variables in the overall model. Because each model employs a different series of forcings, each will give slightly (possibly significantly) different results employing the same data sets. It is prudent, therefore, to use an overview of several different models to obtain a broad understanding of the issues concerned.

VARIABLES

Vertical fluxes are measured in terms of both precipitation and upwards movements of water vapor. These variables have an impact on the circulation of the atmosphere. The extent and temperature of the ocean also has an impact on this circulation and this is further affected by the extent of ice in the sea. These latter variables are included within the category of horizontal mass fluxes, which are measures of northward and eastward (and vice-versa) masses of ice, water vapor and liquid ocean, as well as air masses. Additional variables include the amount and movement of salt masses in the water.

These vary together with the amount of water and energy entering the ocean (for example, melting ice at the poles and level of precipitation) and are further affected by climate conditions, as well as affecting those conditions in turn. Salinity in oceans is measured by using devices that collect data on conductivity, temperature, and depth (CTDs).

Variables exist with respect to water. These include the composition of the water and of water in different states (for example, water vapor, ice, snow) and its movement in three dimensions. Both static and moving water are considered (lakes, oceans or seas, as well as rivers). Interactions between water in different states and land are also included.

Velocity variables measure the speed and direction by which air masses move in the atmosphere. These are overall or average measures, necessarily, because velocity varies rapidly and frequently in a unit period, depending on location and season. Height and pressure are other ways of measuring interactions between atmosphere and land or sea.

PROXY VARIABLES

In addition to measuring current data points using the most advanced equipment available, it is also possible to measure some historical data points. By digging deep into ice cores in permafrost areas, as well as ocean sediment, it is possible to determine certain conditions from the distant past. Variations in the rate of formation of ice or sediment (the same is true of the rings of some trees) indicate the favorability of conditions for formation, while the presence of trace elements can also indicate various atmospheric or climatic conditions. Ice cores are of such an age that they can be used to understand climatic conditions from half a million years in the past.

Unfortunately, of course, data observations are not always available. Only partial coverage may be possible for practical reasons, and it may not be possible to observe the desired data directly. In these cases, it is possible, with some precautions, to use proxy data. Proxy data act as substitutes for the desired data, but may differ in the time or place observed. An alternative method is to obtain data points on a proxy variable which acts in some way as an approximation of the desired data. An example of this would be the measurement of a single element or substance in the atmosphere may act as a proxy for contamination of the atmosphere as a whole, or for human impact on climate change.

There are many methodological problems with using proxies and the degree of confidence in results must generally be adjusted, accordingly. However, these are not insuperable and, when audiences are educated concerning the methods employed, their use should not lead to misunderstanding. Unfortunately, the quality of science teaching in many societies is not sufficient to enable large numbers of people to appreciate the issues concerned.

Climatic Data, Oceanic Observations

CLIMATIC OCEANIC OBSERVATIONS are marine meteorological and deep ocean observations that are performed for a long time (at least over a few decades) using specialized oceanographic vessels, volunteer merchant ships, buoy arrays, floats, and drifters. Marine meteorological observations are performed over a few centuries. Voluntary observations by merchant ships (volunteer observing systems, or VOS) report most of these data. Standard marine meteorological observations include sea-level pressure, air and sea-surface temperatures, humidity, cloudiness, velocity, and direction of wind.

Marine meteorological observations have been collected and generalized in the Comprehensive Ocean-Atmosphere Data Sets (COADS). However, the differences in instruments and observation techniques, and construction and size of various ships, reduce the compatibility of different data for analysis of climate variability and change. One of the most comprehensive analyses of this problem has been done at the CLIMAR 99 WMO workshop.

Between 1948 and 1984, the Ocean Weather Station (OWS) network operated in the North Atlantic and Pacific Oceans. The principal goal of this network was to get oceanic meteorological and aerological data for improvement of the weather forecast in North America, Europe, the North Atlantic Ocean, and the Pacific Ocean. At the same time, OWS performed deep-ocean hydrographic casts and soundings. This network provided long-term and compatible deep-ocean time series of temperature and salinity, and aerological data on wind, pressure, temperature, and humidity within air columns up to about 19 mi. (30 km.). The OWS network initially consisted of 13 stations in the North Atlantic and nine stations in the Pacific. After 1973 (when a world economic crisis occurred), funding was cut off, and in 1984 (soon after beginning of the satellite era in meteorology), OWS observations ceased (with the exception of one Norwegian station in the North Atlantic that is still in operation).

Deep-sea hydrographic observations have been performed since 1872. Pre-1970s hydrographic casts were performed using Nansen bottles, and were the main source of deep-sea hydrographic data. Then, the expandable bathythermograph (XBT) and conductivity-temperature-depth (CTD) soundings replaced the Nansen bottles' measurements. However, the routine oceanographic observations are too sparse and noisy for the reliable detection of low-frequency (long-term) changes of the oceanic fields in the deep ocean (below 2,625 ft. [800 m.]), except near a few standard oceanographic sections and some specific regions with strong oceanographic activity.

Long-term buoy arrays have been deployed in a few key regions of the world's oceans, such as the tropical Pacific and Atlantic, since early 1990s. The Tropical Ocean-Global Atmosphere–Tropical Atmosphere Ocean (TOGA-TAO) and Pilot Research Moored Array in the Tropical Atlantic (PIRATA) mooring networks are in operation. They perform marine meteorological observations and subsurface oceanographic measurement in approximately the first 984 ft. (300 m.), and regularly transmit information to the satellite.

The Rapid Climate Change (RAPID) mooring array has monitored the meridional circulation in the North Atlantic along 26.5 degrees N since March of 2004. First results published by Stuart Cunningham, et al., showed that meridional overturning could be observed with errors smaller than 1.5 Sv (one Sv equals a flow of ocean water of 106 cu. m. per second). This shows the beginning of thermohaline catastrophy (which occurs when meridional overturning in the North Atlantic Ocean shuts down) at the early stage and superimposed high-magnitude interannual variability of meridional circulation.

Surface and subsurface drifters are numerous and effective tools for long-term monitoring, as shown, for instance, by David Fratantoni. They are based on a Lagrange principle of current measurement. Since the late 1980s, they have been the principal source of global data on ocean circulation. Now, ARGO technology is used as a key element of the Global Ocean Observing System (GOOS). This is a subsurface drifter that typically drifts at 1–1.25 mi. (1.5–2 km.) in depth, floats to the surface every 10 days, registers the profiles of temperature and salinity, transmits its information to the satellite, and then sinks back into the depths. The lifetime of each ARGO float is about two to four years. At the moment, there are about 3,000 ARGO floats on the world's oceans. This provides a density of observations of about one float per 776 sq. mi. (300 sq. km.) of water surface all over the globe.

Climatic Data, Proxy Records

CLIMATE SCIENTISTS WOULD prefer to have all climate change information recorded by weather instruments, but suitable instrumentation was practically nonexistent before the 19th century. As a result, investigators of longer-term (paleoclimatic) climate changes rely on datable noninstrumental information. Climate scientists refer to noninstrumental records as proxy records, because they are substitutes for direct measurements taken by instruments. There are four principle proxy record sources: human/historical, glaciological, geological, and biological. The timespan and level of detailed information among the sources vary, but getting the right climate change signal is important, because proxy data play a central role in developing accurate climate prediction models.

Human (or historical) proxy evidence for climate change is taken from a diversity of sources, ranging from clues in prehistoric cave paintings, to remarks about the weather in old letters, diaries, and newspapers. Historical records of changes in crop production also provide valuable proxy information about changes in climate. The other three categories of proxy records are products of climate-related environmental processes. The proxy records can be hundreds, thousands, millions, or even billions of years old. Due to their long timespans, such records are the bases of most paleoclimatic studies.

Glaciological proxy records appear in glacial ice; as the climate changes, so do the physical and chemical characteristics of ice. Geological proxy data rely on the climate-related weathering of rocks and the transport, deposition, and chemistry of the weathered products (sediments) by streams, lakes, wind, and oceans. Plants keep biological proxy data, due to their dependence on climate, incorporated into their structure or reproductive capability. For instance, flowering plants of various climatic tolerances record their location, duration, and abundance by means of production of pollen, so that pollen becomes the plants' climate proxy record.

Climate scientists can infer climatic conditions from analyses of natural phenomena, but without an ability to date the material it is not possible to construct a chronology or calibrate a record. Fortunately, natural proxy records lend themselves to temporal analyses because they accumulate in datable layers, such as growth rings in trees, and layers of sediment and ice laid down in an undisturbed succession over long time intervals. Dating methods include the correlation of proxy records with radiometric (isotopic) dating of igneous rocks, radiocarbon dating of carbon-bearing sediments, and other proxy records, counting annual layers (such as in trees, ice, corals, and lake beds), and correlating proxy records with periods of Earth's orbital cycles.

The timespans of proxy records vary widely. Historical climate records are reliable for a few thousand years. The resolution of the data depends on the person recording the information. Cross-dating tree rings from various sources provide reliable records for tens of thousands of years. Ice cores, lake sediments, and coral reefs yield records for hundreds of thousands of years, and deep ocean sediments for hundreds of millions of years. The oldest climate proxy records are in marine sedimentary rocks that tectonic uplift has preserved on land. Such records are billions of years old, but they are not widely distributed. In general, the reliability, geographical range, and amount of useful climate information, increases rapidly toward the younger part of the record. The resolution of most proxy records that are in layered deposits also depends on the processes that disturb the climate after depositions and the rate of accumulation of the record, which determines how fast it gains protection from disturbances.

Natural proxy records are products of natural systems that depend on climate. Therefore, from these systems it may be possible to derive a climatic signal from the proxy records, but that signal may be embedded in a great deal of random (climatic) background noise. An important goal of climate scientists is to develop models that filter out the noise in order to characterize boundary conditions (such as the size of ice sheets) that they can use as inputs in models that attempt to replicate past and forecast future climates. A fundamental benefit of using proxy-based models is scientists' greater understanding of how Earth's temperature has changed in the past and how it is likely to change in the 21st century.

Climatic Data, Reanalysis

REANALYSIS CLIMATIC DATA is a long-term consistent climatic dataset. The dataset is produced from a state-of-the-art data assimilation system combining both past observations from various sources and short-range forecasts from simulation models to obtain the best statistical estimate of the state of the atmospheric flow. For numerical weather prediction (NWP), the observations from sources irregularly distributed in space and time are analyzed in a unified and consistent manner with the aid of computer models to describe the state and evolution of the atmosphere. Such a procedure combining different data is generally denoted as "numerical analysis" or "data assimilation" and reanalysis climatic data is produced from a state-of-the-art data assimilation system.

Determining the initial conditions of the state of the atmosphere for forecast models is a key process in NWP, whose results heavily depend on these initial conditions. The equations of the motion of the atmosphere are integrated forward from predetermined initial conditions of the atmosphere and appropriate boundary conditions to forecast the atmosphere's evolution.

Ideally, initial conditions are expected to be specified from observations, but this never materializes due to various limitations in observation techniques, such as uneven distribution of observation stations, and errors and limitations inherent in satellite sensors. Due to clear limits in determining initial conditions solely from observations, the idea emerged that initial conditions could be determined by combining new observations of atmospheric variables and "first guess" or "background" estimates of the current state of the atmosphere. The first guess is computed by the forecast model based on earlier observations and is used to determine the initial conditions for the model, creating "analysis cycles." Therefore, the new observations are merged with the new first guesses from the forecast model, which uses initial conditions are estimated from the observations and the first guess. This process in NWP is known as "4-dimensional data assimilation (4DDA)" considering temporal progressions of the 3-D forecast model.

In summary, reanalysis can be understood as a climatic dataset of a past period produced by combining a wide range of reprocessed past observations and forecast models using the most up-to-date data assimilation techniques. Because the model and data assimilation system remain unchanged during the project, it provides an optimal estimate of the 4-D state of the atmosphere with better quality control.

Reanalysis provides a vast range of data encompassing pressure level data (for example, horizontal winds, omega [dP/dt], geopotential height, specific/relative humidity, absolute vorticity and divergence), isentropic level data (for example, horizontal winds, mass-weighted horizontal winds, omega, temperature, potential vorticity, and relative humidity), sigma level data (for example, divergence, temperature, specific humidity, horizontal winds, surface pressure, and geopotential height), radiation related quantities, clouds and precipitation, and others (for example, surface wind stress, latent/sensible heat flux, soil temperature/moisture, sea surface temperature, 2m temperature, 2m humidity, 10m winds, runoff, mean sea level pressure, surface pressure, snow).

GLOBAL AND REGIONAL SCALES

So far several different reanalysis projects have been carried out both at the global and regional scales by organizations in the United States, Japan, and Europe, including the National Center for Environmental Prediction (NCEP), National Center for Atmospheric Research (NCAR), United States Department of Energy (DoE), Japan Meteorological Agency (JMA) and the European Centre for Medium-Range Weather Forecasts (ECMWF).

The NCEP and NCAR commenced a joint project, in 1991, to produce a global reanalysis dataset over the period 1957-96 which is continuing beyond the initial period. The model has a T62 (about 130 mi. or 210 km.) horizontal resolution with 28 vertical levels; the data are provided at the 6-hour, daily, and monthly scales. This reanalysis product is often called NCEP/NCAR Reanalysis 1. Reanalysis 1 has been widely used in climate modeling communities to provide boundary conditions for general circulation models.

The NCEP/DoE AMIP-II Reanalysis (Reanalysis 2) is an updated version, but not the next generation of Reanalysis 1. Based on Reanalysis 1, Reanalysis 2 was developed by improving parameterization of physical processes and fixing errors in Reanalysis 1, with data coverage since 1979.

Japanese 25-year ReAnalysis (JRA-25) was created by JMA in collaboration with Central Research Institute of the Electric Power Industry for the period 1979–2004 and was transitioned to Japanese Reanalysis Project-Categorical Data Analysis System (JMA-CDAS) after 2005.

The global model has a T106 (about 68 mi. or 110 km.) horizontal resolution with 40 vertical layers. It is the first reanalysis project to use wind profile retrievals surrounding tropical cyclones (TCR), Special Sensor Microwave/Imager (SSM/I) snow coverage and digitized Chinese snow depth data.

The European Centre for Medium-Range Weather Forecasts (ECMWF) developed the ERA 15 Re-Analysis project in association with various organizations around the world. ERA 15 Re-Analysis incorporated various observational data including NOAA satellite radiance data for the 15-year period, the Comprehensive Ocean-Atmosphere Data Set (COADS) ship data, the First GARP Global Experiment (FGGE) and the Alpine Experiment (ALPEX) data, and pseudo-observational data from the Australian Bureau of Meteorology. The dataset spans from January 1979 through February 1994 and is available on a 2.5 degrees latitude × 2.5 degrees longitude grid.

North American Regional Reanalysis (NARR) is "a long-term, consistent, high-resolution climate dataset for the North American domain" with major improvements in both resolution and accuracy compared to previous global reanalysis datasets. It has a spatial resolution of 20 sq. mi. (32 sq. km.), a vertical resolution of 45 layers and a temporal resolution of 3 hours from 1979 to the present. It uses the NCEP Eta forecast model with lateral boundary conditions provided by the NCEP–DoE Reanalysis 2 and the Eta model Data Assimilation System. Data added or improved upon for NARR include precipitation measured over the United States, Mexico and Canada, wind and moisture from Reanalysis 2, pressure, wind, moisture from NCAR, ship and buoy data from NCEP/EMC (Environmental Modeling Center), snow depth from Air Force Weather Agency, Great Lakes sea-surface temperature, sea and lake ice data on Canadian lakes and Great Lakes, and tropical cyclones from Lawrence Livermore National Laboratory. The most striking feature of NARR is the successful assimilation of precipitation observations, which lead to the more realistic hydrological cycle.

Climatic Data, Sea Floor Records

THE SEA FLOOR is blanketed with sediments composed primarily of the remains of plants and animals that live in the oceans which cover three-quarters of the Earth's surface. Sea-floor sediments also include particles of soil, dust, volcanic ash, and fragments of vegetation that are washed off the land by rivers and floods, blown in by winds, or left by melting icebergs. In the deep oceans throughout the world, sea-floor sediments have piled up continuously over thousands to millions of year, silently recording the history of changes in climate and ocean conditions as far back as the time of the dinosaurs 60–80 million years ago.

Over the past 50 years, modern engineering and scientific techniques in paleoceanography have accessed these deep-water sea-floor archives and have read their messages about natural climate changes that occurred before the recent global warming started about 150 years ago. The importance of the sea-floor archives is that they allow an examination of past natural cycles of climate change and how the marine and land biological communities responded to fluctuations that include conditions hotter than the increase of 2–6 degrees C forecast for the present global warming.

Before about 1947, knowledge about climate change was mainly based on written historical records and the study of fossil plants and animals scattered over the continents in short sections that escaped destruction by glaciers during the Ice Age. In 1947, the new technology of piston coring and an international Deep Sea Drilling Program (DSDP) that enabled sampling of long sections of sea floor sediments revolutionized the science of climate change. Working from ships dedicated to scientific research, these new methods enabled the retrieval of unbroken sediment cores up to 2,625 ft. (800 m.) long, covering time spans of up to 10 million years. The archival data in the sea floor records consists mainly of tiny fossil marine phytoplankton and zooplankton called microfossils, mixed in with fine sand or mud swept off the land, and dust particles, including pollen grains from forests and grasslands on the continents. The oceanic microfossils, pollen, and sediment particles provide proxy (indirect) records of oceanographic or atmospheric conditions in ancient times.

The main oceanic plant microfossils are diatoms, dinoflagellate cysts, and coccoliths; the main animal microfossils are foraminifera and radiolarians, all of which are less than a few millimeters in length. The shells of even the tiniest (pinhead-size) marine microfossils carry an imprint of the ocean's temperature, salinity, and carbon production at the time they were alive.

When extracted in the thousands from the sea, floor sediments by sieving just a handful of ocean mud, the microfossils can be analyzed by chemical methods (stable isotope measurements), or by statistical analysis of their population composition, to reveal the oceanographic conditions at their time of death. The kinds of pollen found in the sediment samples tell us how much forest or grassland there was on the continents surrounding the ocean, while the amount of inorganic sediment provides a proxy-signal of river flooding or sea ice.

The results of the chemical and biological studies of the sea-floor sediment cores from all the world's oceans show a zigzag pattern of alternating warm and cold climates extending back at least 5 million years. To understand the cause of this saw-tooth climate record, methods were developed for calculating the age of the warm-cold cycles. Radiocarbon dating of the youngest sediments showed that the temperature peaks corresponded to warm periods lasting about 6,000 to 10,000 years, while the dips represented longer periods of glacial conditions lasting 20,000–30,000 years.

Paleomagnetic records of periodic reversals in the Earth's magnetic field, together with dating from the decay of radioactivity in rock fragments containing uranium or potassium and argon, allowed a timescale to be placed against the sea floor proxy-climate records. Cambridge University scientist Sir Nicholas Shackleton then showed that the oxygen in the marine microfossil shells came in two forms, one lighter, one heavier, called isotopes, and he showed that when ice sheets develop on the continents, the lighter oxygen-16 isotope diminishes in the oceans because it is locked up in the frozen water on land. When the ice sheets melt, however, the light oxygen returns to the oceans and again appears in the microfossil shells.

Using this proxy-climatic data from the sea floor records, in 1976, Nick Shackleton, Jim Hays, and John Imbrie were able to decipher the encoded climate messages in the sea-floor sediments and confirmed that the ice-volume cycles correspond to seasonal and geographical changes in the amount of the sun's energy received at the Earth's surface, because of shifts in the position of the Earth's movement around the Sun, as predicted in the early 20th century by Russian scientist Milutin Milankovitch. The sea floor records of climate change revealed a history of 40–50 ice age cycles in the Northern Hemisphere, completely revising the old idea that there were just four glacial intervals during the Pleistocene Ice Age.

The proxy-climate records from fossil phytoplankton (dinoflagellates) in sea-floor sediments in the Canadian Arctic region west of Greenland also confirm climate model estimations of summer ice-free conditions and sea-surface temperature increases of 4–6 degrees C that followed the end of the last glacial cycle. These arctic sea floor records show that the natural warming cycles took place over one to two centuries, long enough for marine and land plants and animals to adjust to the climate change.

Less is known about the older pre–Ice Age sea floor records, but oxygen isotope data from 40 DSDP and ODP sites now extend back over the past 124 million years. These show that several times 50–120 million years ago, temperatures as much as 12 degrees C warmer than today. These proxy-temperature data come from measurements of the ratio of magnesium to calcium (Mg/Ca) in fossil foraminifera. The boron isotopes in these microfossils also suggest that very high levels of carbon dioxide accompanied this hothouse ocean. The sea floor records also reveal several times, just before and after the extinction of the dinosaurs, when vast quantities of organic carbon were buried in some of the ocean basins during periods called Oceanic Anoxic Events (OAEs).

The OEAs seem to be related to times of extreme warmth and great variability of surface water in the subtropical to tropical latitudes of the Atlantic Ocean. The OEAs lasted about .5–1 million years and were accompanied by major extinctions of marine biota and wholesale changes in the composition and structure of marine animal populations. Overall, the sea-floor climate data show that very warm temperatures and hothouse conditions prevailed until about 55 million years ago, after which there was a slow drift toward the Pleistocene Ice Age and the oscillations between greenhouse and icehouse conditions.

Climatic Data, Sediment Records

SEDIMENT LAYERS IN different types of depositional settings, which include floodplains, and the bottom of lakes, rivers, and oceans, can provide a useful archive of past climatic conditions over the last few decades to tens of thousands of years ago. Such sediment records are routinely used to reconstruct natural variability in past environmental conditions, as well as anthropogenic-driven changes in contemporary climate, including changes in effective moisture (the difference between precipitation and evaporation); temperature; atmospheric circulation patterns; wind regimes; sources, diversity, and productivity of organic matter; partial pressure of carbon dioxide (CO_2) in the atmosphere; and paleomagnetic properties of the surrounding environment.

The sedimentary record of past climate change can be made up of biogenic, radiochemical, and magnetic components. Derivation of such information from sediments is possible because changes in climate conditions, such as rainfall and consequent changes in aeration and alkalinity of bottom waters, can influence the rate of sediment input, formation of secondary minerals, and rates of biological productivity in the sediment layer.

The organic matter in sediment layers is a complex mixture of authochtonous and allochtonous (produced in situ or deposited with erosion, respectively) organic compounds from littoral, planktonic, and

With rates of sediment deposition up to two orders of magnitude faster than in the deep sea, lakes offer good climate records.

bacterial sources. Sedimentary basins contain biologically rich and diverse fossil records that can be used to reconstruct surface lake-water temperature (which is strongly correlated with air temperature), water chemistry, and other climatic factors that affect abundance and productivity of floral species. The most common sources of authochtonous organic matter in lacustrine and marine environments are diatom algal floras (diatoms are the most common type of phytoplankton and a major group of eukaryotic algae).

The ecological structure or community assemblages of indicator diatom species are highly correlated with the intensity and duration of some environmental conditions. For instance, the abundance and species composition of diatoms serve as proxies for past conditions in water-chemistry (including salinity and pH) and length of the growing season in the body of water.

On the other hand, allochtonous fossil records, including pollen and spores that are washed from surrounding catchments, give clues about past climatic conditions in the surrounding environment that could have produced the specific assemblage of plant communities. More precise information on factors influencing plant species abundance and productivity (of which climate is among the most important) in the surrounding environment can be retrieved from macrofossils, of large vegetation remains that are washed into the sedimentary basins. Fossils from insects such as chironomids also provide accurate records of lake-water temperature.

PAST CLIMATE CONDITIONS

The stable isotope composition of organic matter and carbonates in sedimentary basins can be used to provide information on past environmental and climate conditions.

Different types of terrestrial and aquatic plants and animals have variable isotopic composition, depending on their specific photosynthetic pathways, positions they hold on the food chain (trophic level), or their feed sources. Carbon and nitrogen isotope composition (δ13C and δ15N) of organic matter in sediment layers can be used to discern sources of organic matter.

Oxygen isotope composition (δ18O) of carbonate sources such as calcite (from ostracod and mollusk, or sedimentary minerals formed by precipitation or recrystallization during sedimentation), biogeonic silica, and organic matter can be used to reconstruct past conditions of temperature. Moreover, biological transfer functions for direct reconstruction of past temperatures are used with fossils of diatoms, chrysophytes (golden algae), chironomids (non-biting midges), and cladocera (water fleas), because presence of specific species in a given body of water and their abundance is strongly correlated with temperature.

Paleomagnetic information in sediment records is sometimes critical to establish chronologies, both to calibrate timescales for changes in source of minerals entering the sedimentary basin and to validate the integrity of the sediment record. The record of magnetism in sediments (variations in magnetic inclination and declination that is preserved in deposited sediments) is useful for interpreting past records of climate change. Temporal variations in the Earth's magnetic field are preserved in rocks and if magnetic particles are eroded from upland terrestrial environments and deposited in low-lying sedimentary basins they show small, but measurable, preferred orientation depending on the magnetic field at the time of sedimentation. This is a phenomenon referred to as depositional remnant magnetisms.

Several pre- and post-depositional factors can influence the utility of sediment records in reconstruction of past climatic conditions. The resolution of the sediment record can vary depending on rate of sediment delivery to the basin and type of the sedimentary basin considered.

For example, lake sediments provide a high-resolution record of past environmental conditions at the timescale of decades or a few centuries, while sediment records from oceans provide a lesser-resolution record of longer time periods. Lacustrine sediment records can provide a high-resolution record of paleoclimatic fluctuations, partly because rate of sediment deposition in lakes are up to two orders of magnitude faster than that in deep sea sediments.

Bioturbation (mixing due to biological activity) is another factor that affects integrity of sediment records and results in important changes to terrestrial sediment once it is deposited in a sedimentary basin. Pristine sediment records can be preserved when the currents at the bottom of a water column are weak and oxygen availability is too low to allow any mixing activity by living organisms. In the absence of bioturbation, contamination of the sedimentary record due to mixing of newly-deposited sediments with old sediments is limited.

Because most of the sediment in floodplains, or at the bottom of river, lake, or ocean floors is made up of mineral particles that were transported from adjacent areas, sediment records provide essential archives of past conditions, not only in the specific basin from which they are collected, but also in the surrounding areas. By investigating the stratigraphy of sediment cores, it is possible to get useful information about mineralogical composition of contributing catchments, rates of sediment transport, and biological productivity. It is important to note that within a basin, the sediment record can be stratified vertically or laterally. Sediment records that include vertical successions of strata are representative of chronology or sequential passage of time, while sediment records that include lateral successions of strata are representative of changes in depositional environments during sedimentation or diagenesis.

When interpreting sediment records, most sediments are derived from multiple sources, each with its own paleoenvironmental record. Moreover, sediment layers do not record direct information about climate change; therefore, scientists must calibrate the information obtained from sediment records (for example, the isotopic composition of δ18O for temperature) to known climatic data.

Climatic Data, Tree Ring Records

PAST CLIMATES CAN be reconstructed by the use of the relationship between the climate and tree-growth parameters (dendroclimatology). Dendroclimatology is a sub-discipline of dendrochronology, which is the analysis of tree rings, including the dating of annual rings and study of patterns of ring characteristics, such as width, density, and isotopic composition. Annual growth rings of trees are natural recorders of climatic conditions (a proxy variable).

Outside the tropics, in the temperate and boreal zones with a distinct growing season and a strong seasonality in either temperature or rainfall, diameter growth of trees is distinguished by the formation of tree rings. Each growing season, new cells are produced by the vascular cambium (a cell layer that separates bark from wood).

While those cells formed toward the outside of the cambial layer become part of the bark, cells formed inward build up rigid wood and are the building blocks of tree rings. The actual tree rings are formed by a change in growth characteristics of wood formation through the season. Wood cells formed at the beginning of the growing season are large, thin-walled, and low in density, and are called earlywood. Toward the end of the growing season, cells become smaller and more thick-walled, forming the latewood. Finally, when the growth season ends, growth stops and cells die, with no new growth appearing until the next spring. The ring boundary is the contrast in cell size between the small latewood cells and the large earlywood cells.

Diameter growth of trees in arid and semi-arid environments strongly responds to changing soil water conditions and, thus, provides information on precipitation, while trees growing at high latitudes (poleward of 30 degrees), or high altitudes, are most sensitive to changing temperatures. In recent years, tree-ring studies have also been conducted in the tropical zone, where some tree species form distinct tree rings in reaction to dry and rainy seasons.

Analyses of tree rings have been carried out for several conifer species (such as spruce, pine, larch, fir, juniper, and cedar) and deciduous tree species (such as oak, beech, aspen, alder, birch, ash, and elm).

Moisture and a long growing season result in a wide ring, while drought and a short growing season results in a narrow ring.

However, deciduous species have not been studied as thoroughly as conifers, because of the more complicated structure and variability in their annual tree-ring growth patterns. Generally, tree species suitable for dendroclimatology are those that are sensitive to climate and show a variation in ring-to-ring growth, while those that lack ring variability are called complacent. Yet, tree-ring characteristics are not only influenced by a number of climate-related factors (soil and air temperature, precipitation or soil moisture, sunlight, wind, snow accumulation, or the length of the growing season), but also by non-climate-related factors such as soil fertility, atmospheric composition, slope gradient, fires, pests and diseases, grazing, logging, tree age, competition, genetic differences, and growth in previous years.

Climate-related factors may alter cell enlargement and subsequent maturation of wood cells by regulating hormone activity or availability, by influencing net carbon gain via restricted photosynthesis, or by modifying metabolic pathways associated with the different growth processes. Variations in temperature and water availability can have direct effects on the rates or duration of cell expansion and wall thickening, and indirect effects on carbon availability and growth-regulator levels. Temperature represents the most critical factor at the beginning of the growing season, when sufficient water reserves are available. As the growing season progresses and soil moisture decreases, radial growth is increasingly exposed to stress due to water deficit. Adequate moisture and a long growing season will result in a wide ring, while drought and a short growing season will result in a narrow ring.

Andrew E. Douglass of the University of Arizona discovered the basic technique of dendroclimatology in the early 1900s. For a good record of climate conditions, many trees need to be sampled to avoid the possibility of all the collected data showing a missing or extra ring. Information is acquired by taking small-diameter radial cores or horizontal cross sections through the trunk of a tree. These are prepared and total ring width, latewood width, maximum latewood density, and isotopic or chemical compositions are measured. Patterns of ring-growth characteristics are matched between several trees throughout a region in a process called cross-dating, which permits the assignation of exact calendar year dates to each individual ring. This matching is calculated by a number of computer programs.

Long-term growth trends associated with the aging of trees and forest dynamics represent an underlying disturbance for the purpose of climatic reconstruction and are removed statistically by detrending tree-ring growth series with a fitted smooth mathematical growth function (standardization). More complex modeling is used to remove the aftereffect of an adverse season to growth in the following years. Yearly growth measurements are then averaged from several trees in a region to form a master tree-ring chronology. This averaged tree-ring chronology enhances the common pattern of variations in growth (signal), while it dampens the non-common variance (confounding noise).

Cross-matching the patterns of a dated chronology with overlapping series of samples taken from dead trees of unknown age preserved in old buildings, river gravels, peat bogs, or lakes, allows chronologies to be extended into the past up to thousands of years (for example, chronology for Bristlecone pine greater than 8,500 years before the present time). By statistically comparing tree-ring chronologies with modern climate records, equations can be developed, which can be used in conjunction with the tree-ring data to reconstruct past climate values.

Tree-ring data are especially useful as climate proxies, in that they provide information of a high spatial and temporal resolution: the information is annually resolved, continuous, and abundant. However, tree ring data also have some limitations: confounding factors, geographic coverage (polar and oceanic climates are not covered), and annual resolution (dormant seasons are not covered). However, compared to corals and ice cores, tree-ring reconstructions show greater agreement with instrumental data over the last 100 years, both in terms of simple correlations and coherency on different timescales. Lake and ocean sediments have a lower time resolution, but provide climate information at multicentennial timescales that may not be captured by tree-ring data. By combining multiple tree-ring studies with the records taken from other climate proxy sources (multiproxy reconstruction), our understanding of past regional and global climates can be extended far beyond the instrumental record.

Climatic Research Unit

THE CLIMATIC RESEARCH Unit is regarded as one of the world's leading institutions concerned with the study of natural and anthropogenic climate change. It was founded in 1972 at the University of East Anglia in Norwich, England, by Professor Hubert Lamb (1913–97). The Unit, often known simply as CRU, was the first research center of its kind with a focus on research into climatology, in particular climatic change, and on interdisciplinary and historical research on the climate of the past. Lamb, one of the best known climatologists of his time, remained CRU's Director until 1978 when he became emeritus professor. In August 2006, the distinctive circular CRU building was named the Hubert Lamb Building. Subsequent directors of the Unit have been Tom Wigley, Trevor Davies and Jean Palutikof. The current Director is Phil Jones.

Lamb was employed by the United Kingdom's Meteorological Office from 1936 onwards. In 1950, he published a classic paper on weather types and natural seasons in Britain. The Lamb Weather Type (LWT) classification described in this paper began a new era in climatological research. In the 1960s, Lamb focused on reconstructions of monthly atmospheric circulation changes over the North Atlantic and Europe back to the 1750s. This research confirmed his growing conviction of the reality of natural climate change and its significance to humans. In 1970, he published a classic paper on the connections between volcanism and climatic change. His estimates of the dust ejected into the atmosphere by historical eruptions became known as the Lamb Dust Veil Index. Lamb was also one of the pioneers in the use of documentary evidence to reconstruct past changes in climate. This continues as a major focus of work in the CRU.

Although Lamb's work was crucial in the early years of the CRU, the Unit has had a number of other outstanding scientists on its staff. Their work has broadened the general aims of the CRU and helped to improve scientific understanding of past climate and its impact on humanity, the course and causes of climate change over the past century, and prospects for the future. The Unit currently employs 46 scientists and graduate students as well as hosting an M.Sc. course in Climate Change. CRU researchers have developed a number of data sets widely-used in climate research, including gridded data sets for surface temperature, precipitation, pressure, tree-ring records that have been important in reconstructing temperature variations over the past 1,000 years, and documentary records of climate and climate impacts. The user-friendly software package MAGICC/SCENGEN, used for making projections of future global-mean temperature, sea level, and patterns of climate change, was developed in the CRU (downloadable from http://www.cgd.ucar.edu).

Climate affects both social and natural systems through the occurrence of weather extremes, through inter-annual climate variability and through longer-term climate change. CRU researchers study aspects of all three of these scales of climate impact, with projects ranging from the United Kingdom to

Europe, Africa and Vietnam. A better understanding of the ways in which climate extremes and variability have affected society and the environment in the past is a pre-requisite for attempting to understand how serious the range of impacts associated with future climate change are likely to be. The results of analyses such as these feed directly into the design of climate-change response policies, whether these be mitigation or adaptation. Specific research areas include: paleoclimatology, dendroclimatology, present-day climate and climatological datasets, climate-change detection and attribution, construction of climate change scenarios, impacts of climate variability and change, links between atmospheric circulation and transport/deposition of air pollution, atmospheric sciences, and hydrology.

Climate Monitor, the seasonal data summary of work in the CRU changed from a printed to a online version in 1998. It is now available on http://www.cru.uea.ac.uk/cru/climon/ and brings together in one place regular updates of important climate and meteorological data, together with commentaries from the world's press and media. The CRU's website also contains a range of downloadable climate datasets and useful information pertaining to climate change.

Clinton Administration

WILLIAM JEFFERSON CLINTON (b. August 19, 1946) was the 42nd president of the United States, serving from January 20, 1993 until January 20, 2001. In the first year of his term, President Bill Clinton promised to bring justice to the practice of environmental racism as well as to work to resolve the tension regarding management of the Pacific Northwest federal forests, and yet throughout his term he would be known as the president who gave tax breaks to oil companies in the Gulf of Mexico, who no longer banned tuna that was not dolphin-safe, and who increased logging in the Tongass National Forest of Alaska.

Environmental racism refers to the fact that lower-income communities, which tend to house peoples of ethnic minorities, as well as communities of non-whites, are at a higher risk of being located near environmentally-toxic sites, such as landfills or hazardous waste dumping grounds. Consequently, people living in these communities are at an elevated risk of developing chronic disorders such as asthma or cancer.

On April 2, 2003, Clinton along with Vice-President Al Gore and several advisors and Cabinet members attended a meeting convened by Clinton to discuss the Pacific Northwest federal forests. This meeting was held in Portland, Oregon. After the meeting, President Clinton promised to develop a plan for sustainable and economic management of the forests, and this plan was released on July 1 of that year. It was called The Forest Plan for a Sustainable Economy and a Sustainable Environment.

The three chief purposes of the plan were forest management, economic development, and agency coordination; of the three, forest management had most to do with the environment. This theme set aside reserves with minimal activity allowed within them, although it did allow thinning and salvage for purposes of returning the forest to its old patterns of growth. Some environmental groups were nonetheless concerned that the salvage activities and thinning would be exploited for corporate gain. Other areas of the forest such as those designated as spotted owl habitat were slated for limited collection annually, in order to preserve the habitats while maintaining a sustainable timber harvest. Additionally, the plan called for improved sales of dead or dying timber within the forestland, in order to clear way for new trees.

After barely one month in office, on February 22 1993, President Clinton outlined his priority: "long-term economic growth that creates jobs and protects the environment." He did so in a Statement on Technology for America's Economic Growth. A significant contribution of the Clinton Administration to environmentalism was that trade agreements between the United States and other nations required that those countries observe environmental standards. This change in United States trade policies was praised for its environmentalism, but criticized for its potential to harm citizens of countries where employers and/or leaders exploited the environment while trying to succeed in the global economy.

To keep with his priority of environmentally safe economic growth, Clinton created a new watchdog position at the Department of State to monitor international environmental conditions. This position of Undersecretary for Global Affairs was assigned to Timothy E. Wirth. Wirth, a former Senator from Colorado, was a member of the Green party and acted as Undersecretary for Global Affairs from 1993 until 1997. Following in this environmentalist spirit, Secretary of State Warren Minor Christopher issued a statement on February 14, 1996 stating that U.S. foreign policy would from that point on keep the environment and its care in focus and that Department of State officials must consider this focus when designing international policies or meetings. Christopher also served from 1993–97.

This international environmental watchdog stance did not extend beyond trade and meeting policies. In 1996, the Clinton Administration challenged China's desire to build a dam to control the flooding of the Yangtze River to curb its enormously high death toll. The reason for the Clinton Administration's refusal of support was that the dam, called the Three Gorges Project, would threaten many species of wildlife, such as freshwater dolphins and Siberian cranes. The Clinton Administration attempted to influence commercial credits for American companies looking to capitalize on the Three Gorges project, and was accused of trying to use its voting power at the World Bank to impede funding for the dam.

Clinton had three Secretaries of Energy during his Administration. They were Hazel O'Leary (1993–97), Federico F. Peña (1997–98), and Bill Richardson (1998–2001). His Vice President, Al Gore, would go on to become a leading environmentalist. In an interview with CBS news in 2006, James Hansen, the Director of the Goddard Institute at the National Aeronautics and Space Administration (NASA), said that the Clinton administration sometimes wanted him to make global warming sound worse than it was. In contrast to this statement, Vice-President Gore was awarded the Nobel Prize for Peace in the year 2007 for his efforts to spread education about global warming and curtail its progress. He shared this award with the Intergovernmental Panel on Climate Change (IPCC).

Cloud Feedback

INCREASES IN SURFACE and tropospheric temperatures produce changes in cloud properties that, in turn, produce changes in temperature. This effect is known as cloud feedback. Cloud feedback has been identified by the United Nations Intergovernmental Panel on Climate Change (IPCC) as one of the most uncertain processes in climate models. Cloud particles (hydrometers) affect both thermal and solar radiation. Cloud particle size and concentration are strongly-affected by updraft velocity, humidity, temperature, and cloud nuclei concentration. In addition, the lifetime of cloud particles depends on the humidity of the ambient air. Thus, cloud properties and coverage are sensitive to climate change.

Clouds produce extremely complex climate feedbacks that lead to large uncertainty in climate simulations because cloud processes are not well understood. Clouds cool the Earth by scattering solar radiation and increasing the amount of solar radiation returned to space. That is, clouds increase the planet's albedo. They also absorb solar radiation, increasing the atmosphere's temperature, and cooling the surface by reducing the amount of solar radiation reaching it. In addition, clouds produce a greenhouse effect by absorbing thermal radiation and re-emitting it at their own temperature. Clouds tend to keep nighttime surface temperatures warmer than they would be in their absence, and keep daytime temperatures cooler.

Cloud feedback is the combined result of changes in cloud cover, cloud height, cloud emissivity, and cloud albedo. Because various cloud processes contribute to cloud feedback, and because different types of clouds such as cumulus, stratus, and cirrus have different effects on the budget of solar and thermal radiation, cloud feedback is complicated. Climate models cannot even determine if the overall cloud feedback is positive or negative. High clouds, such as cirrus, are optically thin and cold. Because they are reasonably opaque to thermal radiation, they scatter a relatively small amount of solar radiation when compared to the amount of thermal radiation they emit. Thus, high clouds usually have a net warming effect on the planet.

Low clouds, such as stratus, are warm and highly opaque to solar and thermal radiation. However, because low clouds are not much colder than the surface, their main effect is to increase the amount of solar radiation scattered to space. Therefore, low clouds usually produce a net cooling of the planet. On the other hand, low clouds over bright and cold surfaces such as snow or ice can have a positive climate feedback. The net result depends on details of cloud properties, such a particle size distribution and concentration.

The effects of clouds on climate are uncertain, because they depend on the cloud particle number, size distribution, phase, cloud height, temperature, and many other physical parameters. Cloud feedback is the source of the largest uncertainty in the Global Climate Models (GCMs) used to calculate human-induced global climate changes. The International Satellite Cloud Climatology Project (ISCCP), started in 1983, was the first internationally-coordinated satellite cloud climatology project. This pioneering program served as a prototype to many other global satellite cloud climatology projects. The U.S. Department of Energy (DOE) Atmospheric Radiation Measurement Program (ARM) has focused on surface and cloud measurements. These measurements are used to study cloud processes to produce solid cloud climatology.

Clouds, Cirrus

CIRRUS CLOUDS ARE the thin and wisp-like clouds seen at high altitudes (higher than 20,000 to 26,000 ft., or 6,000 to 8,000 m.). The name cirrus comes from the Latin word for curl. They are composed predominantly of tiny ice crystals, because they form in the cold region of the troposphere. If cirrus clouds drop their ice crystals, these crystals evaporate before they arrive at the ground.

Cirrus clouds can take on a variety of formations, including a more tuft-like characteristic called cirrocumulus, which also include supercooled water droplets. Some cirrus clouds are called cirrostratus; this

Cirrus are the high, wispy clouds composed predominantly of tiny ice crystals formed in the cold region of the troposphere.

type of cloud formation occurs when the thin strands of clouds are so dense that they cannot be deciphered. Other formations include cirrus aviaticus (also called contrails, the artificial cirrus clouds generated by aircraft), cirrus castellanus (castle-like, with towers rising from a base), cirrus duplicatus (multiple sheets), cirrus fibratus (fibrous, and resembling a horse's tail), cirrus floccus (rounded above), cirrus intortus (tangled), cirrus Kelvin-Helmholtz (slender and signaling atmospheric turbulence), cirrus radiatus (with horizontal banding), cirrus spissatus (thick and gray in color when in front of the sun), cirrus uncinus (hooked, and reminiscent of cirrus fibratus but with more curling at the ends), cirrus vertebratus (rib-like horizontal strips of clouds), and cirrus with mammatus (rounded underneath).

Cirrus clouds are generally seen in fair weather, sometimes following a thunderstorm, and their wisps typically point in the direction of the high-altitude wind flow. In the case of Cirrus Kelvin-Helmholtz, the clouds lie in the turbulent atmospheric region. Cirrus clouds usually form in the summer and winter, when opposing weather fronts meet, such as warm, dry air and cool, dry air. Some meteorologists use cirrus clouds to predict rain.

Because of the high altitude of these clouds, their albedo effect is often overridden by their greenhouse effect. This imbalance is due to the fact that lower clouds are weaker at conserving solar heat, but are very good at reflecting it back into the atmosphere. In contrast, the high cirrus clouds can both conserve heat and reflect it, but are often better at conserving it. Studies are currently being conducted at the United States National Aeronautics and Space Administration (NASA) to determine the role of cirrus clouds in global warming and the Earth's climate. The modeling of these clouds and their effects is difficult, due to the irregular nature of the sizes and shapes of their ice crystals.

Clouds can be found in the atmospheric layer called the troposphere. The troposphere is the lowest atmospheric region and is where all weather takes place. At the equator, it reaches up to 11 mi. (18 km.) from the earth's surface. The next atmospheric layer is the stratosphere, extending to 31 mi. (50 km.) from the Earth's surface. A cloud forms when water vapor reaches its dewpoint and condenses to form a water droplet. These droplets condense around cloud condensation nuclei (CCN), which are often particles of aerosol providing a scaffold around which the cloud can form. Each CCN is approximately one one-hundredth the size of the cloud droplet, which is itself approximately one one-hundredth the size of a rain droplet (usually about .08 in. or 2 mm. in diameter). The nature of the clouds allows them to reflect sunlight away from the earth, known as the albedo effect, but also to trap infrared light beneath them on the earth's surface. This latter phenomenon adds to the greenhouse effect.

In 2007, investigations at the University of Alabama at Huntsville found that global warming might paradoxically be leading to a thinning of these greenhouse-inducing cirrus clouds.

Clouds, Cumulus

CUMULUS CLOUDS ARE puffy and usually have well-defined boundaries. They form from the condensation or deposition of moisture in particles known as cloud nuclei present in the moist updrafts of convective plumes. The cloud particles can be composed of liquid water, supercooled water, or ice. These cloud particles are denser than air; therefore they increase the density of cumulus updrafts. However, water vapor is lighter than dry air, and therefore, except for the effects of the cloud particles, the moist updraft air is lighter than dry air at the same temperature and pressure. This effect of moisture on air density is known as virtual temperature. Scientists have shown that the virtual temperature effect is responsible for about 50 percent of the buoyancy of convective plumes that form cumulus clouds in the tropics and subtropics, but has negligible or even negative effects over desert and semi-desert areas.

The base of cumulus clouds is usually flat, because they form when moist air rising from the surface reaches its lifting condensation level. The height of the lifting condensation level depends only on the properties of the updraft air, therefore it is constant in updrafts mixed by turbulent eddies. The height of the cloud bases usually ranges from a few hundred meters over the oceans, to more than 16,404 ft. (5,000 m.) over dry desert and semi-desert areas. The shape and size of cumulus clouds depends on the intensity of the updrafts causing them to form. Individual updrafts form the various cumulus towers that compose single cumulus clouds. The rounded tops of these towers are the boundaries of convective plumes reaching their level of neutral buoyancy. Cumulus clouds can develop into giant cumulonimbus in environments convectively unstable over large depths.

Cumulus are the puffy, tall clouds composed of liquid water, supercooled water, or ice.

Convective circulations are heat engines because they convert heat into bulk fluid motion such as convective updrafts, downdrafts, and the complete convective circulation. The efficiency of this conversion of heat into kinetic energy depends on the depth of the convective layer. Therefore, deeper convection produces stronger updrafts and more well defined cumulus towers than shallow convection. Cumulus clouds can cause showery rain. Over deserts and semi-arid regions, the rain evaporates before reaching the surface. This is known as virga.

Global climate warming will likely produce increases in the amount of cumulus clouds. This happens because surface warming, coupled with stratospheric cooling, increases convective instability. The height of the bases of cumulus clouds might increase over land because global warming is expected to increase the surface temperature and reduce humidity. Illumination and wind has strong effects on cumulus clouds, in particular, on their appearance and organization. Changes in illumination and background cause changes in color and the apparent surface relief of cumulus clouds. Wind shears can shred the top of cumulus clouds, forming the species known as cumulus fractus. Wind can also orient clouds into rolls or cloud streets and produce waves and lenticular clouds to form above them.

Clouds, Stratus

STRATUS CLOUDS ARE those clouds that resemble a sheet across the atmosphere. These clouds typically rest at a low altitude, found below 6,000 ft. (2,000 m.). Their color can vary between white to dark gray. A stratus cloud that rests at ground level is known more commonly as fog. Stratus clouds a bit higher than fog block the sun from view and cause a cloudy day' The name stratus is the Latin word to spread out.

The formation of stratus clouds occurs when a sheet of cool air passes under a sheet of moist, warm air. At the layer where these two sheets meet, the warm upper air is cooled to condensation and forms a stratus cloud. The cloud will extend as far as the overlap between the sheets of air.

Because stratus clouds are typically fog that has been elevated, they usually do not bode precipitation. At the most, stratus clouds might bring a drizzle. A type of stratus cloud, nimbostratus, do bring precipitation. Weather associated with nimbostratus clouds might be rain or snow. These clouds are so named because nimbus means rain in Latin. They are dark gray and typically rest in lower altitudes, no higher than 8,000 ft. (2,400 m.).

Yet another form of stratus cloud is the combination of a stratus cloud and a cumulus cloud, called a stratocumulus cloud. Stratocumulus clouds bring light precipitation, often a drizzle, and are found at the same elevation as nimbostratus clouds. They are somewhat fluffy, due to their cumulus nature, but darker than typical cumulus clouds. Generally, stratocumulus clouds do not bring much in terms of weather; they are used to predict dull weather.

There are many variations of stratocumulus clouds. These variations are classified as one of two types: stratocumulus undulatus (undulated, or waved) or stratocumulus cumuliformis (cumulus-shaped). The types of clouds in the stratocumulus undulatus category are tratocumulus lenticularis (lens-shaped, elongated and flat), stratocumulus opacus (dark and thick), stratocumulus perlucidus (occasionally exhibiting pockets of inconsistency that allow sunlight through), and stratocumulus translucidus (sheets of stratocumulus clouds, between which a clear sky can be seen). Stratocumulus cumuliformis clouds include stratocumulus castellanus (towers of clouds billowing from a common base), stratocumulus diurnalis (low altitude clouds resulting from spreading of cumulus or cumulonimbus clouds), stratocumulus mammatus (from mamma, the Latin word for breast; having rounded clouds hanging underneath the stratus layer), and stratocumulus vesperalis (generated by air cooling patterns that occur in the evening).

High stratus clouds are called altostratus. Altostratus clouds are also translucent for sunlight. They are formed from great patches of air that are elevated and condensed, due to the cold temperature at higher altitudes. Altostratus clouds are composed of ice crystals and, therefore, threaten to deposit layers of ice on airplanes passing through. Altostratus undulatus clouds are similar to altostratus clouds, but with undulations, or waves, and therefore are often called billow or wave clouds.

A type of cloud, called cirrostratus, combines features of cirrus and stratus clouds. They are a sheet of wispy clouds made of ice crystals and tend to form at a higher altitude than regular stratus clouds. Because of their ice-crystal composition and high altitude, cirrostratus clouds are translucent; that is, sunlight and moonlight can be seen through them. Due to the ice crystals and their light refractive properties, cirrostratus clouds often cause a halo effect around the moon or sun when viewed from below.

Clouds can be found in the atmospheric layer called the troposphere. The troposphere is the lowest atmospheric region and is where all weather takes place. At the equator, it reaches up to 11 mi. (18 km.) from the Earth's surface. The next atmospheric layer is the stratosphere, extending to 31 mi. (50 km.) from the Earth's surface. A cloud forms when water vapor reaches its dewpoint and, thus, condenses to form a water droplet. These droplets condense around cloud condensation nuclei (CCN), which are often particles of aerosol providing a scaffold around which the cloud can form. Each CCN is approximately one one-hundredth the size of the cloud droplet, which is itself approximately one one-hundredth the size of a rain droplet (usually about 2 mm. in diameter). The nature of the clouds allows them to reflect sunlight away from the earth, known as the albedo effect, but also to trap infrared light beneath them on the Earth's surface. This latter phenomenon adds to the greenhouse effect.

Coal

COAL IS ONE of a variety of energy sources that both developed and developing nations use. It is the fossil fuel that is relied upon most heavily for electricity generation in the United States. Organic matter from the Carboniferous period, which occurred approximately 360–286 million years ago, forms currently accessible coal deposits. There are several different types of coal, each with varying degrees of thermal value. In the process of electricity and heat generation, coal combustion releases many pollutants into the air, water, and land. These pollutants include mercury, sulfur oxides, nitrogen oxides, methane, and carbon oxides. The dispersal of such toxins into the environment has many ecological, human health, and economic effects. More specifically, coal combustion contributes to the climate-changing effect of increased atmospheric carbon. Because of this, alternatives to coal combustion are presently being researched and developed. Coal is presently a necessary and inexpensive way of producing electricity and heat; however, the use of this resource has significant consequences.

TYPES OF COAL

There are four main classifications of coal. Each type of coal is formed as a result of the exposure to assorted combinations of temperature and pressure during formation. For instance, coal that was exposed to low temperatures and pressures is usually moister, softer, and has lower energy content. The four coal classifications include lignite, subbituminous, bituminous, and anthracite.

The first type of coal, lignite, is soft with a high moisture content and low thermal value as compared with other types of coal. Lignite is usually light brown to brown-black in color and resembles deteriorating and compressed wood. In the United States, most lignite deposits are found in the western states; specifically, North Dakota is the state that produces the largest amount of lignite. This type of coal is relatively inexpensive and, thus, highly desirable, from an economic standpoint, to fuel electric power plants.

The next classification of coal is subbituminous. This type of coal is the intermediate between lignite and bituminous coal. It has a moisture content of between 20 and 30 percent. This is higher than bituminous coal and anthracite; however it is lower than lignite. Subbituminous is desirable from a pollution standpoint because it has a low relative sulfur and carbon content, but the thermal value of subbituminous coal is low. However, many power plants prefer to burn subbituminous coal, as it provides cleaner energy generation. Subbituminous coal is found primarily in Alaska, Montana, and Wyoming and is recognized by its unpolished black color.

POLLUTION CONTROLS

Bituminous coal is the third type of coal. Though it is harder than lignite or subbituminous coal, bituminous coal is often referred to as soft coal. This is due to the high sulfur content. Because bituminous coal has such a high amount of sulfur present, electricity generators that choose to burn this type of coal must equip their plants with sophisticated pollution-control systems. These mechanisms are called scrubbers because they scrub the pollution from the air by binding reactive toxins with inert, calcium-based substances located in the air stacks of power plants. The best available technology allows scrubbers to remove 98 percent of all sulfur emissions and 99 percent of all particulate matter from smoke stacks. Bituminous coal is dark black in color and may have dull-black bands striated throughout. This type of coal is typically found in Appalachian Mountain regions, the Great Lakes, the Mississippi Valley, and north and central Texas.

The final classification of coal is anthracitic coal. This is the hardest type of coal, thus, many people call it hard coal. This hardness is derived from the compact nature of the coal, which is a result of extremely high temperatures and pressure during coal formation. This coal is preferred because it has the highest thermal value and lowest sulfur content. This means that anthracite generates the most energy per unit of heat produced during combustion, and releases the smallest amount of sulfur pollutants per unit of heat emitted. Anthracite appears to be dark, shiny, and black. It has moisture content of 4 percent, and, in 2000, a ton of anthracite sold for about $40. This type of coal is found most frequently in Pennsylvania and other areas east of the Mississippi River.

Each of the four types if coal must be removed from the Earth's surface layer. Most coal is located in seams, ranging from .98 in. (2.5 cm.) to 98.4 ft. (30 m.) thick. These seams are relatively easy to locate, and, thus, most of the available supply in the United States is well-known. Therefore, industry and scientists can focus less time searching for new coal deposits and more time devising methods for remedying the effects of the associated pollution.

Coal is mined in two different ways: surface mining or subsurface mining. The kind of mining chosen depends on the surface conditions and the depth of the coal seam. Usually, mining companies pursue surface mining, also called strip mining, when the coal seam is located within 98.4 ft. (30 m.) of the surface. Through this process, the Earth's surface is scraped away and the coal is then removed using machinery. Approximately 60 percent of all the United States' coal supply is acquired through strip mining.

The most destructive type of surface mining is mountaintop removal. This occurs when dynamite is detonated and removes the surface material above the coal seam. Also, a dragline may be used to remove large portions of earth. This machine acts as a gigantic shovel. Debris from this removal process is then placed in nearby valleys and streams. Presently, 15 to 25 percent of all mountaintops in West Virginia have been subjected to this type of destruction.

Subsurface mining provides the United States with the other 40 percent of its coal supply. This method is used when the coal seam is located deep within the Earth's crust. Long networks of tunnels and shafts are dug underground along the coal seam. Miners then recover coal. This type of mining produces less landscape effects, however, compared to surface mining, the subsurface mining method is more expensive, less effective at removing all coal, and more dangerous to mine workers.

PRE-MINING CONDITIONS

The Surface Mining Control and Reclamation Act of 1977 (SMCRA) requires that the environment surrounding coalmines be restored to pre-mining conditions. Prior to the passage of this piece of legislation, mining companies left open pits, trenches, and large holes exposed. This created dangerous and unstable land conditions and often led to the collapse of such areas when disturbed by humans or wildlife. Also, sediment and contaminated soil and water were swept away by rain events, polluting nearby streams and rivers. SMCRA mandated regulations to prevent these types of activities. It also limited mining operations in national parks, national historic places, wildlife refuges, and wild and scenic rivers. Finally, SMCRA established a fund to restore mining areas that were abandoned prior to 1977.

EFFECTS OF COAL

While coal provides an affordable and easily accessible form of fuel for electricity generation, there are severe environmental, human health and economic effects of coal. The combustion of coal contributes more pollution than any other type of fossil fuel. Fifty percent of all U.S. electricity comes from coal combustion. Just one 500-megawatt coal-fired power plant produces about 3 million tons of carbon dioxide per year. Using this much coal for electricity generation causes environmental problems such as acid rain, land pollution, and global climate change. Coal has also been linked to increased incidence of respiratory ailments such as asthma, shortness of breath, and chest pains. Finally, remediating the damage done by coal combustion can cost thousands to millions of dollars.

The first major environmental problem associated with coal combustion is acid rain. This occurs when nitrogen oxides and sulfur oxides produced in burning coal are released into the atmosphere. These oxides then react with atmospheric moisture to produce dilute acids such as sulfuric acid, nitrous acid, and nitric acid. Dry particles can fall to Earth's surface as precipitation, as well. This is referred to as acid deposition or dry deposition. When these particles interact with clouds, the resulting rain events can have a lower pH than normal. The pH of normal rain is slightly acidic, usually between pH 5–6; however acid rain can have a pH as low as pH 2.

This can decrease the pH of water bodies, thus changing the aquatic chemistry, killing plants, fish, and other aquatic organisms. Because most freshwater lakes and ponds do not have high buffering capacities, small additions of acid have significant impacts. Acid rain can also cause the number of forest species to decline. This happens for a variety of reasons. First, acid rain can harm the leaves, bark, and seeds of trees, thus hindering both individual growth and community regeneration. Acid deposition can also affect root growth and impair nutrient uptake. Finally, years of prolonged exposure to acid rain can acidify the soil, thus leaching nutrients and releasing harmful minerals that may have been bound in the cation and anion exchange capacities.

Acid deposition and acid rain can fall upon buildings and monuments, reacting with building materials such as marble, concrete, and iron. In the United States, damages caused by acid deposition are estimated to be around $10 billion each year. Industrialized nations such as most of Europe, Russia, North America, and China are subject to the majority of effects of acid deposition and acid rain.

Land use and land-based pollution issues are the second problem created by the heavy use of coal for electricity production. The mountaintop removal method, for example, causes irreparable damage to the landscape. Once the topsoil and other soil horizons are removed, usually only the bedrock or other impermeable surfaces remain. In these areas, vegetation cannot grow, so erosion from water and wind usually carries away any remaining soil.

Also, abandoned mines can fill with water and then drain throughout the topography into nearby streams and valleys, creating acid mine drainage problems. This situation occurs when rainwater permeates the iron-sulfide-laden materials deep within subsurface mines and in mine waste. The water and iron sulfide react, creating sulfuric acid. Acid mine drainage can occur in most places where coal or metals have been mined. This is because carbon and metal compounds usually occur as sulfides. Acid mine drainage can quickly reduce the pH of an affected water body, devastating local fish, waterfowl, and plants in the watershed. Intense, or chronic, rain events can lead to highly-acidic conditions into a watershed.

GLOBAL CLIMATE CHANGE

The third major environmental, human, and economic problem associated with the use of coal as an energy source is global climate change. Evidence suggests that anthropogenic increases in atmospheric carbon are leading to increased mean global temperatures, and changes in regional climates.

Several gases, including methane, carbon dioxide, nitrous oxide, and ozone, known as greenhouse gases, absorb infrared radiation and lead to increased atmospheric temperatures. This, in turn, creates a negative feedback loop of increased ice melts at high latitudes and high elevations, and lower overall albedo. The Intergovernmental Panel on Climate Change (IPCC) has issued several reports suggesting that even if greenhouse gas emissions were reduced to zero, there is enough system-wide momentum that climate change impacts will be felt for years into the future. The IPCC reports also predict increased droughts in middle latitudes, as well as stronger storm events in coastal regions. If humans continue with "business as usual," mitigating the effects associated with global climate change is likely to cost billions of dollars.

MITIGATION OF COAL-BASED POLLUTION

Due to these significant environmental, human, and economic impacts, scientists are exploring potential solutions to coal-based pollution. Coal mining and electricity production are robust industries, which provide industrialized nations with inexpensive energy. Also, the supply of coal is large when compared with other fossil fuels.

However, industry and scientists are exploring several new technologies that will lessen the impacts associated with coal-fired power plants. These include alternative forms of energy, carbon capture and sequestration (CCS) methods, and Integrated Gasification Combined Cycle (IGCC) technology.

First, many nations are investing in renewable energy technologies. These include electricity generation by wind, solar, geothermal, biomass, and tidal and wave action. In recent years, renewable energy technology has become more affordable and widely utilized; however renewable technologies only account for a small portion of the world's total electricity supply. U.S. policies such as production tax credits for renewable technology, and state-mandated renewable portfolio standards, are lessening the need to use coal technologies and promoting the use of renewable ones.

Carbon capture and sequestration (CCS) methods hold promise for reducing the negative effects of coal combustion. Power plants and other large carbon dioxide emitters use this process. Carbon dioxide is captured in gaseous form, compressed, and then pumped miles underground for storage under impermeable substrate.

The carbon dioxide may react with calcium-rich substances forming calcium carbonate or other mineral carbonates. Presently, few power plants utilize this technology, because it is expensive and the long-term effects of underground carbon dioxide storage are not fully understood. Finally, IGCC is a process by which methane gas is produced from coal. Heating the solid coal produces the methane, referred to as syngas or synmethane. Then, the methane is burned to produce stream, which turns turbines and generates electricity.

The benefit of using this technology is that the syngas that it produces burns extremely cleanly. In particular, emissions of mercury and sulfur are reduced over 90 percent by utilizing this method. The disadvantage to IGCC is that the technology is not widely-used, and is still considered by many to be cost-prohibitive.

Coal is an abundant and inexpensive fossil fuel used for electricity generation in developed and developing nations. The four types of coal each have varying degrees of thermal value, moisture content, and pollution potential. Mining coal, either by surface or subsurface mining techniques, can create worker safety problems and environmental and landscape degradation. Also, the combustion of coal can lead to acid rain and acid deposition, irreversible landscape harm and acid mine-drainage, as well as increased global climate change effects. Because of this, new technologies are being developed to lessen these impacts and continue to make coal a viable energy source.

Colombia

COLOMBIA, LOCATED IN the northwest of South America, is a highly-diverse country in terms of environment and climate. Colombia is dominated by the Andes, where the tropical diurnal climate is characterized by small differences in monthly temperature (less than 3 degrees C), although daily fluctuations may be large (up to 20 degrees C), especially during dry seasons. Three Cordilleras of the northern Andes are described by approximately 22,966 ft. (7,000 m.) of altitudinal change; this altitudinal rise equates to a temperature change of nearly 30 degrees C, and results in a significant change in vegetation recorded over a relatively small area. For example, there are transitions from cool high-altitude grasslands, to temperate forests at mid-altitudes, and some of the most diverse tropical rainforests in the world within the Chocó Pacific region.

Away from the Andes, the extensive lowlands are also incredibly diverse, ranging from lowland rainforests in Amazonia, to extensive savannas of the Llanos Orientales. The diversity of lowland ecosystems is mirrored by the climate; precipitation is highest in the Chocó Pacific region, due to the proximity of the Pacific-based moisture source and the steeply-rising ground of the Western Cordillera. Within Andean Colombia, low rainfall is recorded within rain shadow areas of the inter-Andean plains.

Colombian paleoecological archives of vegetation change represent a remarkable record for Latin America and the wider tropics. The Colombian pollen data allows an understanding of regional environmental change and its impact on tropical vegetation composition and distribution that rivals the resolution commonly available from more temperate latitudes where Quaternary science research has a longer ancestry and wider research base.

For example, one record from the Funza sedimentary basin within the high plain of Bogotá (8,366 ft. or 2550 m.), situated on the eastern Cordillera of Colombia, is a 1,968 ft. (600 m.) sedimentary sequence that documents vegetation change over the past 3.5 million years, according to H. Hooghiemstra.

This exceptional record, possibly the best record of vegetation change in the world, has resulted as sediment infilling during the Quaternary was in balance with subsidence of the basin floor and Andean uplift, leading to a permanent lake environment. The record has shown that during interglacial periods, the upper forest limit of the northern Andes was located maximally between 11,155–11,483 ft. (3,400–3,500 m.). During glacial periods, the forest limits have been placed at approximately 6,562 ft. (2,000 m.), with the area surrounding the core site being characterized by an increase in grass-dominated communities.

The extensive paleoecological data from Colombia that cover all major ecosystem types and climatic zones have been used in several synthesis studies. The reconstructions successfully describe the composition and distribution of vegetation, and in particular, altitudinal shifts in vegetation associated with the northern Andean Cordilleras and transitions from Amazonian lowland rainforest to savanna, according to Rob Marchant, et al. Under climatic conditions of the last glacial period, montane vegetation types extended to low altitudes where there was a concentration of moist vegetation type and concomitant expansion of the savanna areas.

As climate ameliorated, the reverse situation occurred. For example, in the mid-Holocene, the vegetation is characteristic of warmer environmental conditions than those of the present day. This trend continues until between 4,000 and 3,000 years before the present era, when there is a shift to more mesic vegetation that is thought to reflect an increase in precipitation levels, according to Marchant and Hooghiemstra. The influence attributed to human-induced impact on the vegetation is recorded from 5,000 years before the present era, but is particularly important from 2,000 years before the present era. The extent of this impact increases over the late Holocene period, recorded at increasingly higher altitudes. Despite these changes, many sites do not change their vegetation, such as those with asynchronous vegetation response results from site location, non-linear response of vegetation to Late-Holocene environmental change, regionally differential signals, and localized human impacts.

Colorado

HOME TO SIX national parks and recreation areas, more than 1,000 soaring Rocky Mountain peaks, and nearly 30 ski resorts, Colorado is a prime tourist destination. It is also a rapidly growing state. Its population expanded by 34 percent 1990–2000, and, in 2006, the U.S. Census Bureau identified it as the eighth fastest-growing state in the United States. The combination of rapid growth and a S2.4 billion tourist industry already place heavy pressure upon the state's resources. Between 1807 and 1907, Colorado's precipitation decreased as much as 20 percent in many parts of the state, and recent droughts have left Colorado facing half-full reservoirs. Predictions that global warming could bring hotter, drier summers that will affect all areas of the state's economy have prompted the state to take decisive action to lower greenhouse gas emissions and focus on sustainability.

Colorado's climate change plan, *Climate Change and Colorado—A Technical Assessment*, has been in effect since 1998. The state's carbon efficiency rate improved by 29 percent 1990–2001, the seventh best record in the nation. This improvement was accomplished with an economy growing by 91 percent. Although Colorado did not have the problems with air quality that more heavily-industrialized states did, carbon dioxide emissions were growing at a rate even faster than the population, a 39 percent increase 1990–2004. The state ranked 23rd in its emissions, but its increase rate was the fifth largest in the nation, more than double the national increase of 18 percent. Fossil fuel combustion created 78 percent of the state's greenhouse gas emissions in 1990.

By 2004, the state's snow pack had been below average for 14 of the last 18 years, and melting was occurring earlier in the spring. For a state that depended upon snowmelt for 70–90 percent of its water, the changes were alarming. A 2004 study, using a conservative climate model, concluded that in just one generation, the Colorado River basin could have 3 percent less precipitation, 24 percent less snow pack, 14 percent less runoff, and 36 percent less water storage. Such a scenario would mean increased droughts, more wildfires, and a range of changes in the ecosystem.

Such losses could ravage ski resorts, and yields of the state's two major crops, corn and wheat, could decline from 8–33 percent due to decreases in soil moisture and water available for irrigation. Habitats throughout the state would be threatened. Species from the endangered greenback cutthroat trout in Colorado's cold waters, to the migrating whooping cranes in the marshes of the Platte River basin, to the alpine-dwelling American pika, already extirpated in some locations that have grown too warm, would be at risk. Such loss of habitat and wildlife would lead

Colorado wind power has the potential to generate over 450 billion kilowatt-hours a year, enough to power the state.

to job losses and damage to the state's economy. The Intergovernmental Panel on Climate Change Report on Emissions offered two scenarios: unchanged emissions and more than a 50 percent snow pack reduction in most areas; or reduced emissions and 50 percent reduction in some areas.

Leaders in the public and private sector have begun working to find solutions. In November 2004, Colorado became the first U.S. state to create a renewable portfolio standard (RPS) by ballot initiative. With this act, utilities serving 40,000 or more customers were required to generate or purchase 10 percent of their retail electric sales from renewable-energy resources. In the summer of 2006, the Colorado Climate Project was launched. The mission statement of the Climate Action Panel is modeled after similar statements in other states; its purpose is to make recommendations that will render the state less vulnerable to climate changes without undue damage to the economy. But, the Colorado plan is unique in that the impetus came not from government action, but from the collaboration of elected officials, business leaders, and environmental activists on a private initiative.

In March 2007, Governor Bill Ritter signed into law a bill that increased Colorado's 2004 RPS. Under the new standard, large investor-owned utilities are required to produce 20 percent of their energy from renewable resources by 2020, 4 percent of which must come from solar-electric technologies. The law also requires municipal utilities and rural electric providers to provide 10 percent of their electricity from renewable sources by 2020. Although the act allows considerable choice concerning the source of the renewable energy, including solar, wind, geothermal, biomass, and small hydroelectric, wind power is likely the most popular choice. Colorado ranks 11th in the nation in its wind energy resources, and although some wind farms have developed, their numbers are few. Experts estimate that Colorado wind power has the potential to generate over 450 billion kilowatt-hours annually, more than enough to meet the state's needs.

Colorado cities have taken action, too. Aspen already generates enough energy from wind and hydropower to meet 75 percent of its electricity needs, and has set a goal of 100 percent within five years. In an effort to decrease carbon dioxide emissions, the city of Aspen provides free transit for residents and tourists and has purchased electric hybrid automobiles for city officials' use when traveling out of the city. Denver has initiated its own climate action plan to reduce carbon dioxide emissions by 4.4 million metric tons by 2020, the equivalent of eliminating two small coal-fired power plants or taking 500,000 cars off the road. The city of Boulder recently enacted the nation's first tax on carbon emissions from electricity.

Colorado Climate Center

THE COLORADO CLIMATE Center (CCC) is part of the Department of Atmospheric Science in the College of Engineering at Colorado State University. The aim of the center is to assist the state of Colorado in monitoring climate change over time, ranging from weeks to years. The CCC provides climate-related services to business, government, industry, researchers, educators, and the general public. The center tries to understand the complex interactions between the atmosphere, oceans, continental glaciers, land, and vegetation processes. The CCC has stressed the importance of observation and data collection for climate monitoring, research, and service. It is involved in snow measurement research in collaboration with the National Weather Service.

The services provided by the center aim to reduce the state's vulnerability to climate variability and change. The CCC provides links to regional climate centers, and to the National Climate Data Center, where detailed climate information is provided. It also provides access to other important databases. The CCC website is the primary means with which information is supplied; it also center publishes its own magazine, *Colorado Climate*.

The CCC is recognized by the American Association of State Climatologists, and was established in 1974 by the state-funded Colorado State University Agricultural Experiment Station. Its primary aim was to provide information and expertise on Colorado's complex climate.

The CCC has a threefold program of Climate Monitoring (data acquisition, analysis, and archiving), Climate Research, and Climate Services that focus on climate-related questions and problems affecting the state of Colorado. The CCC is also home to State Climatologist Nolan J. Doesken. He has been with the center since 1977, and is also director of the historic Fort Collins Weather Station on the campus of Colorado State University.

The CCC is responsible for monitoring of daily weather conditions and the interpretations of seasonal and annual weather patterns and variations. The National Weather Service's Cooperative (COOP) Network has over 200 stations in the state, and reports daily on temperature and precipitations. These data provide the oldest continuous records to describe climate change, dating back to the 1880s.

The CCC also monitors weather through data from other organizations, such as the Natural Resource Conservation Service's snow survey, and Remote Snow Telemetry (SNOTEL) stations. SNOTEL is particularly useful to study drought and monitor water supply. The CCC also provides assistance to Colorado State University and to federal groups to maintain an automated network for weather observations to serve agriculture users. The Colorado Agricultural Meteorological Network provides hourly weather data from 60 stations throughout the state that represent different agricultural areas.

The CCC has also been involved in climate research since its foundation. Thomas McKee pioneered drought research and devised the Standardized Precipitation System, an index to monitor drought that has been adopted internationally. The CCC also closely collaborates with the National Weather Service to develop more accurate ways to observe weather from stations. The CCC is leading a national survey of automated snow measurement systems, and is involved in research on energy, crop production, and engineering applications of climate information.

In April 2007, the National Oceanic and Atmospheric Administration named Doesken one of 10 environmental heroes for the creation of an amateur precipitation-monitoring network that gathers 4,000 volunteers nationally. This network is part of the CCC's commitment to involve citizens in climate monitoring. Through the Community Collaborative Rain, Hail, and Snow network (CoCoRaHS), thousands of citizens of all ages take part in measuring and mapping precipitation patterns in Colorado and several other states.

Colorado State University

COLORADO STATE UNIVERSITY is a premier system of public higher education committed to excellence, setting the standard in teaching, research, and service. The board of governors presides over Colorado State University (CSU), which is composed of Colorado State University (located in Fort Collins, Colorado) and CSU-Pueblo. At Colorado State, research and outreach from the sciences to the humanities are advancing on multiple fronts to explore climate-change phenomena and find solutions.

The Center for Earth-Atmosphere Studies fosters the training and education of scientists working on climate and radiation-cloud problems. Graeme Stephens has been the principal investigator of the National Aeronautics and Space Administration's (NASA's) CloudSat mission since 1993. His research focuses on atmospheric radiation and on the application of remote sensing in climate research, with particular emphasis on understanding the role of hydrological processes in climate change. The department offers a wide range of courses for students interested in climate research. Courses include large-scale atmospheric dynamics, analysis and diagnosis of observed climate variability, climate modeling, the global carbon cycle, the global hydrologic cycle, and radiative transfer.

The Colorado Climate Center is part of the Department of Atmospheric Science at CSU. The goal is to assist the state of Colorado in monitoring climate over time scales of weeks to years, as well as recognize that climate involves complex interactions between the atmosphere, the oceans, continental glaciers, and the land. Vegetation processes are an important component of the climate system. This service should contribute to a reduction in the state's vulnerability to climate variability and change. One of the latest efforts to address climate change began with the creation of a sustainability advisory committee. Vice President for Research Bill Farland and Vice Provost Lou Swanson, who leads Outreach and Strategic Partnerships programs at CSU, were appointed co-chair of the committee.

Fernando Herrera
University of California, San Diego

Columbia University

ONE OF THE biggest developments of 1996, from the perspective of those who were interested in global warming and climate change, was the formation of the new Columbia University Earth Institute, designed to bring together 11 separate centers for research, education, and innovation. The move happened at a crucial time; 1995 and 1996 were among the warmest years yet recorded.

Columbia University, founded in the 1750s as Kings College, which boasted luminaries such as Alexander Hamilton among its early students, had long been in the forefront of the study of the Earth and its changes. Columbia had the nation's first full-time department of geology in the 19th century, and, as the school grew, so did the size of its Earth-oriented faculty.

THE LAMONT-DOHERTY EARTH OBSERVATORY

Columbia was already one of the leaders in the field when, in 1949, the widow of New York banker Thomas W. Lamont (1870–1948) announced she would give his estate, located on the banks of the Hudson River in Palisades, New York, to Columbia. Dwight D. Eisenhower, who was then president of Columbia, accepted the gift, and the Lamont Earth Observatory was founded in 1950. The *Columbia Geologist*, a school publication, heralded the event and proudly proclaimed on its masthead one of the guiding motifs of the Columbia geology program, "Speak to the Earth and it will teach Thee."

The observatory's first director was Professor Maurice "Doc" Ewing (1906–74). Born and raised in Texas, and the veteran of a number of summer building projects, he was the antithesis of the absent-minded professor. Keenly interested in the details of administration, he was also a hands-on leader, taking a three-masted schooner purchased by Columbia on a number of fact-finding missions. Ewing's principal contribution to science was his part in finding answers about plate tectonics, a theory that was accepted only in the latter part of his time at Lamont, but he also played a role in training hundreds of young scientists, many of whom went on to become department chairs around the country. By 1972, the year Ewing retired, Columbia was the leader in almost every aspect of studies of the Earth; he died in 1974.

In 1969, three years before Ewing's retirement, the Lamont Observatory was renamed the Lamont-Doherty Earth Observatory, in honor of a major bequest made by Thomas Doherty. This change, and Ewing's retirement, brought about a change at Lamont-Doherty, which soon found itself in the forefront of concern about the environment. The U.S. space program accelerated concerns about the environment (with the Apollo VIII photographs of the earth from space, for example). There was a growing connection between the National Aeronautics and Space Administration's (NASA's) Goddard research center and the Lamont-Doherty Observatory, both located at Columbia.

HOT SUMMERS AND THE EARTH INSTITUTE

At first, environmental concern was about global cooling. The 1960s were, climatologists now believe, the coldest decade of the 20th century, and several winters toward the end of the 1970s and beginning of the 1980s seemed to accelerate the trend. Numerous major magazines, such as *Time* and *Newsweek*, ran cover stories proclaiming the possibility of a new ice age, and the sudden rise in the price of home heating oil—starting with the Arab Oil Embargo of 1973–74—only increased worries about the Earth growing colder. Staff at the Lamont-Doherty Observatory were asked to comment on global cooling a number of times, but none of their pronouncements on the subject came anywhere close to the importance given to the first major statement about global warming, which came in the summer of 1988.

Although 1987 had a relatively cool summer, with plenty of dampness, 1988 started hot and stayed that way. A heat wave of unprecedented scale hit the East Coast and Midwest in late June, with temperatures soaring well above 100 degrees F (38 degrees C) in urban areas. New York and Washington, D.C., almost shut down for a few days at the peak of the heat wave, in late July. The trend did not reverse itself until about August 18, when a front of cool air moved in from Canada. This was the normal course of events in the American northeast, but it had taken about three weeks longer than normal to transpire. Near the height of this heatwave, Dr. James Hansen of the Goddard Center testified before U.S. Senators:

> If our climate model calculations are approximately correct, the greenhouse warming in the 1990s will be sufficient to shift the probabilities such that the chance of a hot summer in most of the country will be in the range of 55 to 80 percent…I believe it is obvious that the man in the street will notice by then that the dice are loaded. There will be more hot summers than now, and the hottest ones will be hotter than they used to be.

Had Hansen made this prediction in the summer of 1987, few people would have given it much notice; but as he did it in the heat of 1988, millions of people paid attention. Suddenly, Hansen and Columbia were at the forefront of the debate about global warming.

The summer of 1990 was even hotter than 1988, and 1991 surpassed 1990. The hottest summer to date was 1995, and one year later Columbia announced the creation of its new Earth Institute, intended to bring together the activities of 11 institutions: the Lamont-Doherty Earth Observatory; the Center for Environmental Research and Conservation; the Biosphere 2 Center; the Goddard Institute for Space Studies; the International Research Institute; the Laboratory of Populations; the Earth Policy Center; Columbia's School of Public Health; the Earth Engineering Center; the Center for Environment, Business, and Renewable Resources; and the Program on Information and Resources. All 11 institutions would retain their individual identities, but all 11 also became part of the new Earth Institute. Columbia did its best to hire top scientists away from other research universities and bring them to the New York campus.

CONTEMPORARY SCHOLARSHIP

For a few years, it seemed as if the new Earth Institute would be just another highly-endowed think tank for liberal environmentalists, with much of the nation paying little attention to its pronouncements. However, Columbia showed it was committed to hiring scholars from across the disciplines, and not all of them proved to be liberal or traditional environmentalist groups. There were sharp disagreements among Columbia scientists, about the extent of global warming, or if global cooling still remained an even greater threat. By 2000, the mainstream U.S. media paid more attention to Columbia's scientists than to those of almost any other major educational institution.

In 2002, Columbia hired Jeffrey Sachs away from Harvard, where he had been a professor of international trade for the previous 18 years. Born in Detroit in 1954, Sachs was a most unusual academic, one who spent as much time actually advancing change as discussing it. Sachs was a brilliant and controversial leader, one who had worked with numerous Third World nations in attempts to rebalance or pay off their debts to First World countries. Tireless and devoted, Sachs still ran into plenty of headaches as director of Earth Institute, an inevitable situation given the bright and challenging minds assembled there.

By 2006, the year Al Gore's *An Inconvenient Truth* was released in cinemas, most Americans had become conversant with the terms *global warming* and *climate change*, yet there was still plenty of controversy swirling around them. Columbia had over 200 top scientists watching the climate in that year, and they put out varying statistics about the state of the Earth. More importantly, they presented various alternatives to approach the problems. For example, Dr. James Hansen, while believing global warming was quite serious, believed that humans could make major progress against it over the course of one or two decades; and Dr. Walter Broeckner, a geochemist who believed that the state of the earth was a state of emergency, claimed that truly drastic cutbacks in greenhouse gases were essential.

A major source of controversy was the Kyoto Climate Accords, signed by most industrialized nations in 1997. The United States, under the George W. Bush administration, declined to participate in Kyoto, leading to outrage on the part of many environmentalists. But Hurricane Katrina, in the early autumn of 2005, provoked the greatest concern of all. Not only did New Orleans and the surrounding area endure a Category 3 hurricane, but the efforts of FEMA (Federal Emergency Management Administration) seemed either feeble or counterproductive. Americans looked to their scientists, who seemed quite certain that global warming was a reality, but who differed over how it could best be combated. Columbia's Earth Institute is one of the most prestigious and successful of all such institutions, yet it, too, lacks a clear directive on how the nation, and the world, should proceed.

Comoros

AN ARCHIPELAGO OF four islands in the Indian Ocean, the Comoros Islands have a land area of 838 sq. mi. (2,235 sq. km.), with a population of 798,000 (2005 est.), and a population density of 710 people per sq. mi. (275 people per sq. km.), the highest population density of any African country. The Federal Islamic Republic of the Comoros, formerly a French colony, has 3.5 percent arable land, with an additional 7 percent used for meadows and pasture. Some 16 percent of the land area is forested, with a timber industry operating on the island of Njazidja.

The country is relatively poor and undeveloped, and even though it has a burgeoning tourism industry, it has a very low carbon dioxide emissions, with less than 0.1 metric tons per capita in 1990, rising to 0.12 metric tons per person in 2003. Some 89.4 percent of its electricity production is from fossil fuels, with the remainder from hydropower. All the country's carbon dioxide emissions are from liquid fuels, with much of this coming from automobiles and buses, and domestic electricity consumption. There is a small public transportation system in the islands.

Located in the Indian Ocean, global warming and climate change pose a severe risk of flooding for the islands, which are subjected to annual monsoons. Scientists envisage a loss of marine wildlife around the Comoros in the future, owing to the rising average temperature of the Indian Ocean. Scientists also foresee a shortage of drinking water.

The Comoros government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention two years later. The government of President Azali Assoumani has not expressed an opinion on the Kyoto Protocol to the UN Framework Convention on Climate Change.

Compliance

COMPLIANCE, ACCORDING TO the *American Heritage Dictionary,* is: "the act of complying with a wish, request, or demand; or acquiescence." In medicine, it is the willingness to follow a prescribed course of treatment. Generally, it is a disposition or tendency to yield to the will of others. In a machine, compliance is the extension or displacement of a loaded structure per unit load, or flexibility. In reference to the climate system as defined by the United Nations Framework Convention on Climate Change (UNFCCC), all the above meanings of compliance are relevant. The climate system is the totality of the atmosphere, hydrosphere, biosphere, and geosphere, and their interactions. Consequently, changes in the climate may have implications for the full range of human life.

In the context of law, compliance is sometimes referred to as conformity, where compliance is the intended outcome of law. Being out of compliance usually carries legal consequences that are provided for by the applicable rules. For example, the UNFCCC and the related Kyoto Protocol provide rules that are referred to in identifying compliance. Compliance is facilitated, promoted, and enforced by the appropriate authority that is specified and authorized to do so in the regulatory regime. In the case of international law, applicability of the regulatory regime is complicated and determined initially by voluntary commitment of a sovereign state. Only parties to the Kyoto Protocol would then be bound by the terms of its agreement and the compliance mechanism.

THE KYOTO PROTOCOL

In the Kyoto Protocol, as with many regulatory regimes, the compliance mechanism has multiple functions. It is intended to reinforce provisions in the protocol that are designed to address environmental integrity. It also enables the operation of the market for carbon, including the emissions-trading system envisioned by the protocol. A third function is to address and improve the transparency of accounting procedures used by the parties. The implementation of the legal regime relies on strong and effective compliance systems, processes, and enforcement.

To achieve compliance, the Kyoto legal regime uses a two-pronged approach in its organization. These components are the branch that facilitates compliance, and the branch that metes out consequences for those who remain out of compliance. The first is known as the facilitative branch, and the second as the enforcement branch. The decision to adopt a compliance regime to facilitate, promote, and enforce the protocol's commitments was made in October/November 2001 at COP 7 (Conference of the Parties 7), also known as the Marrakesh Accords. The text of the procedures and mechanisms related to the compliance was adopted by decision 24/CP.7 at the same COP 7 meeting.

Not all compliance mechanisms include a facilitative branch. Compliance mechanisms that do not include an enforcement component may rely on other methods to achieve compliance. These include a party's interest in membership in a group, altruistic interests, or social or peer pressure. Participation in the Kyoto Protocol is first an example of an interest in compliance with the practices in the international community, and not the result of the actions of a facilitative or an enforcement branch.

Whether facilitative or enforcement or otherwise structured, where compliance is through organized mechanisms, it requires procedural rules. Such rules may be provided in regulations included with the enabling legislation or agreements. As required by Article 18 of the Kyoto Protocol, the procedures and mechanisms to determine and address cases of non-compliance were adopted by the COP at their first meeting. The rules of procedure for the Compliance Committee were submitted and approved by the COP at their second meeting in November 2006. At the international and the national levels, critical issues in compliance mechanisms include the identification of specific consequences of noncompliance, as well as the membership of applicable decision-making bodies.

As with regulation, legal compliance within the jurisdiction of sovereign states is a domestic matter. Within a domestic sovereign state, compliance is relative to the particular regulatory regime. Compliance with planning regulations could refer to whether the regulations themselves comply with planning rules, and whether particular parties are in compliance with the planning regulations. In a more fundamental regulatory context such as constitutional law, the discussion would need to consider if the constitution is in compliance with the intentions of the population. At that point, compliance between the legal and political realms is significant and determinative in the formulation of policy, and will be accorded some interpretive consideration in judicial processes.

SPECIFIC CONSEQUENCES

Judicial processes and bodies must themselves be in compliance with their enabling legislation and rules. Rules of procedure applicable to the judiciary are as significant as the specific consequences for noncompliance by a party. In some jurisdictions, the right to be heard and the right to a fair hearing in judicial processes are enshrined in the constitution. Compliance, in such cases, requires procedural and substantive compliance.

Frequently, compliance involves acquiescence in particular circumstances. Where a party is within the rules, acquiescence would preserve compliance. Similarly, if one were not within the rules, the same disposition would mean noncompliance. In this sense, acquiescence as inertia may mean either compliance, or its lack.

Intent may or may not be relevant to a consideration of compliance. Statutory rules can provide for a determination of compliance regardless of intent, or may require intent. For example, intent in operating a vehicle at speeds higher than permitted by law is usually irrelevant to a determination of compliance to the legal speed limit. On the other hand, intent to cause injury will typically escalate the gravity of an offense and will be relevant to compliance with a principle of not causing injury.

HEALTH

Adaptation and responsiveness to changing climatic conditions is relevant to all species living on the planet. In a changing climate, all species face the fundamental issue of survival. For species that can survive, there is an issue about maintaining health. Compliance in this context involves two dimensions: that of compliance with the rules of nature, or the context in which the species must live to gain and maintain health; and compliance with regimes that the individuals and species must maintain in restoring health from illness. The renewed recognition of the forces of nature and its rules as the context in which the health of a species relies, is partially relevant to the interest in climate change and its regulation. Determination of the rules of nature leads to the necessity of compliance with such rules for survival of a species.

Theoretically, there is an option to modify the rules of nature by human intervention. This approach has been considered and attempted in experiments to modify weather. Such meteorological experiments were used, for example, in seeking to precipitate rain by seeding clouds with silver iodide crystals, and in proposals to install orbital systems to strategically modify weather patterns for security reasons. Whether climate change is the result of intentional or unintentional anthropogenic actions, compliance with the rules of nature as they exist does not appear to be optional for the survival of the species.

Because species are interconnected as a web, survival or extinction of any species results in changing circumstances for all species with attendant consequences. In this approach, human compliance with the rules of nature is determinative of the health of all species, not just of humans, and is so, regardless of whether or not anthropogenic emissions are responsible for climate change. Should such emissions and human decision-making be a relevant contributory factor in climate change, anthropological compliance, or noncompliance would be more significant. The health of a species is contingent on compliance with the rules of nature.

With the interconnectedness of species, compliance with the rules of nature by each species may mean a radical change in the continuity of species or, possibly, be a matter of survival for all. With human health, compliance may involve a proactive approach to healthy living that is advocated by some alternative health regimes or a pathological approach such as in conventional allopathic medicine. This distinction approximates the twin approach of the Kyoto compliance mechanism with its facilitative and enforcement branches. Both approaches can include preventive and remedial features in achieving compliance.

MACHINES AND TECHNOLOGY

For climate systems at the local level, technological compliance with regulations has long been recognized as the consequence of human decision-making. Machines can be designed with more or less flexibility, which can also be described as having more or less compliance. As with judicial systems, technological processes and management systems are inseparable from machines and technology in determining compliance, and are also susceptible to compliance issues.

Compliance of a machine is the extension or displacement of a loaded structure per unit load. Originally conceived in mechanical terms, the concept of a load now includes energy loads, and in the emergent context of the internet, virtual loads. Regardless of the form of the load, extension or displacement occurs and constitutes compliance. If the climate system is understood as a closed system and a machine or a technological entity, and compliance is the extension or displacement of the atmosphere per unit load, the application of the principle of cause and effect leads from compliance to inescapable consequences. The cause of the compliance is of interest in relation to human decision-making if the intent is to vary the result. Because acquiescence can be compliance, acquiescence can also occur in the context of climate change.

Multiple meanings of compliance indicate a plurality and hence a possible conflict in contemporaneous compliance. For instance, the capacity of a human being or other species to remain in compliance within the laws of nature in a changing climate may be divergent from compliance with human laws. Such competing compliances would necessitate decision-making with consequences for the climate system and survival of the species. Specifically, if global warming occurs, and human beings comply with such climate changes by acquiescence, then the increase in the global mean temperature will lead to a point at which the survival of the species will be an issue.

Compliance in the context of climate change is not a singularity, but a plurality of compliances that may be contemporaneous and intersect, compete, or diverge at various points. Human decision-making and anthropogenic causes will have consequences in determining which compliance is to continue and which is to die. The complexity of compliance may be understood by its correspondence to the complexity of atmospheric modeling and contributory systems. Anthropogenic compliance is also complex, involving the various dimensions of human life, which will contribute directly or indirectly to changes in the climate system.

Computer Models

A CLIMATE MODEL is a computer-based representation of the Earth system. Climate models solve mathematical equations that describe the planetary energy budget, with the aim of understanding and reproducing the processes that control climate. Climate models differ widely in their complexities; some consider only the balance of energy entering and leaving the Earth, whereas others attempt to describe the entire climate system, including the complex interactions between different components of the planet (such as the ocean and the atmosphere).

The first climate models were developed to study fundamental processes in the Earth system. These models attempted to capture the broad features of the climate and tried to reproduce the current climate state. Since this time, the issue of human-induced (anthropogenic) climate change has changed the focus of climate modeling; now many models are designed to investigate the effect of changing human emissions on climate and the prediction of future climates. Climate prediction is done with Earth System Models (ESM). These models are very complex and require large computer resources to run. Even so, many important processes must be simplified before they can be represented in a climate model.

Climate prediction models attempt to forecast the climate many years in the future. They do not aim to predict particular small-scale events (in comparison to weather forecasting, which attempts to predict, for example, the occurrence of a storm on a particular day). Instead, climate prediction takes a statistical approach in which the general properties of the climate are predicted; often the mean and the variance of the climate variable are predicted (such as the average temperature in July).

Climate models consider a number of different climate variables; some of which can be modeled with a relatively high degree of confidence (such as temperature), while others remain much more uncertain (such as precipitation). Climate models must capture different types of variability in the Earth system; natural and human-induced changes must be captured, along with variability that occurs on a range of timescales (from a few days to many years).

HIERARCHY OF MODELS

There is a range (or hierarchy) of climate models with very different levels of complexity and, correspondingly, different strengths and weaknesses. This hierarchy allows scientists to use computer resources efficiently and run models with the complexity needed for the experiment of interest.

The simplest are the Energy Balance Models (EBMs), which model the climate in terms of the global energy budget. EBMs are normally zero-dimensional or one-dimensional models that ignore many features of the Earth system (such as atmosphere/ocean dynamics). These models simply consider the energy entering and leaving the planet. This simple approach is sufficient for the reasonable simulation of many large-scale climate features, like the seasonal cycle in temperature. The simplicity of EBMs gives them a number of advantages; they are very fast, which means many experiments can be run and long time periods can be considered. In addition, they neglect many of the features that can complicate analysis, thus they allow the study of the more fundamental factors affecting climate.

EARTH SYSTEM MODELS

At the other end of the hierarchy, Earth System Models are the most complex climate models; they take a holistic approach and attempt to treat all the components of the climate system and the interactions among them. ESMs are based on a type of model called a General Circulation Model (GCM). GCMs represent the movement and properties of air and water throughout the globe and, thus, form the core of ESMs. ESMs are more complex than GCMs as they also treat other components of the Earth system, such as the cryosphere (regions of ice and snow) and the biosphere (vegetation).

For a full climate simulation, ESMs must account for the interactions among the different components of the Earth system. For example, ocean circulation is driven partly by wind stress on the ocean surface. Changes in wind patterns (such as, those due to climate change) may, therefore, alter ocean dynamics. In turn, changes in ocean dynamics can alter atmospheric dynamics and wind speeds. Thus, wind speed and ocean dynamics are somewhat affected by each other. To represent this two-way interaction between the atmosphere and the ocean, the two components must be coupled in the model. Coupling those in models is challenging as the atmosphere and ocean react on very different timescales; ocean processes are typically much slower and take longer to reach equilibrium.

There is a growing body of work to couple other climate components in ESMs; many models now contain coupled vegetation models so the modeled atmospheric conditions (such as temperature and rainfall) are used to predict the growth of vegetation. If the model is fully coupled, then these changes in vegetation will be taken into account in the simulation of atmospheric conditions. For example, vegetation can take up carbon dioxide, thus, changes in vegetative cover may affect the amount of carbon dioxide in the atmosphere, which affects temperature. Including these carbon feedbacks in models is important for predicting future climates.

This coupling of components in an ESM is important because many of the interactions in the climate system can act together to produce greater (or smaller) net effects. For example, warming in the Arctic could melt some of the highly-reflective snow and ice, exposing dark land beneath. As the newly-exposed dark land is able to absorb more solar radiation than the bright white snow, the region will be able to absorb more of the available solar radiation. Thus the change in surface reflectance (albedo) produced by the melting snow could contribute to further warming, potentially leading to further snowmelt and even more warming.

To capture this positive feedback in a climate model, the atmosphere model must be coupled to an interactive snow/ice scheme. Failure to include this coupling could underestimate the rate of future warming. There are many potential feedbacks in the climate system and work is still ongoing to represent many of them in ESMs. Some positive feedbacks have the potential to cause rapid temperature changes (such as the melting of the Greenland Ice Sheet), ESMs are well-placed to investigate these feedbacks.

For experimental purposes, researchers can run simplified ESMs (or GCMs) with differing complexities, depending on the nature of the experiment. For example, atmosphere-only GCMs can be run in which the main ocean characteristics are prescribed (not simulated). This is useful, as running the ocean component of a model is very computationally expensive. Another possibility would be to run a GCM with a slab ocean in which only the top 164 ft. (50 m.) of the ocean is represented (with the main properties of the deep ocean treated in a simplified manner). Again, this is much faster than running a full ocean model. This spectrum of ESM and GCM complexities allows scientists to target the model used to the experiment chosen, for example, complex ocean models have been run with simple atmospheric models to study trends in ocean circulation, work that could have been done with a coupled atmosphere/ocean GCM, but with a much larger computational overhead.

Earth System Models of Intermediate Complexity (EMIC) also have been used for climate simulations. These models bridge the gap between simple models and full ESMs. They are similar to ESMs, in that they treat the full Earth system, but they use a much simpler representation of physical processes and lower resolution, making them much more computationally efficient. These intermediate complexity models can be used to simulate the long time periods (tens of thousands of years) important for studying natural climate variability and paleoclimate (the pre-historic climate). Results from EMICs can only provide information on large scales; their output is too uncertain for it to be applied to regional studies. Regional climate models, which represent particular geographical areas in higher resolution, have recently been developed and used for climate studies. These are useful for investigating geographical regions with extreme topography (as in mountainous regions), which are not well-represented in lower resolution models.

MODEL GRIDS

GCM (and ESM) models divide the planet into a three-dimensional lattice of grid points. In the atmosphere, global climate models typically have a horizontal resolution of 124–186 mi. (200–300 km). and a vertical resolution from a few hundred yards (m.) to 0.6–1.2 mi. (1–2 km.). The vertical resolution of the models is generally finer at the surface (where it is needed to resolve important small-scale processes) and becomes coarser at higher altitudes. At the surface, the model levels are normally terrain-following (the levels run parallel to the surface topography), but at higher model levels the effect of the surface topography is less, and the model levels become flat. The ocean component of an ESM/GCM typically has a finer resolution than the atmosphere component because small-scale structures such as eddies are important for heat transport in the ocean. The ocean resolution is typically about 410–820 ft. (125–250 m.) in the horizontal and 656–1,312 ft. (200–400 m.) in the vertical.

In the horizontal direction, the grid points typically run parallel to the lines of latitude and longitude, creating rectangular grid boxes that are grouped more closely together at the poles than at the equator. This is a waste of computational effort at the poles where there are lots of small grid boxes. In addition, this bunching of grid points at the poles can lead to computational instabilities. To avoid this problem, some researchers are developing models that run on non-rectangular grids such as Geodesic grids made up of hexagons and pentagons rather than rectangles, but this is still in the relatively early stages of development. In addition, tri-polar ocean grids have been developed; these grids have three regions where the grid points bunch together, each of which is located over land (so there is no need to treat the ocean in these areas). This removes the problem of numerical instabilities in the ocean model.

MODEL FORMULATION

GCMs solve equations of motion to simulate the movement and properties of fluid (air and water) around the globe. The physics used to represent these processes can be divided into three categories. First, some of the physics can be calculated from first principles; well-known concepts such as the conservation of energy can be utilized. The second category includes physics that is well-known in theory, but that in practice must be approximated. For example, fluid flow is treated using the Navier-Stokes equations, which cannot be solved analytically. Finally, the third category contains empirically-known physics (derived from observations), such as formulas for evaporation as a function of humidity and wind speed.

Some important climate processes occur on scales smaller than a model grid box. These processes cannot be explicitly resolved in a climate model. One example is the process of cloud formation. Individual clouds are often smaller than the model grid boxes in which they form, so a climate model cannot distinguish between the cloudy and non-cloudy regions within a grid box. Instead, an average value representing the fraction of cloud in the grid box is predicted. This representation of small-scale processes to produce average grid box values is called parameterization. Developing parameterizations is a complex process; the goal is to identify the key effects of the sub-grid process and represent them in a simple manner. If a process is parameterized, it is not explicitly treated; instead, the impact of the process on the large-scale processes is estimated.

Sub-grid parameterization is not the only form of simplification used in a climate model. Simplifications are also used to treat processes that are not well understood and processes that are too complex to be included. For example, most vegetation models consider only a few general types of vegetation such as forest or grassland. It would be too computationally expensive to represent individual plant types or even to treat a large number of general types. This simplification of complex and sub-grid process is vital: without it, ESMs would be far too complex to run, but simplifying complex processes can introduce uncertainties in to the model, which must be assessed carefully. There are many parameterizations used in ESMs, some of which represent complex processes very well. Others (such as cloud formation) are more difficult to parameterize, and, thus, are the subject of ongoing research.

To run an ESM over a period of time (to do past and future simulations), scientists need to provide the model with information about changes in external factors, such as solar irradiance and also the variation of natural and anthropogenic emissions over the time period. For past time periods, much of this information is available, although uncertainties do exist. To simulate future periods, modelers typically consider a range of different emissions scenarios, which range from scenarios with lots of anthropogenic emissions reductions, to scenarios with large increases in future emissions.

MODELING STRATEGIES

Uncertainties in the parameterizations used in climate models contribute to uncertainty in the climate predictions. To investigate the sensitivity of the model to these uncertainties, scientists carry out ensemble simulations in which they run multiple model simulations are run. For an ensemble experiment, the different model simulations vary only in the detail of the parameterizations used. For example, if a model parameterization makes use of a parameter, X, but the exact value of this parameter is yet to be fully determined, multiple model simulations are run, each with a slightly different value of X. In this way, scientists can explore the sensitivity of the model to this parameter, which helps them to assess the uncertainties involved. Ensemble simulations help scientists estimate the model error and highlight key uncertainties that have a large effect on the model results (areas that can then be targeted in future research).

The largest ensemble climate model experiment run to date is that of www.climateprediction.net, in which members of the public are encouraged to run different versions of a climate model on their home computers. Ensemble simulations can only be carried out with relatively fast-running climate models (those with lower resolution or a low degree of coupling between different components) as multiple simulations must be run.

Condensation

CONDENSATION IS THE change of phase of a substance from vapor to liquid. It is the opposite of evaporation, the change of phase from liquid to vapor. The condensation of water is one of the most important physical processes of the Earth's climate system. Condensation forms cloud particles and precipitation. It is the main sink of atmospheric water. On Earth, water can be found in the solid, liquid, and gas phases. Evaporation (and sublimation) of water substance, the transport of water vapor, and condensation away from its sources, is the most important heat transport mechanism in the Earth's climate system. Condensation is an extremely important process in the earth's water cycle because it is responsible for the formation of clouds and precipitation.

Weak forces between molecules cause them to stick to each other and produce the various phases of a substance. Random thermal motions cause some molecules to overcome these intermolecular forces and escape from the liquid and form a gas phase around it. The number of molecules that leave the liquid phase increases with its temperature because of the increase in the thermal energy, and, therefore, kinetic energy, of the substance. The molecules in the gas phase jiggle and move randomly because of their thermal energy. Some of the gas molecules stick to the liquid when they strike it. The numbers of molecules that return to the liquid phase increases with their concentration.

Condensation is integral to the most important heat transport mechanism in the earth's climate system.

Thus, the concentration of molecules in the gas phase increases until a balance between molecules leaving and returning to the liquid surface is reached. This is called thermodynamic equilibrium. The concentration of molecules in the gas phase, in equilibrium with the liquid phase at a given temperature, is defined as the saturation value.

The molecules that leave the liquid phase are the ones moving faster than the average molecule in the liquid. That is, they have larger kinetic energy than the average molecule. This is the reason a liquid cools while it evaporates. There is a sudden large attraction when a molecule of water vapor approaches the surface of liquid water. This speeds up the incoming molecule and increases its kinetic energy. Thus, a liquid releases heat while it condenses. This is known as the latent heat of condensation. The saturation vapor pressure depends on the curvature of the surface of the liquid phase.

This has important implications for climate processes. In a curved surface, such as that of a cloud droplet, each water molecule has fewer nearby neighbors than on a flat surface. Thus, the intermolecular attractive forces holding them together are smaller; a water molecule can escape a curved surface easier than a flat surface. At equilibrium, the concentration of water molecules in the gas phase has to be larger than over a curved surface over a flat surface to compensate for the fact that a larger number of molecules leave the liquid at a given temperature. Therefore, the saturation water vapor pressure is larger over curved surfaces.

Condensation occurs when the concentration of molecules in the gas phase exceeds the equilibrium, or saturation value, at a given temperature. Relative humidity is defined as the ratio of the water vapor concentration to the saturation value, with respect to a flat surface of pure water. Thus, the relative humidity of the air in equilibrium with a cloud droplet can be much greater than 100 percent, depending on the curvature (or size) of the droplet. This frequently occurs in clouds and is called supersaturation. Therefore, condensation and cloud droplets form preferentially over impurities that reduce the curvature of the surface of the liquid phase. These impurities are called cloud condensation nuclei.

When the temperature of the liquid phase is lowered, a smaller number of molecules leave it, and the saturation water vapor concentration is reduced. This is what occurs when moist air rises in convective updrafts and cools adiabatically. Thus, when the air rises sufficiently for saturation to occur, clouds form. This is the process by which convective clouds form. The cloud base is at the saturation condensation level of the rising air parcels. However, the fraction of the condensate that falls as rain, as opposed to evaporating and moistening the environment, is not easily determined. In fact, this is one of the most uncertain processes in cloud models. Cloud processes have been identified by various researchers, and more recently by the United Nations Intergovernmental Panel on Climate Change (IPCC), as one of the most uncertain processes in climate models. Condensation partially controls the content of vertical distribution of water vapor, the most important greenhouse gas in the Earth's atmosphere.

Congo

THE REPUBLIC OF the Congo, a former French colony, has a land area of 132,047 sq. mi. (342,000 sq. km.), with a population of 3,999,000 (2006 est.), and a population density of 31 people per sq. mi. (12 people per sq. km.). Forests cover 62 percent of the country, with less than one percent of arable land, and 29 percent used for meadows and pasture, mainly for low-intensity grazing. The substantial cattle industry contributes to the country's methane emissions.

The carbon dioxide emissions from the Congo, on a per capita level, are relatively low: 0.5 metric tons in 1990, rising to 0.8 metric tons in 1997, and falling to 0.37 metric tons in 2003. This low rate is because of the dense forests that cover a large part of the country, and the fact that 99.3 percent of the electricity production in the country comes from hydropower. Most of the carbon dioxide emissions (91 percent) come from liquid fuels, some from gas flaring from the recently established petroleum industry, and the remainder from gaseous fuels. Most emissions are contributed by transportation, due to a poor system of public transportation, and limited train service.

The Congo government of Denis Sassou-Nguesso took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and his successor, Pascal Lissouba, ratified the Vienna Convention. The Congo ratified the Kyoto Protocol to the UN Framework Convention on Climate Change on February 12, 2007, the 167th country to do so.

Congo, Democratic Republic of

THE DEMOCRATIC REPUBLIC of the Congo, formerly known as Zaire, has a land area of 905,351 sq. mi. (2,344,858 sq. km.), with a population of 63,655,000 (2007 est.), and a population density of 65 people per sq. mi. (25 people per sq. km.). Forests cover 80 percent of the country, with only three percent of the land arable, and 7 percent is used for pasture, mainly grazing cattle and sheep.

Only two percent of electricity production comes from fossil fuels, with 98 percent produced from hydropower. Most of the hydropower is generated from the hydroelectric plants at the Inga Dams, located on the Congo River. The two plants Inga I and Inga II provide electricity for the Shaha province, with plans to build Inga III and the Grand Inga plants, which would generate 4,500 megawatts and 39,000 megawatts, respectively. Grand Inga provides more hydroelectric power than is currently consumed by the entire African continent.

As a result of this hydroelectricity, and the undeveloped nature of the country, the Democratic Republic of the Congo has one of the lowest per capita rates of carbon dioxide emissions in the world, with less than 0.1 metric tons per person in 1990, which fell to 0.03 metric tons per person by 2003. Only three countries have lower per capita emissions: Afghanistan, Chad, and Somalia. Manufacturing and construction account for 28 percent of carbon dioxide emissions from the country, with transport accounting for 19 percent, and residential use, 11 percent. As a result, the overall level of carbon monoxide emissions is high, making up nearly 13 percent of all carbon monoxide emissions in sub-Saharan Africa.

The government of Mobutu Sese Seko took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and two years later ratified the Vienna Convention. The Democratic Republic of the Congo, under Joseph Kabila, was the 143rd country to agree to the Kyoto Protocol to the UN Framework Convention on Climate Change, signing it on March 23, 2005.

Connecticut

THE THIRD SMALLEST state in the United States in land area, Connecticut is a state with multiple identities. Its western border with New York makes it part suburban, its northern border shared with Massachusetts makes it part historic New England, and its 250-mi. (402 km.) Long Island Sound shoreline makes it a $4 billion-a-year tourist retreat. Such geographic and cultural diversity means that the state's environmental concerns are equally diverse. They include the poor air quality common to dense metropolitan areas, the protection of forests that constitute nearly 60 percent of the state, coastal erosion, and wetlands preservation.

The nonprofit organization Environmental Defense reported in 2004 that temperatures in Conneticut increased during the 20th century at a higher rate than the rest of New England. Estimates of the accelerated rise in temperature due to unchecked global warming indicate temperatures in the state could rise around 4 degrees F (.5 degrees C) by 2100. Connecticut has responded to the challenge through unprecedented regional cooperation and strong measures within the state to check greenhouse gas emissions.

Connecticut ranks in the lowest 10 percent of the states in its per capita carbon dioxide emissions. Because the state is largely a service economy, with the largest industries being finance, insurance, and real estate, energy consumption is comparatively low. Nearly 40 percent of Connecticut's greenhouse gas pollution is produced by the transportation sector. The state's oldest and most heavily populated cities, such as Hartford and New Haven, home to thousands of commuters, help to keep the state's emissions low. In contrast, residents of Connecticut's exurbs, fast-growing bedroom communities at the far margins of large cities where cars are the only form of transportation, produce about three times more carbon dioxide per person than those who live in the city. Transportation is the leading source of global warming pollution in Connecticut, and much of it from the 96 percent of exurban residents who commute in vehicles carrying only the driver.

DEFORESTATION

The effects of global warming are not limited to metropolitan areas. Reforestation began in Connecticut in the early part of the 20th century as farmland was abandoned and reverted to forests; the change leveled off in the early 1970s. In the early 21st century, about 85 percent of Connecticut's forests are privately owned. Many believe private ownership makes the forests more likely to be sold to developers. Researchers at the U.S. Department of Agriculture's Forest Service predict that by 2050, more than 60 percent of Connecticut will be urbanized. Development of this magnitude will mean deforestation that will increase the effects of global warming. Surviving forests could change substantially, as the conifers, sugar maples, oaks, and hickories that are left lose the spectacular colors that have made Connecticut autumns famous. In an environmental spiral, species of songbirds could disappear from the state's forests, leaving invasive pests, such as the gypsy moth, to decimate the vegetation.

In the past century, sea level in Connecticut has risen by 8 in. (20 cm.), and the state's current rate is above the global mean. A two-year study of Knell's Island, part of the Charles E. Wheeler Wildlife Sanctuary, reveals an erosion rate of as much as 3.3 ft. (1 m.) annually. Predictions suggest increases of at least 5.1 in. (13 cm.) by 2020, to a minimum of 11.2 in. (28 cm.) by 2080. These increases, and the storm surge increases that would accompany them, place rail lines, roadways, an airport, the University of Bridgeport, the Navy Reserve Center, sewage-disposal plants, and the oil tanks at Johnson Creek at flood risk. Stewart B. McKinney National Wildlife Refuge, home to the endangered roseate tern, would also be at risk. A large portion of Connecticut's wetlands, already suffering from the effects of development, could disappear.

The scenarios are grim, but Connecticut has begun implementing strategies to reduce greenhouse gas emissions. The American Council for an Energy-Efficient Economy (ACEEE) ranked Connecticut, along with Vermont and California, as tops in the nation in overall energy efficiency. In 2001, Connecticut joined other New England states and provinces in eastern Canada in developing a Climate Action Plan that adopted the Kyoto target of reducing greenhouse gas emissions to 10 percent below the 1990 base; the group set 2020 as their target date. In 2003, Connecticut became a member of the Regional Greenhouse Gas Initiative (RGGI), a cooperative of nine northeastern and mid-Atlantic states committed to a cap-and-trade program covering carbon dioxide emissions from power plants. RGGI requires carbon dioxide emissions to be stabilized by 2015, with a 10 percent reduction by 2019, and, eventually, to achieve sharp reductions in all greenhouse gases.

In 2007, after a two-year period of legislative debate, Connecticut passed an omnibus energy bill that required that RGGI requirements be implemented. The action also extended the state's Renewable Portfolio Standard (RPS) to require utilities to provide at least 20 percent of Connecticut's electricity from clean, renewable sources, such as wind and solar by the year 2020. It also required utilities to purchase all cost-effective energy efficiency and similar measures before expensive and polluting new generation resources, and provided incentives and sales tax exemptions for solar power, efficient furnaces, air conditioners, and cars getting over 40 miles per gallon in fuel efficiency.

Connecticut has also adopted the California Clean Cars tailpipe pollution standards, reducing greenhouse gas emissions from new cars 30 percent by 2016. Other recent measures include major investments in mass transit, a fund established for the preservation of farmland, and the purchase of a fleet of more than 500 alternative-fuel and hybrid state vehicles.

The state also initiated one of the nation's strongest renewable energy standards with the goal of seven percent of electricity coming from clean, renewable sources by 2010.

Conservation

CONSERVATION IS A line of environmental thought and action that emerged in the United States during the last half of the 1800s. Conservationists are often seen as opposing growth, but this universal judgment is problematic. The underlying premise of the predominant branch of conservation's philosophy is wise use, that is, the preservation of the land's natural resources through efficient management based on science, strategic planning, and carefully-monitored extraction. This approach is dedicated to lessening polluting emissions into the environment and opposes growth in cases where there will be unnecessary environmental damage.

Another significant branch of conservation thought focuses on preservation of lands in their natural state as a haven for humans to recuperate from the stress and strains of everyday life. Land is viewed for its intrinsic value, rather than its economic worth. Proponents of this branch of conservation are clearly opposed to growth that threatens tracts of land that remain relatively untouched by human activity. Preservationists believe people need to recognize that there are limits to growth, which is causing widespread damage to the Earth's fragile ecosystems. Lands need to be left in their natural state, not only as havens, but also to filter the waste released into the environment.

APPROACHES TO CONSERVATION

Conservation, sometimes called the conservation movement, gradually emerged in the United States in the context of rapid population and industrial growth during the 19th century. It was a reaction to widespread, rapacious exploitation of what most people saw as seemingly limitless natural resources. The movement's leaders in the late 19th century included Theodore Roosevelt, the avid outdoorsman who later became president; Gifford Pinchot, head of the U.S. Forest Service and a governor of Pennsylvania; and John Muir, founder of the Sierra Club.

From its beginnings, the conservation movement has been split into two major camps. Mainstream conservationists are pragmatic. They believe natural resources are for human use, for the benefit of everyone, not just a few. Conservation also has a strong element of stewardship. Natural resources need to be used efficiently now for the benefit of future generations. Conservation emphasizes the economic value of natural resources, based on efficiency in minimizing waste that occurs while extracting and processing those resources.

This was a major departure from the predominant path of development during the 19th century, which was based almost entirely on immediate needs, with no regard for the future. By the turn of the 20th century, Roosevelt and Pinchot's conservation views were ascendant, focusing mainly on forestry, which included soil and water conservation. Their approach was widely implemented by the U.S. Forest Service, which evolved in the 1870s and was established in 1891 in the U.S. Department of Agriculture. This agency manages National Forests for multiple uses, such as timber-harvesting, mineral extraction, and recreation.

Muir led the alternative branch of conservation, focusing on preservation without use to leave vast tracts of land virtually untouched by humans. Human use of wilderness areas should be limited almost exclusively to recreation, which Muir believed was sorely needed for escape from a rapidly-urbanizing society. Muir, who was born in Scotland, successfully worked to preserve natural treasures such as Yosemite in California. His philosophy has been carried out, not only through the Sierra Club, but also through the National Park Service, whose charter makes it responsible for preserving land in relatively pristine condition.

Muir's preservationist ideas blended well with the New England Transcendentalism of Henry David Thoreau and Ralph Waldo Emerson, who saw human interactions with nature as a transformative experience that left people richer spiritually. Muir's activist emphasis on preserving the wilderness continues to create lively tension among environmentalists, eco-philosophers, social scientists, politicians, and business leaders. The preservationist stand is seen as opposing growth. The notion that the land has value in and of itself challenges the mainstream conservationist position of management for efficient human use.

Nature, in the mainstream view, has economic value related to its most productive use; it is not to be left on its own. Yet, the preservationist view can complement the utilitarian view. The burden for preservationists has been to prove the value of pristine land, and the needs to conserve it. Arguments for preservation of natural areas often rely on emotion and aesthetic values, although economic models developed in recent years now account for values such as carbon sequestration, watersheds, and recreation.

Given the environmental context of raiding natural resources during the Gilded Age of the late 1800s, Pinchot's conservation stand offered a compromise to balance the rapidly-growing economy with preservation for future generations. Scientific forest management allows for using forests and their products while conserving the country's forest base. Pinchot, a trained forester, understood the biological constraints on forest production and the possibility for conserving, or renewing, that resource by calculating the maximum sustainable yield. In this view, forests are an economic resource. Conservation assures an adequate supply of wood and wood products for production to keep the economy moving.

Despite these economic arguments, conservation faced considerable resistance. The idea was new to the United States, and not yet recognized as a way to increase corporate efficiency and profits. Proponents of laissez-faire capitalism argued that conservation represented undue government interference in business, which would stop profitable logging and damage overall economic growth. Pinchot believed government could, and should, play a role in managing natural resources for the good of all people, and to keep the economy moving. Muir, who also believed the government had a role in preserving pristine areas for the future, stretched the boundaries of thinking about conservation to include aesthetics and human needs; this approach would later be extended to include the economic value of preserved land for its role in cleaning the environment and for recreation.

ROOTS OF CONSERVATION

Early on, the U.S. conservation movement was rooted in a growing recognition of the impact of forest destruction after European contact in the 1600s, when much of the continent was heavily wooded. The establishment of the U.S. Department of the Interior, in 1849, to oversee natural resources on federal lands suggests rising consciousness across the country about how to handle the settlement of western lands, with peripheral concern for the future of the environment. Congressional approval of the U.S. Department of Agriculture, in 1862, recognized the importance of the government's role in educating farmers about best practices to make their land use operations more profitable; these best practices emerged during the first part of the 20th century as conservation techniques to increase production, preserve soil, and improve water quality.

Logging and mining intensified tremendously during the 1850s and 1860s. Farmers deforested land for market-oriented production to serve the burgeoning urban population. Increasing industrialization demanded timber for railroad ties, coalmine supports, and housing for workers. Federal land sales at bargain-basement prices to corporate interests and land speculators spurred the rapid spread of people across the land, often in company with poor land-use practices. In the widely accepted view of citizens and policymakers, little, if any, value was placed on land in its natural state, so cheap land became a subsidy for natural-resource-based industries that were building national and international markets for their commodities.

Few loggers thought about resource depletion, much less conservation; the supply of wood seemed unlimited. Loggers adopted "cut and run" practices, leaving vast tracts of unused wood to dry out. As a result, huge forest fires destroyed remaining forests and nearby towns. For example, the 1871 forest fire near Peshtigo, Wisconsin, killed about 1,500 people and burned 1.3 million acres. Across the south, forest fires preceded farming as a way of clearing the land. Fires and poor logging practices exposed the forest floor, which eroded, silting and killing waterways and contributing to widespread flooding. Communities were left impoverished as loggers moved from state to state, in search of new forests.

In Europe, regenerative forest practices emerged, in Germany in the 1750s, to counter widespread deforestation that had occurred over centuries. The abundance of forest in the United States slowed the adoption of these conservative practices here until several reports published during the 1860s and 1870s pointed out the risks of natural resource depletion, especially in the nation's forests. The scientific basis for conservation began to emerge in the United States, with the growing recognition that widespread clear-cutting not only threatened future supplies of wood, but also damaged watersheds.

Destruction from poor farming practices matched the damage from over-cutting of timber. Repeated cultivation of tobacco depleted the rich soils of the Virginia Piedmont during the 1700s, followed later by other areas of the south leached by cotton. Throughout the country, thousands of tons of topsoil were blown or washed away from poorly managed farms. The soil fouled streams, caused flooding, and killed wildlife. The worst example of wind erosion occurred during the prolonged drought of the mid-1930s, when the Dust Bowl clouded skies across the country with precious soils stripped from the midwestern wheat belt.

ROMANTICISM AND CONSERVATION

Researchers and other intellectuals, including artists, began to recognize the local impacts of environmental degradation around the turn of the 19th century in the United States and Europe. For scientists, powers of observation were based on empiricism and the scientific method that were honed during the Enlightenment. Artists and intellectuals observed natural beauty and captured it in the painting, music, and literature of the Romantic period. Romanticism emerged along with the Industrial Revolution, which was a practical expression of technical knowledge garnered during the Enlightenment.

Romanticism was, in part, a reaction to industrialization's impact on nature and was a precursor of the conservation movement. Transcendentalism, as one facet of Romanticism, stirred a persistent place-based heritage that fostered nature-inspired artistic endeavors and a heightened sense of spiritualism. These efforts, in turn, led to the preservation of wild areas based on the intrinsic value of nature and the land. This view helped widen the possibilities for the conservation movement and fit well with Muir's later efforts to preserve pristine landscapes in the United States.

Romanticists played a vital role in launching the conservation movement on multiple fronts. They were uniquely capable of communicating the beauties of nature and were sensitive to environmental changes in their communities. While many Romanticists worked to reconcile industrial changes on the landscape, others reacted negatively, noting the environmental damage and seeking ways to preserve the rural countryside and its lifestyle. Even as they reveled in the glories of nature, many noted soil erosion, the loss of wildlife, dirtier air, and changes in streams and lakes. Their observations about local environmental decline found support in scientific observations. By the 1820s, for example, scientists were developing a rudimentary understanding of carbon dioxide as a greenhouse gas. By about 1850, researchers were documenting acid precipitation around English industrial cities, a climate change brought on by coal-burning for factories and homes.

Perhaps the most significant work to bridge Romanticism and conservation as a physical and biological science and a social science came from Aldo Leopold, a forester, writer, astute observer of nature and human activities, teacher, and internationally-known conservationist and ecologist. Leopold's contribution to conservation comes from his conceptualization of healthy land and its relationship to human communities. Leopold did not separate the land from human activities. Rather, he extended the definition of community to include not only the places where people reside and interact with each other, but also the surrounding ecology in the landscape. Leopold added a rich component to conservation by giving it an ethical basis.

His land ethic puts environmental considerations at the front of community decision-making, demanding consideration for soil, water, air, and other living creatures. Natural resources are for human use, but the surrounding ecology has intrinsic worth that is vital to the immediate quality of life and long-run community sustainability. Leopold's land ethic moved the conservation movement toward increased consciousness of the relationship of humans to the larger environment. His *Sand County Almanac* stands as a conservation classic, linking the wonder of nature with human activity, and, more importantly, human responsibility for taking care of the environment as an integral component of community. Leopold's thinking opens the way for an ethical systems approach to conserving the environment.

CONSERVATION AND CLIMATE CHANGE

Knowledge about climate change has come slowly alongside the emergence of the conservation and, later, environmental movements. Differing approaches to conservation moved toward a more holistic understanding of human impact on dynamic environmental processes. For example, in an 1867 report to the Wisconsin Legislature, I.A. Lapham showed the relation of forests to stream flow. His suggestion about the need to plant more trees to protect watersheds foreshadowed the conservation movement. At about the same time, researchers also began to speculate about possible climate change related to forest removal, reflecting increased knowledge about the role of forests in cleansing the environment.

Emphasis on conservation helped feed understanding about interconnections between human activities and the environmental impact of pollution, raising human consciousness about wasteful practices. While pollution was easily visible at the local level, understanding its broader impact depended on the development of more sophisticated measurement tools, with computers capable of analyzing massive amounts of data taken from complex and dynamic ecosystems. The planning required for widespread conservation efforts demands a systems approach to human-environmental relationships, especially those associated with burning nonrenewable fossil fuels.

After World War II, increased understanding of the sources of smog and acid rain and their negative environmental impact, led to pressure from conservationists to clean up pollutants from coal-fired plants and motor vehicles. Improved combustion and scrubbing technologies, developed partly in response to government prodding in the Clean Air Act and state emissions laws, led to more efficient use of coal, and mitigated some smokestack emissions. In addition, new technologies helped increase auto fuel economy and reduce tailpipe emissions. Environmental economics developed as a specialty field to develop cost-benefits models to show the impacts of conservation and anti-pollution policies on firms and the economy. More recently, interdisciplinary teams of scientists have made significant strides by finding crucial links between pollutants and climate change. The gradual evolution of conservation helped spur techniques that reduced waste and conserved resources for future generations.

Convection

CURRENTS MOVING IN fluids are convection. More specifically, fluids—liquids, gases, and rheids—undergo movements as convection currents. Convection plays a major role in heat transfers. In fluids, both movement of mass in the fluid, and the heat it contains, occurs in a random way, if Brownian motion occurs. However, in the process of advection, large motions develop in the fluid, which move not only its mass, but also the energy it contains. Convection means the transfer of mass and heat by diffusive and advective movements. Heat is the transfer of energy from one body to another. Heat is a cause of convection currents in fluids, because the fluid motion is initiated and continued by the energy transfers occurring in the fluid.

As a fluid is heated, it expands. If a part of the fluid is cooler than another part, then its density is greater, and it sinks in the fluid. However, the opposite occurs to a part of the fluid that is heated to an energy state that is greater than surrounding parts of the fluid. As a consequence, it acquires buoyancy and rises because gravity is causing the denser part(s) of the fluid to sink. The effect is called a convection current. The convection current allows the fluid to engage in convective heat transfers. Convection is a very common occurrence in nature. Convection currents cause movements in water, in the atmosphere, and in the mantle of the earth. It is familiar as rising warm air over a fire, or the steam rising off of a heated pan of water or soup. These familiar examples are very localized; however, in the atmosphere the same principles are at work on a grand scale.

The surface of the Earth is heated by solar energy. However, the sunlight that strikes the Earth does not do so in an even manner. Clouds block parts of the solar energy; it hits bright surfaces such as the ice caps and is reflected, or it hits dark areas and is absorbed so that the heating of the Earth's surface is very uneven. The energy that does hit is transferred to the atmosphere as radiant energy. The ground, trees, grasses, water, or other surfaces radiate energy, but very unevenly, so the air above these surfaces is heated unevenly. Local convection currents combine to form larger convection currents in the atmosphere over larger and larger areas. The results are winds or other atmospheric phenomena. As the heated air rises, its lighter density causes lower pressure at the surface from which it is rising to be lower than the surrounding, cooler, pressures. The denser air then moves in to fill the lower pressure area that now functions like a vacuum. The warmer air also displaces cooler air above it, so that as the warmer air rises, the cooler air sinks, contributing to convection currents and to heat transfer.

Very localized convection currents visible in desert areas are dust devils. These are thermal convection currents composed of rising hot air that has begun to spin, resembling a miniature tornado. All of the grand weather phenomena, such as thunderstorms, cyclones, hurricanes, and, ultimately global atmospheric circulation, are forged from convection. A convection cell is a single region of air that is alternately heated and cooled. Its convection currents can give rise to lateral movements that cause breezes, winds, and other weather phenomena.

The oceans are affected by the variable distribution of solar radiation they receive. Tropical waters receive tremendous amounts of direct sunlight. They warm in the open oceans and, in the summer months become quite warm, especially in relatively shallow areas such as the Gulf of Mexico. The warm water then moves toward the polar regions, and colder water moves toward the tropics in order to fill in the lower pressure areas that the warmer waters have created. However, convection can also occur without the involvement of heat. For example, a convention current that is not due to heat is the movement of air masses due to variation in the amount of water vapor they contain.

Buoyancy can be caused by variations in the density of substances apart from the application of heat. For example, ocean convention currents can be caused by variations in the salinity of ocean water. The ocean currents are powered by differences in the salinity of the ocean waters. The saline differences create thermohaline convection. The differences in the density of warm salty water and cooler, lower salinity water are such that the dense, warm salty waters sink, bringing up less dense, cooler water. At the same time, heat is transferred and transported.

Free convection is the natural heat convection found in nature. It is not the same as forced heat convection. In forced convection, the heat transfer is not due to natural buoyancy forces. Rather, it is the result of movements in fluid inserted by artificial means. Fans, pumps, convection ovens, and other forms of circulating hot air or fluid cause a disequilibrium in the system.

The resulting disequilibrium is applied to various tasks by the forced convection. The core of the Earth is heated under enormous pressures. Part of its heat is due to radioactive decay. Movements in the core are usually convection currents. The outer core has dense metals, mainly nickel and iron, that are a part of the Earth's magnetic field. As they move in a fluid way under enormous pressure, they give off electricity, which generates magnetic fields.

Cooperative Institute for Arctic Research

THE COOPERATIVE INSTITUTE for Arctic Research (CIFAR) was created in 1994, at the University of Alaska following several years of teamwork between the university and the National Oceanic and Atmospheric Administration's (NOAA) Environmental Research Laboratories (ERL). Among the 13 NOAA-university joint institutes established to promote greater collaboration between researchers from NOAA laboratories and U.S. universities, CIFAR is the only one solely concerned with the study of the Arctic. Global warming is expected to change the Arctic more than any other area of the world. CIFAR is located at the University of Alaska at Fairbanks (UAF), in the International Arctic Research Center. CIFAR maintains affiliations with the Center for Global Change (CGC), the Institute of Marine Sciences, the Institute of Arctic Biology, the UAF's Geophysical Institute, and School of Agriculture and Land Resource Management.

CIFAR also maintains strong partnerships with NOAA's Pacific Marine Environmental Laboratory, Arctic Research Office, National Marine Fisheries Service, Ocean Exploration Program, and the National Weather Service. CIFAR's research supports NOAA's aim to recognize and anticipate shifts in the Earth's environment, and utilize natural resources in an integrated manner that fulfills the economic and environmental needs of the United States. CIFAR's nine research areas include Arctic atmospheric and climate research, fisheries oceanography, tsunami research, climate dynamics and variability, and environmental assessment and statistical modeling. Additionally, CIFAR oversees the administration of the Arctic Climate Impact Assessment, an international project that evaluates and integrates research on climate change and variability.

CIFAR plays a major role in communication and scientific exchange regarding the Western Arctic/Bering Sea region, which, because of its rich natural resources and troubling changes caused by climate warming, is of greater interest and study by the global community than ever before. During its 1997 fiscal year, NOAA's Office of Oceanic and Atmospheric Research, in partnership with the Cooperative Institute for Arctic Research, used a 1996 appropriation of $1 million by the U.S. Congress to initiate support of 15 research projects focused on the Western Arctic/Bering Sea ecosystem. CIFAR's integral role in the execution of programs that fall within NOAA's Arctic Research Office ensures that NOAA's priorities receive further support from experienced Arctic scientists.

CIFAR researchers disseminate their findings through the release of 18 scientific publications annually, the majority of which are peer-reviewed. Included among the 2006 published writings based on research that received partial or full funding through CIFAR, were articles appearing in *Geophysical Research Letters*, *Journal of Geophysical Research*, *Marine Resource Economics*, *Journal of Climate*, *Science*, and *Science of Tsunami Hazards*. Areas of research ranged from marine ecosystem restoration, an ecosystem shift in the northern Bering Sea, trends of snowfall and snow cover, to tide-tsunami interactions.

Publications in 2006 included several Ph.D. dissertations, representing the School of Fisheries and Ocean Sciences, and the Institute of Marine Science. CIFAR is a key partner and collaborator in the Center for Global Change's annual Student Research Grant Competition, established in 1992 to promote interdisciplinary research with a focus on the Arctic and sub-Arctic, and further supports student research efforts in areas that promote NOAA's mission and capacity-building in Alaska. Seventeen awards were granted to support 23 students working on a range of polar issues in the biological, physical, and social sciences during the International Polar Year 2007–08. Participation in the Student Research Grant Competition provides students with the experience of crafting proposals in an environment similar to that utilized by science funders. Three of the projects approved in 2007 were funded by CIFAR. Research and academic work at CIFAR is supported by the Keith Mather Library, which serves the International Arctic Research Center and the Geophysical Institute.

Coriolis Force

BECAUSE EARTH SPINS on its axis, the Coriolis Force bends wind right or left from the direction of its flow. The Coriolis Force, therefore, causes wind to deviate from a straight path. If Earth did not spin on its axis, wind would blow following the Earth's curvature, with no deviation. A wind blowing from south to north would not deviate northeast or northwest. In 1835, French mathematician Gustave Gaspard Coriolis discovered the force that bears his name, and derived the mathematical equations that describe the Coriolis Force.

The Coriolis Force is weak, compared to other meteorological phenomena. At the equator, the Coriolis Force is nonexistent because wind does not rotate at the equator as it does at the poles. At the equator, wind follows the Earth's curvature, without deviating right or left. The absence of the Coriolis Force explains why hurricanes do not form at the equator, but rather in tropical waters, at least 5 degrees north and south of the equator. Absent the Coriolis Force at the equator, a hurricane or other tropical storm that formed in the north will not cross into the Southern Hemisphere, nor will one in the south cross into the Northern Hemisphere. The equator, therefore, acts as a barrier against the movement of tropical storms. The Coriolis Force keeps tropical storms in the hemisphere of their origin. By contrast to the weakness of the Coriolis Force as one nears the equator, the force gains strength as one approaches the poles and reaches a maximum at the poles, where winds experience the full effect of the Earth's rotation on its axis. At the poles, wind rotates sharply right in the Northern Hemisphere or left in the Southern Hemisphere with maximum force.

The Coriolis Force accounts for the trade winds that mariners used to navigate the ocean in past eras. So predictable are these winds in direction and force that Christopher Columbus used them in his later voyages to retrace the route of his first voyage. The winds originating in the Northern Hemisphere are called the Westerlies, whereas those that originate in the Southern Hemisphere are called the Easterlies.

On land, the Coriolis Force can form tornados. A tornado will rotate counterclockwise in the Northern Hemisphere and clockwise in the Southern Hemisphere. The direction of rotation may seem counterintuitive, however, because wind flows to the right in the Northern Hemisphere, one might expect that it would rotate clockwise rather than counterclockwise. The same rationale applies in the Southern Hemisphere, where the flow of wind to the left might be expected to produce counterclockwise rotation, rather than clockwise rotation. However, a countervailing force, the difference in air pressure at the center and at the periphery of a tornado, forces a tornado to rotate counterclockwise in the Northern Hemisphere and clockwise in the Southern Hemisphere. The counterintuitive rotation of tornados underscores the weakness of the Coriolis Force. The Coriolis Force could be compared to gravity; both are relatively weak, unseen forces, whose existences were undefined for centuries.

Cornell University

CORNELL UNIVERSITY, AN Ivy League school and land-grant college located in the scenic Finger Lakes region of central New York, has seven small to mid-sized undergraduate colleges. The Department of Earth and Atmospheric Sciences offers undergraduate and graduate courses of study in the colleges of Arts and Sciences, Agriculture and Life Sciences, and Engineering. The Science of Earth Systems major is offered in all three colleges, while the College of Agriculture and Life Sciences also offers the Atmospheric Science major.

Established in 1983, the Northeast Regional Climate Center (NRCC) is located in the Department of Earth and Atmospheric Sciences. It serves the 12-state region that includes: Connecticut, Delaware, Massachusetts, Maryland, Maine, New Hampshire, New Jersey, New York, Pennsylvania, Rhode Island, Vermont, and West Virginia. Major funding is provided by a grant from the National Oceanic and Atmospheric Administration. The NRCC's staff works cooperatively with the National Climatic Data Center, state climate offices, and other scientists in the northeast to acquire and disseminate climate data. The NRCC conducts research studies that focus on the development of new climate information products, data analysis techniques, and applications of climate data. Researchers also seek to understand and characterize regional climate and variability as it may affect the economic or societal well-being of the northeastern United States.

Examples of research include: the development of methods to estimate soil frost depths, monitor water resources, predict agricultural crop development, and characterize extremes of snow-pack water equivalent in the northeast. Arthur DeGaetano, associate professor and director of NRCC research, focuses on weather and climate extremes by enhancing the use and utility of climate data and information in weather-sensitive decisions. Observed climate variability investigates the interannual variability of such meteorological phenomena as East Coast winter storms and extreme temperature occurrences.

Such studies look at trends in these data through time, as well as causal mechanisms associated with year-to-year variations. The accuracy of the climate data archive is important for documenting observed climate variability, as well as the use of these data by decision-makers. Work in this area involves detecting nonclimatic changes in the data record due to changes in observing practices, and time-dependent shifts in the environment of the observing site.

The Center for the Environment is a Cornell University-sponsored unit that specializes in crafting interdisciplinary collaborations among scientists and professors from Cornell and partnering institutions, and applying new knowledge to environmental problems and needs around the world. The center plans and organizes lectures, seminars, conferences, student grants, and scholars' visits, and publishes a weekly electronic newsletter. It brings a prominent environmental leader to Cornell through the endowed Jill and Ken Iscol Distinguished Environmental Lecture Series every spring. The center also awards student research grants to Cornell University graduate students researching environmental topics. With its own ongoing research efforts, the center serves the Cornell academic community and partnering institutions with grant applications, team development, and administrative support. Current projects address pollution mitigation, marine and coastal environments, environmental complexity, and sustainability on local, state, and international levels.

The Doris Duke Charitable Foundation (DDCF) Climate Change Initiative is a five-year, $100 million program, launched in 2007 to help build a clean-energy economy. Many research projects at Cornell are funded through this initiative. The DDCF awards funding for research performed in three areas: pricing policies for greenhouse gases, technology deployment and development policies, and adaptation strategies. The DDCF will support the development of optimal domestic and international pricing policies for carbon and other greenhouse gases becoming competitive in the marketplace. It will also promote the development of policies that bring available technologies to market more quickly, particularly technologies related to energy efficiency. The foundation supports efforts to assess the likely effects of climate change and identify adjustments that can be made to reduce their impact. Given the DDCF Environment Program's mission to preserve wildlife through habitat protection, the foundation may focus on examining the impact of climate change on biodiversity conservation.

Cornell University, as well as performing research and promotion of climate change on a global scale, acts locally with student-run programs. The Cornell Sustainability Hub is a student-run organization dedicated to promoting and furthering sustainability on campus. The Hub is a coordinating body for a number of students and pre-existing organizations and seeks to aid them in the development of their goals and campaigns. It serves as a meeting place for various efforts, and an outreach committee focuses on publicizing their achievements to the Cornell community. Through the Hub, students have a chance to realize their visions of what Cornell could do to make itself more sustainable.

Fernando Herrera
University of California, San Diego

Costa Rica

THIS CENTRAL AMERICAN Republic, which has coastlines on the Pacific Ocean and the Caribbean Sea, has a land area of 19,725 sq. mi. (51,100 sq. km.), with a population of 4,238,000 (2005 est.), and a population density of 220 people per sq. mi. (85 people per sq. km.). Only 6 percent of the country is arable, the smallest percentage of any of the Central American countries; 46 percent is meadow and pasture, much of it used for raising cattle, which, in turn, contribute to an increase in methane. Over 34 percent of the country is still forested, and there have been stringent ecological controls, with the Costa Rican tourist industry relying on an eco-friendly image. Twenty-seven percent of Costa Rica is covered by a system of national parks, wildlife refuges, and biological reserves.

The most prosperous country in Central America, there is extensive public transportation throughout Costa Rica, with the local bus service regarded as the best in Central America. There has been a recent promotion of the use of bicycles. The carbon dioxide emissions per capita for Costa Rica have risen from 0.9 metric tons per person in 1990, to 1.5 metric tons per person in 1994, and then stabilized between 1.3 and 1.5 metric tons per person per year. Carbon dioxide emissions come from liquid fuels (88 percent), and from the manufacture of cement (12 percent), with negligible use of solid fuels or gaseous fuels.

Partly because of the increasing reliance on ecotourism, there have been many studies of wildlife in the country. The reduction of the dry-season mists, owing to the increase in the temperature of the Pacific Ocean, has been linked to the disappearance of about 20 species of frogs and toads previously found in the Monteverde Cloud Forest, northwest of the capital, San José. Medical studies have also shown that there has been an increase in the spread of dengue fever, which had previously not been known over 3,300 ft. (1,006 m.), now being found at 4,000 ft. (1,219 m.).

The Costa Rican government of Rafael Ángel Calderón Fournier took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and on April 27, 1994, in its last month in office, the government of José María Figueres Olsen signed the Kyoto Protocol to the UN Framework Convention on Climate Change, a decision that was ratified on August 9, 2002, and took effect on February 16, 2005. Support for the Costa Rican government's role has been given by the National Biodiversity Institute, located in San José, with N. Mateo addressing the Fifth World Bank Conference on Environmentally and Socially Sustainable Development at Washington, D.C., in October 1997. The increase in cyclones through global warming and climate change was discussed at the World Meteorological Organization's 6th International Workshop on Tropical Cyclones, held at San José in November 2006.

Geelong Grammar School, Australia

Côte d'Ivoire

LOCATED IN WEST Africa, the former French colony of Côte d'Ivoire (formerly known as the Ivory Coast) has a land area of 124,502 sq. mi. (322,460 sq. km.), with a population of 17,654,843 (2006 est.), and a population density of 145 people per sq. mi. (56 people per sq. km.). Over 26 percent of the country is forested, much of it equatorial rainforest, with an extensive timber industry. Arable land accounts for only 8 percent of the country, with a significant amount used for the production of coffee. Forty-one percent of the land is used for meadows and pasture, mainly low-intensity grazing of cattle, sheep, and goats.

The country generates 75.4 percent of its electricity production from fossil fuels, with the remainder from hydropower. Because of low electricity use in the country, per capita carbon dioxide emissions are also low, at 0.4 metric tons per person in 1990, falling to 0.32 metric tons per person by 2003. Some 98 percent of these emissions come from the use of liquid fuels, with the remainder from cement manufacturing.

The generation of electricity accounts for 48 percent of emissions, with 21 percent from transportation. The high use of liquid fuels is due to the poor public transport infrastructure. The one train route in the country connects Abidjan, the capital of Côte d'Ivoire, with Ouagadougou, the capital of Burkina Faso. It is notoriously inefficient, leading most people to use private bus companies to make the journey. Côte d'Ivoire makes up 1.3 percent of the carbon monoxide emissions in sub-Saharan Africa.

The government of longtime president Félix Houphouët-Boigny took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention in the following year. Côte d'Ivoire was the 169th country to agree to the Kyoto Protocol to the UN Framework Convention on Climate Change, which took place on April 23, 2007.

Cretaceous Era

THE CRETACEOUS ERA spanned the time period from 144 to 65 million years ago. It was the final epoch of the dinosaurs. It ended when the dinosaurs became extinct. At its height, the Cretaceous was a period of great warmth. The poles were ice-free, and warm ocean currents spread from the equator to the poles. The concentration of carbon dioxide was higher than it is today, causing a greenhouse effect. The abundance of plants was not enough to lower the amount of carbon dioxide in the atmosphere. The vigor of their growth implies that the Cretaceous climate was warm and wet, although, curiously, rainfall in the tropics was not heavy enough to support rainforests. Plants grew as far north as the Arctic Circle, proving that high latitudes were far warmer than they are today. The climate cooled, however, and rainfall diminished during the Late Cretaceous. The Cretaceous climate reached its nadir 65 million years ago, when a meteor impacted earth, ejecting debris, dust, and ash into the atmosphere, blocking out sunlight and cooling the Earth.

The sun was not the reason the Cretaceous era had a warmer climate than today; it produced 1–2 percent less heat. Earth was warmer during the Cretaceous era because the atmosphere contained 3–6 times more carbon dioxide than the current era. Carbon dioxide formed from the decay of large amounts of dead plants. Moreover, the Cretaceous, particularly the mid-Cretaceous, was a period of extreme volcanism, with the eruption of volcanoes releasing carbon dioxide into the atmosphere. The weathering of carbonaceous rocks also liberated carbon dioxide. All of this carbon dioxide created a greenhouse effect, in which carbon dioxide trapped sunlight as heat, warming the atmosphere.

A reservoir of heat, the ocean displayed the consequences of the greenhouse effect in its warmth, particularly in the tropics. During the Cretaceous Era, tropical waters were between 82–111 degrees F (28–44 degrees C). At 30 degrees latitude, ocean temperatures dipped to 68 degrees F (20 degrees C). At 60 degrees latitude, ocean temperatures were 54 degrees F (12 degrees C), and at 90 degrees latitude, temperatures were a cold 40 degrees F (4.5 degrees C). Polar temperatures, thus, though cold, were nonetheless above freezing and the poles did not have ice, at least not during the Late Cretaceous, though climatologists are less certain about the earlier periods of the Cretaceous. As is true today, the Cretaceous era oceans were cooler at lower depths, yet even at great depths they were warmer than today's oceans.

Plants absorbed carbon dioxide during the Cretaceous, though they may not have absorbed as much of the gas as they do today, accounting for the greenhouse effect during the Cretaceous. The tropics were drier during the Cretaceous than they are today, and so did not support a rainforest. The absence of a rainforest may have meant that Cretaceous plants were not numerous enough and did not grow vigorously enough to absorb as much carbon dioxide as today. Although this may have been true of the tropics, high latitudes had forests where today there is only tundra. These forests must have taken carbon dioxide out of the atmosphere, but on balance, plants did not remove carbon dioxide in sufficient quantities during the Cretaceous to reduce the greenhouse effect.

Plants reveal that the Cretaceous had a tropical climate, even at high latitudes. The plant *Heilungia* grew in Alaska. Although it is extinct, its relatives grow in Mexico and the Caribbean, suggesting that Alaska had a tropical climate during the Cretaceous. Temperatures must have varied little, staying around 80 degrees F (27 degrees C) year-round at high latitude. Rainfall must have exceeded 80 in. (203 cm.) a year.

The fact that Alaska had swamps during the Cretaceous also suggests that rainfall was abundant. Moreover, plants grew in profusion and density in Alaska, implying high rainfall and warm temperatures. Tree rings were wide, suggesting a warm, wet climate. Conifers grew at lower latitudes, implying that the climate was less moist and that the climate became drier toward the equator, the opposite of conditions today.

In Siberia, plants grew in the Arctic Circle. Summer temperatures averaged 70 degrees F (21 degrees C), whereas winter temperatures averaged only 43 degrees F (6 degrees C). Arctic Siberia therefore had seasons, with summer 27 degrees F (15 degrees C) warmer than winter. The difference between summer and winter temperatures during the Cretaceous is less than the seasonal difference today at high latitudes. The climate was warm enough this far north to permit plant growth for more than seven months each year. Autumn was brief, with the transition from summer to winter coming rapidly. South of Siberia, in what is Czechoslovakia today, temperatures averaged 68 degrees F (20 degrees C). Summer temperatures averaged 82 degrees F (28 degrees C), whereas winter temperatures averaged 52 degrees F (11 degrees C).

The climate of the Late Cretaceous is an enigma. The oceans remained warm and the poles ice-free, but on land, temperatures and rainfall decreased. The final blow came at the end of the Cretaceous 65 million years ago, when a meteor hit Earth, ejecting debris into the atmosphere and blocking out sunlight, cooling the Earth. The meteor impact ended the Cretaceous, temperatures continued to decrease, falling low enough to cause ice ages, the last of which ended only 10,000 years ago. As the concentration of carbon dioxide diminished and ice collected at the poles, tundra replaced forests at high latitudes. Rainfall increased in the tropics, giving rise to the rainforests.

Croatia

ONE OF THE constituent republics of the former Yugoslavia, the Republic of Croatia is located in the Balkans and has a land area of 21,831 sq. mi. (56,542 sq. km.), with a population of 4,493,312 (2006 est.), and a population density of 208 people per sq. mi. (81 people per sq. km.). Some 21 percent of Croatia is arable, with another 20 percent used for meadow or pasture. In addition, 37 percent of the country is forested, the pine from the region has been used for making ships since ancient times. The forestry and the lack of heavy industry have helped the environment in Croatia for many centuries, but there is now increased logging; also, up to half of the forests are affected by acid rain created by other countries.

For electricity generation, 45 percent of Croatian power comes from fossil fuels, with 55 percent from hydropower. This is generated from four hydroelectric power plants, one near the Slovenian-Hungarian border at Varazdin, and the other three are at Senj, Obrova and Zakucac, along the Adriatic Coastline. As a result of this heavy use of hydropower, Croatia has a relatively low rate of greenhouse gas emissions, given the prosperity of the country and the high automobiles ownership.

In 1992, Croatia was responsible for 3.7 metric tons per person of carbon dioxide, rising gradually to 5.3 metric tons per person in 2003. Of this, 65 percent comes from liquid fuels, 25 percent from gaseous fuels, 5 percent from solid fuels such as coal, and the remaining 5 percent from cement manufacturing. By sector, electricity production and transportation account for, respectively, 26 percent and 24 percent of all carbon dioxide emissions, with manufacturing industry accounting for another 19 percent, and other energy industries accounting for 12 percent.

Croatia became independent in 1991, and soon afterward it ratified the Vienna Convention. In May of the following year, it took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and signed the Kyoto Protocol to the UN Framework Convention on Climate Change on March 11, 1999. It was ratified eight years later, on April 27, 2007.

Justin Corfield
Geelong Grammar School, Australia

Croll, James (1821–90)

JAMES CROLL WAS a 19th-century Scottish scientist who developed a theory of climate change based on variations in the Earth's orbit. Croll was the leading proponent of an astronomical theory of climate change during the 19th century. Taking into account the precession of the equinoxes, variations in the eccentricity of the orbit, and tilt of the axis, Croll proposed that climate change must be the result of the relation of the Earth to the Sun.

He further speculated, "geological and cosmical phenomena are physically related by a bond of causation." Although his theory has often been criticized, it influenced the work of Serbian geophysicist Milutin Milanković and provided important insights into the interplay of astronomical and geological elements.

James Croll was the second son of David Croll, a stonemason, and Janet Ellis. He was born in the village of Little Whitefield, Perthshire, Scotland, on January 2, 1821. He grew up on a farm and received almost no formal education. However, Croll was attracted to philosophy and science from an early age and began to read widely in those subjects. He initially preferred those two disciplines to geology. Croll held a variety of odd jobs, including tea merchant, innkeeper, insurance salesman, and caretaker at the Andersonian College and Museum in Glasgow. All these jobs allowed Croll to read and write about his favorite subjects. His first book, *Philosophy of Theism*, was published in 1857, at the age of 36. This was followed by a number of scientific publications on electricity, heat, and most importantly, on astronomical controls on geological climate.

His paper, "On the Physical Cause of the Change of Climate During Geological Epochs," published in *Philosophical Magazine* in 1864, provoked the interest of leading scientists in Scotland and England. In this paper, Croll introduced changes in the Earth's orbital elements as periodic and extraterrestrial mechanisms responsible for the beginning of multiple glacial epochs. Croll argued that the eccentricity of the Earth's orbit was sufficiently great to explain every extreme of climatic change evidenced by geology. His theory of ice ages was built on the precession of the equinoxes and variations in the shape of the Earth's orbit. It forecast that one of the two hemispheres would experience an ice age whenever two conditions occur simultaneously: a markedly elongate orbit, and a winter solstice that occurs far from the Sun.

FELLOW OF THE ROYAL SOCIETY

In 1867, Croll accepted a job in Edinburgh with the Scottish Geological Survey as secretary and accountant. This employment came "more by accident than by choice," as Croll himself admitted. Croll's tasks included ordering, printing, coloring, and selling maps and keeping the accounts and stores in order. The director, Archibald Geikie, encouraged Croll to carry out his own research. In addition to his work on orbital theory, Croll made field excursions on glacial deposits and discovered a pre-glacial riverbed running from Edinburgh to Glasgow. Although in later life he suffered from severe headaches that limited his intellectual work, he still produced numerous papers on climate change, glacier motion, geological time, ocean currents, and astrophysics.

In 1875, Croll published his major book, *Climate and Time*, a work that his ill-health delayed by several years, but that, once published, was widely admired. The publication of this book led to his election as a Fellow of the Royal Society. The University of St. Andrews also awarded him an honorary degree. He was invited to lecture at the Royal Institution, but turned down the invitation due to ill-health and his reserved character.

He rarely attended the meetings of the British Society for the Advancement of Science. By 1871, Croll was growing increasingly dissatisfied with geological subjects and wanted to devote most of his time to the study of philosophy. In 1880, Croll retired from the Survey, expecting a full pension because of his advanced age. He was only given credit for 13 years of employment and saw his income drop dramatically. Because of this precarious financial situation, Croll was forced to give up housekeeping and go into rented lodgings.

During his retirement, Croll wrote two more scientific books: *Discussions on Climate and Cosmology* (1886), and *Stellar Evolution and its Relations to Geologic Time* (1889). The former was largely a reply to his critics and further developed his theory of the secular change of the Earth's climate.

His health increasingly deteriorating, Croll returned to his first love, philosophy, and saw the publication of his fifth book, *The Philosophical Basis of Evolution* (1890), a response to Darwinism and Spencerianism, in the year of his death. He died on December 15, 1890.

The astronomical theory of climate change emerged 1864–90 thanks to the work of James Croll. However, because of uncertainties in the timing of ice ages and in the stratigraphic record, and because Croll's theory envisaged glaciation in only one hemisphere, the theory was criticized and largely dismissed for at least three decades.

The astronomical theory reemerged from obscurity, thanks to the work of Milutin Milanković, who reformulated it into a mathematical theory 1920–41. Even in the case of Milanković's theory, consensus was far from unanimous because of thermal lags in the climate system and, in part, because of the unexplained lack of continental glaciation prior to the Pleistocene.

However, in 1976, the paleostratigraphic work of James Hayes, John Imbrie, Nicholas Shackelton, and others who documented the astronomical signals in a number of independent proxy climate records confirmed the theory.

Cuba

LOCATED IN THE Caribbean, the Republic of Cuba has a land area of 42,803 sq. mi. (110,861 sq. km.), with a population of 11,382,820 (2006 est.), and a population density of 102 people per sq. mi. (264 people per sq. km.). Traditionally, the Cuban economy has been closely tied to the tobacco and sugar industries (the latter still accounts for nearly half of the country's exports).

A total of 24 percent of Cuba is arable land, with a further 27 percent of the country devoted to meadows and pasture. Approximately 94.6 percent of electricity production comes from fossil fuels, mostly petrol sourced from Venezuela. Hydropower is responsible for only 0.4 percent of all electricity. Although there is low automobile use in Cuba, many of the automobiles in the country are older models with heavy fuel consumption, and many still use lead-based gasoline.

For this reason, the vast majority of the carbon dioxide emissions from Cuba (96 percent) are from the use of liquid fuels, while most of the remainder come from the manufacture of cement. By sector, electricity and heat production account for 39 percent of carbon dioxide emissions, with manufacturing and construction making up nearly 40 percent of the emissions, and transport only 7 percent, with residential use some 3 percent. About 24 percent of the country is forested, with much mahogany used for export, and cedar turned into cigar boxes.

Global warming and climate change have had the effect of raising the temperature of the waters in the Caribbean, and it seems likely that this trend will continue, along with higher average temperatures. These higher water temperatures are already having a detrimental effect on the fish in the Caribbean Sea, affecting the local fishing industry, which is the third most important industry in the country, after sugar and nickel.

The Cuban government ratified the Vienna Convention in 1992, and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. It signed the Kyoto Protocol to the UN Framework Convention on Climate Change on March 15, 1999, and ratified it on April 30, 2002, with it taking effect on February 16, 2005.

Culture

A FUNDAMENTAL CONCEPT in social sciences and philosophy, culture gathers all human productions of a specific group or society at a given moment. What is known as culture includes a given language, art and literature, history and traditions, religious beliefs, the media, and comprises the way people live and prepare food. Usually, groups recognize themselves and identify with their own culture. However, a culture is different from a civilization: for instance, the civilization of Ancient Greece does not exist anymore as all of its people are dead, but their culture remains accessible because of their monuments, art, and the knowledge of their philosophers and poets through books and translations. The same applies to the culture of the Ancient Egypt: modern Egyptians no longer believe in the ancient gods and goddesses, but there is still a fascination with ancient structures.

Today, what we know as the American way of life is understood to be the way most people in the United States live and consume, based on a system that encourages and values consumption. American tourists who travel to other countries discover many cultural differences while abroad. They may be surprised to find frogs and snails on the menu at France's finest restaurants, served by peopel who would never think of eating the American staple of peanut butter.

A culture is often specific to a country, a nation, or a group; culture is a part of a group's identity. Culture is not limited to the borders of a given country. For example, even Americans who visit Louisiana acknowledge the fact there is a unique culture and way of life in New Orleans. Whenever U.S. citizens go to England, they feel that although the language is quite similar, they are into a much different context: that difference is mainly cultural.

Understanding culture is essential to understand how individuals rely on their group or society. Cultural practices are studied by anthropologists, sociologists, and media experts. Strategists in marketing observe how people consume, and what motivates them to buy a product. In many cases, the strategies crucial to lessen society's effect on climate change, or to reduce greenhouse gas emissions, require a change in the way people live: partaking in recycling, using automobiles less frequently, carpooling, perhaps even choosing a job closer to home to reduce commuting distances.

The adoption of ideas such as "consuming creates global warming" contradicts the models of the consumer-based societies in which most individuals in industrial countries live.

The media are an essential part of our culture. A popular topic of social interaction is to discuss what they have seen on television, or what they have read in the newspapers. For instance, media experts have studied how a certain groups use television, particularly channels pertaining to the weather. Researchers have found that about 10 percent are obsessed by any unusual event related to the weather; they do not use forecasts as an instant information, but rather as a dramatized narrative about what could happen tomorrow.

The distinction between culture and ideologies are fundamental in philosophy and social sciences. To summarize, it could be said that the ideology is what you generally think and believe in, while culture is what you generally do. In other words, ideologies are a set of coherent ideas that are linked together, while culture is a set of practices related to a group. There are many opposing ideologies related to climate change and global warming: those who agree with the idea of climate change and those who reject the idea of a global warming. These beliefs are organized into ideologies that guide our attitudes, behaviors, and actions.

Although there are exceptions, most individuals try to act according to their beliefs. Whenever they do not, they usually become aware that their actions are not aligned with their convictions. For instance, a bus or truck driver might neglect to turn the engine's motor off while waiting for passengers for a long period, knowing that he is contributing to air pollution. The bus driver employed by the city would not be affected by wasting energy or consuming too much because he does not have to pay for the gasoline that is consumed. An independent, private truck driver may turn off the engine, because he pays for the fuel consumed.

CULTURE OF ENTERPRISES

Corporate cultures are a set of practices that are encouraged for employees during working hours at a given company. Some corporations will encourage

Children learn about the environmental at the U.S. Fish and Wildlife Service's San Luis National Wildlife Refuge. Researchers in the United Kingdom found in a 2007 study that 50 percent of children are anxious about the effects of global warming.

employees to take action to reduce consumption. For instance, in order to encourage employees who use their bicycles, corporations may upgrade their facilities to include bathrooms with showers. Other initiatives are created as well, sometimes within governmental policies, which can have an impact on workers who change or adapt their habits and behaviors.

MEDIA AND CULTURE

In his book, *Cultural Citizenship*, Toby Miller investigates the obsession that can be created by the weather for some of the population. He also analyzes sponsors for such programs and networks.

There have been numerous films touching on the subject of global warming, including *The Day after Tomorrow*, and *State of Fear*. The film *Waterworld* told the story of a flood that suddenly engulfed many countries. In 2006, a film titled *The Great Global Warming Swindle*, by Martin Durkin, challenged Al Gore's influential documentary, *An Inconvenient Truth*.

Books about global warming have been written especially for children. These books are not only tools for environmental education, but they demonstrate to the youngest readers that the idea of global warming is present. More than one generation of children have been taught about climate change and global warming in schools, and therefore echo these debates in their families and circles of friends. Many museums, not only those dedicated to science, organize exhibitions related to climate change and global warming.

The growing presence of news, debates, and narratives about climate change and global warming confirm that these issues are part of our culture, and are an element in every sphere of society, not only of importance in scientific research, or solely in the Arctic. These issues are debated by nonscientists, like politicians, citizens, environmental groups (such as Greenpeace), other nongovernmental organizations, and in the media.

Current

A CURRENT IS the ordered movement of a fluid in time. A number of different physical factors including tides, landslides, winds, horizontal pressure gradients, and changes in water density can put water into motion. Of these factors, regional winds, horizontal pressure gradients, and density changes can drive currents on basin-wide or global spatial scale. These moving water parcels, in turn, transport not only matter, but also heat. Therefore, changes in the strength or location of currents that cover sufficiently large distances can alter global climate.

Wind-driven currents are produced when winds transfer energy into the surface layer of the water column. Once the water is set into motion, the Coriolis force acts upon it, and the surface layer is deflected 45 degrees to the right of the wind stress in the Northern Hemisphere, and 45 degrees to the left of the wind stress in the Southern Hemisphere. Friction occurs between each of the infinite number of layers composing the water column. Therefore, as it moves deeper, the Coriolis force further deflects each layer, and its velocity is diminished. The depth at which the layer of water no longer is influenced by the wind is called the depth of frictional influence. The parcel of water from the surface to the depth of frictional influence is referred to as the surface Ekman layer. The surface Ekman layer flows 90 degrees to the right of the wind stress in the Northern Hemisphere, and 90 degrees to the left of the wind stress in the Southern Hemisphere. Movement of the surface Ekman layer can lead to a change in sea-surface height over a distance, producing the conditions favorable for geostrophic circulation.

Horizontal pressure gradients serve as another mechanism that causes and maintains large-scale ocean currents. The balance between the horizontal pressure gradient forces drives geostrophic currents, resulting from the change in sea-surface height and/or water density over a distance, and the Coriolis force. Variability in sea-surface height may be produced by winds, tides, or proximity to a coastal boundary. When a difference in sea-surface height occurs, water tends to flow "downhill," or move from areas of high to low pressure. Once in motion, the Coriolis force deflects the water until its motion directly opposes that of the horizontal pressure gradient. The net result is a geostrophic current flowing 90 degrees to the right of the pressure gradient force in the Northern Hemisphere, and 90 degrees to the left of the pressure gradient force in the Southern Hemisphere.

A combination of wind-driven currents and geostrophic flow sets up the circulation in ocean gyres, or ocean-basin scale (at least 621 mi. or 1,000 km.) circular currents. Subtropical gyres, or those that occur at mid-latitudes, are driven by a combination of westerlies and trade winds, which force them to flow anticyclonically. The eastern boundary currents of subtropical gyres can bring cool water toward the equator, and are relatively slow and diffuse. In contrast, western boundary currents, such as the Gulf Stream, are concentrated and fast, quickly transporting warm, salty water from the equator toward the poles.

In addition to winds and pressure gradients, changes in water density can drive global-scale ocean circulation. Thermohaline circulation, or meridional overturning circulation, results from sinking of high-density surface water. This sinking process is usually localized in the north and south Atlantic oceans. High-density water in these regions is made from both seasonal cooling of saline water, and freezing of sea ice. This dense water sinks, and moves equatorward. Because water mass and heat must be conserved, the equatorward movement of cold, dense bottom waters is compensated for with poleward movement of warm surface waters. It has been suggested that melting of ice sheets caused by global warming has already reduced, and will continue to decrease, the intensity of global thermohaline circulation and cause climate to change significantly.

In addition to global-scale circulation patterns, regional currents, such as those driven by upwelling and downwelling circulation, can affect local climate. Upwelling circulation occurs when surface waters diverge from either a coastal boundary or another water mass. To conserve mass, deeper, cooler water moves in to take the place of the surface water. An example of this is seen off the coast of California, where surface waters flow offshore and are replaced with cooler deep water. This leads to a well-mixed water column near shore, and, subsequently, a highly-productive marine ecosystem. Conversely, downwelling circulation occurs when water piles up along a coast or converges with another water mass and sinks. Downwelling is observed in the centers of subtropical gyres, leading to low primary production, or low phytoplankton growth there.

Currents may be measured or studied using two different approaches: Eulerian and Lagrangian methods. In a Eulerian approach, a stationary instrument is placed in the water, and currents at that location are measured over time. While an Eulerian design, such as a moored array of current meters, provides a detailed description of flow in a specific location and may resolve vertical current shear, it lacks spatial coverage, and cannot track water flow over long distances. In contrast, a Lagrangian method follows water parcel trajectories by employing instruments such as drifting buoys. This approach works well for producing realistic water parcel tracks, but must be repeated numerous times to account for the sensitivity of a particle track to its starting location. Historical changes in the strength and position of currents may be studied using paleoceanographic methods. One approach is to take sediment cores from regions throughout the world and compare the distribution of fossils of planktonic organisms over time. Variability of the ranges of species through time suggests long-term shifts in water temperatures or circulation, which may indicate changes in global climate.

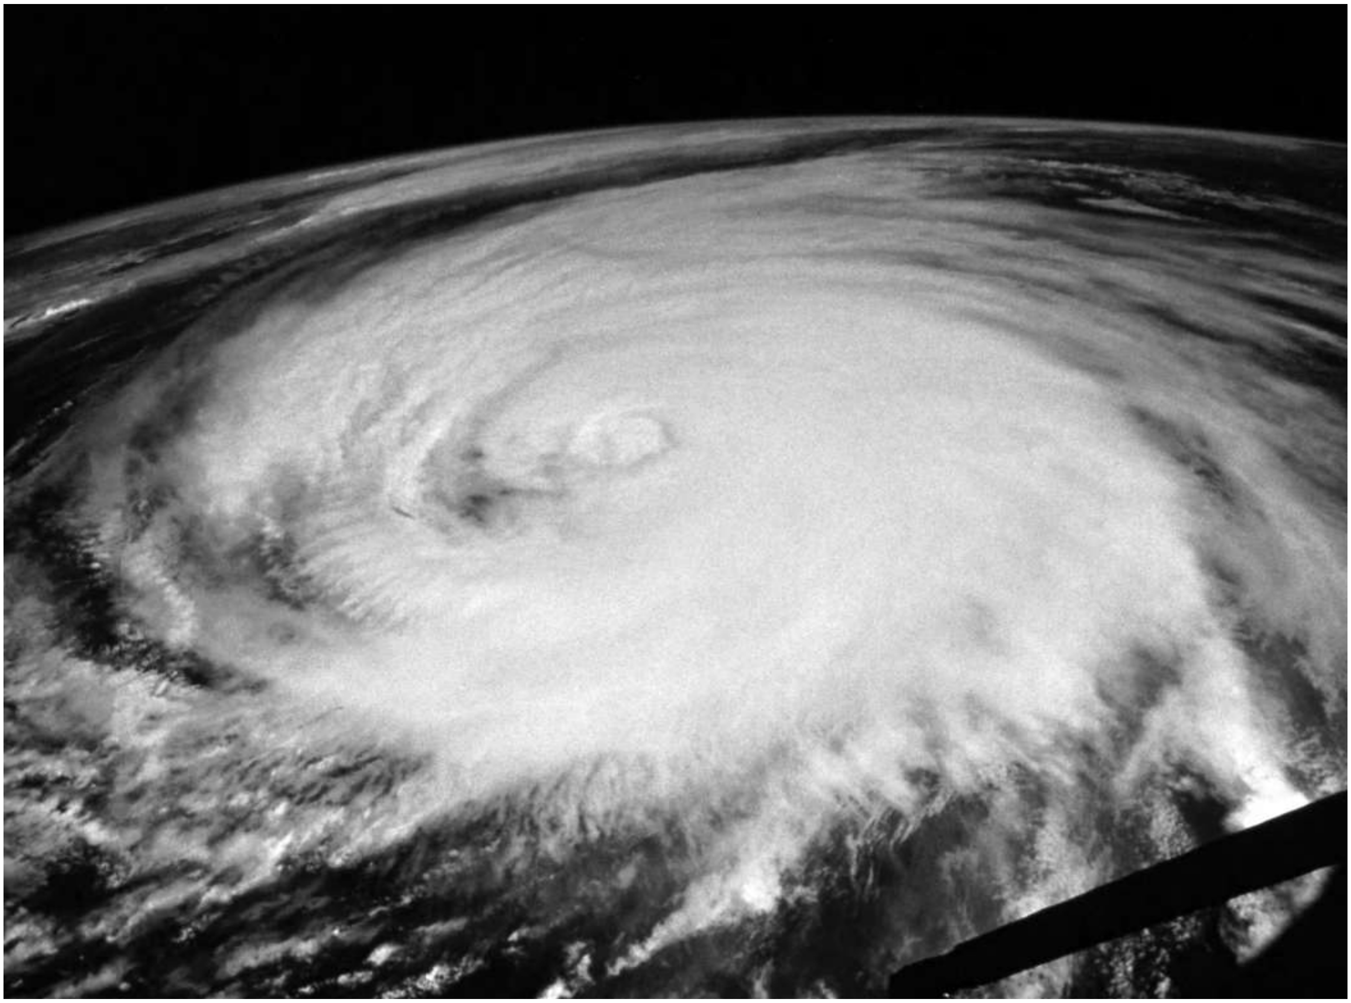
Cyclones

CYCLONES ARE METEOROLOGICAL systems consisting of areas of low pressure where the winds in the Northern Hemisphere and Southern Hemisphere rotate counter-clockwise and clockwise, respectively. The biggest storms around the world, such as cyclones, are intensifying. It is reported that the number of category four and five tropical cyclones, which are very intense, have increased over time. One reason for this is the impact of global warming, in particular, the effect of increased sea-surface temperature. Cyclones are often subdivided into other types, which include tropical cyclones and extra-tropical cyclones. Other types of cyclones include polar, polar low, subtropical, and mesoscale cyclones.

Tropical cyclones are low-pressure systems consisting of large rotating systems of clouds and winds, which occur over tropical and subtropical waters. They also have thunderstorm activity and cyclonic surface wind circulation. Depending on their location and strength, there are various terms by which tropi-



The number of category four and five tropical cyclones, which are very intense, has increased over time. One reason for this is the impact of increased sea surface temperatures due to global warming.

cal cyclones are known, such as hurricane, typhoon, tropical storm, cyclonic storm. and tropical depression. These cyclones have no fronts and the center of the storm is warmer than the surrounding air. They are known as tropical storms if the wind reaches 56 ft. (17 m.) per second and hurricanes if the winds reach 108 ft. (33 m.) per second. Hurricanes occur in the North Atlantic Ocean and the northeast Pacific Ocean, east of the dateline. There are several environmental conditions favoring tropical cyclones, such as warm ocean waters, winds that do not vary greatly with height, and a minimum distance of 311 mi. (500 km.) from the equator. There are seven tropical cyclone basins where storms occur on a regular basis. These are the Atlantic basin, Northeast Pacific and Northwest Pacific basins, North Indian basin, Southwest Indian basin, Southeast Indian/Australian basin, and Australian/Southwest Pacific basin.

Extratropical cyclones, sometimes called mid-latitude cyclones, are storms that form outside the tropics, sometimes as a tropical storm or hurricane changes, such that they have neither tropical nor polar characteristics. They form where cold and warm air masses come into contact with each other, and are formed in middle or high latitudes, in frontal zones. The center of the storm is generally colder than the surrounding air.

A subtropical cyclone is a non-frontal low-pressure system that has characteristics of both tropical and extratropical cyclones. Compared with tropical systems, they have a broad zone of maximum winds located further from the center. They also have a less symmetric wind field and distribution of convection.

They can be formed in a wide band of latitude, from the equator to 50 degrees both North and South. A subtropical cyclone is known as a depression if the winds reach wind speed of 38 mi. (62 km.) per hour or less and as a storm if the speed reaches 39 mi. (63 km.) per hour or more. Many times, these subtropical storms transform into true tropical cyclones.

There is another type of subtropical cyclone known as a mesoscale. This is a cyclonic vortex of air with an average diameter of 1–6 mi. (2–10 km.) within a convective storm. They are often associated with supercells, which are rare thunderstorms with a rotating updraft (current of rising air).

Some supercell thunderstorms can maintain themselves for several hours and are responsible for many extreme weather events, such as tornadoes. There are many other characteristics that are associated with supercell thunderstorms, such as a flanking line (a line of cumulus clouds) and a thunderstorm with back-shaped anvil (the flat top of a cumulonimbus cloud; back-shaped anvils have high severe weather potential).

A mesocyclone is an area of vertical atmospheric rotation, typically 2–6 mi. (3–8 km.) across. Mesocyclones are formed when change in wind speed or direction occur dramatically, with changes in height; this sets the lower part of the atmosphere spinning horizontally. Polar cyclones are low-pressure systems in which the air circulates counterclockwise in the Northern Hemisphere.

Usually, polar cyclones range from 60–600 mi. (96–965 km.) across, with surface winds of 30–100 mi. (48–160 km.) per hour. Polar cyclones may occur through any time of the year, however, as they usually occur in areas with little or no population, they are viewed as less destructive than other types of cyclones.

Cyprus

CYPRUS IS AN island in the eastern Mediterranean separated territorially between the Republic of Cyprus and the Turkish Republic of Northern Cyprus, an independent state formed in 1983, but only recognized by Turkey. Cyprus buffers the three continents of Europe, Asia, and Africa, in the Mediterranean basin.

The island presents diverse landscapes, including two mountain ranges, the central plains of Messariois, and a differentiated coastline. The political and territorial partition of the island shapes the fragmented contemporary national environmental response to climate change and pollution.

The exodus of a large number of refugees from the north of the island, following the Turkish deployment of troops in 1974, triggered rapid development of the Greek-Cypriot region, a process notable in the construction of a vibrant tourist industry, which has evolved from attracting mass tourism to targeted flows of visitors seeking first-class amenities. This led to the construction of golf courses, swimming pools, and elite resorts, resulting in disturbed wildlife habitats and increased demands on scarce natural resources, including water. A large military environmental footprint also disturbs fragile resources.

The growth in the tourist sector and expanding material wealth has created challenges in controlling waste management, including industrial, human, and animal waste. The expansion of the Port in Limassol, and the escalation of sea freight generated by exports to other European Union members, has generated marine pollution beyond the Akrotiri Bay from ballast and foreign algae, which is degrading the wider coastal environment. Water is a key resource issue in Cyprus. Having no extensive natural reservoirs or water catchments, groundwater contamination from agriculture and surface contamination linked to industrial pollution in chemical substances and aggressive organic compound emissions, are compromising the sustainability of freshwater reserves. Lower rainfall linked to climate change is producing droughts.

The Republic of Cyprus's membership in the European Union and its need to comply with environmental legislation in air quality and emission standards is producing positive change. Various bodies, such as the Petitions Committee within the European Parliament Health, frequently debate issues related to expanding technologies (for example, mobile telecommunications masts), but progress is often uneven and contentious. In the Turkish sector, domestic water supplies are often precarious, culminating in serious supply issues that impact public health.

POLLUTION CONTROL

With border restrictions increasingly relaxed, and a willingness from the Turkish Republic of Northern Cyprus to become a member of the European Union, it is possible that coordinated policies on specific issues will stem the challenges arising from climate change. The increased tourist flow, however, to the northern part of the island, and improved living standards, will place additional demands on existing resources. For the island as a whole, there is no generic strategy that controls the management of policies on water sustainability, pollution arising from industry, and expanded marine pollution control.

Czech Republic

FORMERLY THE WESTERN part of Czechoslovakia, in Central Europe, the Czech Republic has a land area of 30,450 sq. mi. (78,866 sq. km.), with a population of 10,306,709 (2006 est.), and a population density of 337 people per sq. mi. (130 people per sq. km.). Approximately 41 percent of the land is used for arable purposes, 11 percent for meadows and pasture, and 34 percent is forested. In 1992, the Czech Republic recorded per capita carbon dioxide emissions of 13.1 metric tons per person, which had fallen to 11.4 metric tons per person by 2003. Some 67 percent of the carbon dioxide emission comes from solid fuels, with coal providing much of the electricity production in the country.

About 77.8 percent of the electricity comes from the burning of fossil fuels, with 18.5 percent from nuclear power, and only 2.5 percent from hydropower. Most of that hydroelectricity comes from the Dalescie Dam, located on the Jihlava River, which was built 1970–78.

Liquid fuels account for 16 percent of the country's carbon dioxide emissions, with 15 percent from gaseous fuels. By sector, electricity production accounts for 54 percent of carbon dioxide emissions, with manufacturing and construction industries causing 23 percent, and transportation, 10 percent, despite a good public transport system, the use of electric trams, and also the heavy promotion of carpooling, cycling, and car-free parts of some towns and cities. The Czech government of Václav Klaus took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and the government of Václav Havel signed the Kyoto Protocol to the UN Framework Convention on Climate Change on November 23, 1998. It was approved by the Czech parliament on November 15, 2001, and took effect on February 16, 2005.

David Suzuki Foundation

THE DAVID SUZUKI Foundation is an independent Canadian charity, based in Vancouver, British Columbia, which has worked since 1990 to protect biological diversity and quality of life. Through science and education, the foundation works broadly to advance principles of sustainability. Dr. David Suzuki, one of Canada's best-known contemporary environmental advocates, built his career first as a geneticist, and then as a broadcaster, journalist, and popular educator. In November 2004, Dr. Suzuki was voted fifth in the Canadian Broadcasting Corporation's (CBC's) Top Ten Greatest Canadians. Other significant awards include: 15 honorary doctorate degrees, a United Nations Educational, Scientific and Cultural Organization (UNESCO) prize for science, a United Nations Environment Program medal, various honors from Canada's First Nation peoples, and induction as an Officer of the Order of Canada (Canada's highest civilian honor for outstanding lifetime achievement).

Dr. Suzuki has hosted the CBC's award-winning *The Nature of Things* since 1979, and excels at relaying scientific concepts to the lay public. Much like other environmental icons (notably, Rachel Carson, Carl Sagan, and E.O. Wilson), Suzuki has helped to shift popular consciousness in favor of environmental protection. He founded the David Suzuki Foundation, in 1990, to identify and advance new ways for society to live in greater harmony with the natural world. Supported by donations from approximately 40,000 individuals from across Canada and around the world, and by grants from other charitable organizations, the foundation does not generally accept government grants (though some scientific research is funded directly through the National Sciences and Engineering Research Council of Canada).

The David Suzuki Foundation is one of a number of key nongovernmental organizations that seek to advance a sustainability agenda. To this end, the foundation collaborates with scientists and academics, as well as representatives from business and industry, government, and other nongovernmental organizations. Ultimately, the foundation adopts an integrative and pragmatic approach to environmental protection, supporting a clean, competitive economy that does not undermine the ecological services upon which it ultimately depends.

The foundation regularly critiques Canadian environmental policies and programs, and puts forward innovative solutions to promote greater eco-efficiency, full-cost accounting, and closed-loop manufacturing. The foundation operates five interrelated program areas: protecting human health, conserving our oceans, promoting global conservation, building a sustainable economy, and solving global warming.

The David Suzuki Foundation works toward evaluating impacts, mitigating risks, and positing creative solutions to the impending challenges of climate change. Above all, substantial reductions in greenhouse gases require a fundamental shift in the ways in which energy is produced and consumed. The foundation has advocated strongly for Canada to meet its international commitment to adhere to the United Nations Kyoto Protocol on greenhouse gas reductions. The foundation has actively published on climate change since 1997, and in 2002 jointly commissioned *The Bottom Line on Kyoto: Economic Benefits of Canadian Action*, and *Kyoto and Beyond: The Low Emission Path to Innovation and Efficiency*. The foundation challenges global warming skeptics, and seeks to shed light on their underlying motives by drawing explicit attention to their funding.

The foundation encourages organizers of large public gatherings, including conferences, sports events, concerts, festivals, celebrations, and conventions, to be carbon neutral by mitigating and offsetting greenhouse gas emissions. Climate-friendly practices (such as waste minimization and energy and water conservation) can be consciously integrated into virtually every aspect of an event, from the choice of venue, to policies around registration, transportation, food and beverage services, and procurement. Remaining emissions can be offset, rendering the event effectively carbon neutral. In so doing, event organizers demonstrate environmental leadership, with a view to inspiring others to take comparable steps. Multiple benefits ensue, including reduced costs, improved public image, and mitigated emissions. The foundation also encourages people to fly less, and to opt, instead, to connect virtually (through videoconferencing or webcasting), and to vacation close to home.

The foundation's Nature Challenge has spurred some 341,142 individuals to critically examine their lifestyle choices around food, transportation, and energy use. Participants opt to: reduce home energy use by 10 percent (for example, by installing low-flow showerheads and faucets); buy an energy efficient home and appliances, and a fuel-efficient vehicle; eat locally-grown, seasonal, organic foods that are low on the food chain; walk, bike, carpool, or take public transit; and live in close proximity to work or school. All of these actions are framed as simple solutions to help fight global warming. David R. Boyd's *Sustainability within a Generation* explores at length the foundation's vision for transforming human-environment relations. This document examines root causes for Canada's unsustainable ways (that is, an economy that relies almost exclusively on consumption of energy and natural resources), and identifies critical goals and necessary policy shifts toward a more prosperous, just, and sustainable future.

Deforestation

THERE ARE VARIOUS definitions of deforestation. The United Nations Food and Agriculture Organization (FAO) defines deforestation as:

> A non-temporary change of land use from forest to other land use or depletion of forest crown cover to less than 10 percent. Clear cuts (even with stump removal) if shortly followed by reforestation for forestry purposes are not considered deforestation.

According to the FAO there were 3,952 million ha. of forestland in the world in 2005. The most forested countries in the world are the Russian Federation, with 808.79 million hectares (ha), followed by Brazil with 477.70 million ha, and Canada with 310.13 million

Deforestation caused by agriculture, logging, fuelwood use, and cattle ranching releases approximately 1.7 Pg of carbon a year.

ha. According to the FAO, deforestation occurred at a rate of 8.87 million ha (–0.22 percent) a year 1990–2000, and 7.32 million ha (–0.18) a year 2000–05. The country with the highest deforestation rate is Brazil, with 2.68 million ha a year 1990–2000, accelerating to 3.1 million ha a year 2001–05. The second is Indonesia, with 1.87 million ha deforestation a year 1990–2005. The country with the largest gain in forest area is China, with 1.99 million ha a year 1990–2000, and 4.06 million ha a year 2001–05.

The Rainforest Alliance has estimated that, globally, the main causes of tropical deforestation are land clearing for agriculture (64 percent), logging (18 percent), fuelwood collection (10 percent), and cattle ranching (8 percent). However, the amounts vary geographically and temporally. Fuelwood collection is particularly destructive in dry lands or high altitudes because of slow natural regeneration rates, while cattle ranching is estimated to cause up to 60 percent of the forestland clearance in Central and South America. The exact proportions of each cause of deforestation are also difficult to estimate because land might be used for multiple purposes. While forests might be cut for the logs, the land can then be used for agriculture or cattle ranching.

According to H.J. Geist and E.F. Lambin, the underlying causes of deforestation include: the unequal access to land by the rural poor; the high debt of many developing countries; unsustainable farming practices, especially in tropical countries; unsustainable land tenureship rules that give ownership of land to those who clear it; and the demand for cheap beef for the fast food industry, which in Central and South America generates demand for both cattle ranching and soybean production to feed cattle in North America and Europe.

The consequences of deforestation are global and local: including atmospheric pollution, release of CO_2, climate change, disruption of the hydrological cycle, disappearance of wildlife, soil erosions, and landslides. Deforestation, mainly in the tropics, is estimated to release approximately 1.7 petagrams (Pg) of carbon (C) per year (one Pg is one thousand million metric tons). With a small amount of uptake (about 0.1 Pg C) in temperate and boreal areas, deforestation releases around 1.6 Pg of carbon per year. This can be compared to the carbon released by burning fossil fuel, which is currently at about 7 Pg C per year.

While tropical deforestation is an important source of atmospheric CO_2, the Kyoto Protocol only gives carbon credits for the CO_2 that is sequestered by forest plantations, not for the CO_2 that is retained by natural forests. A post-Kyoto protocol is expected to address this problem by giving credits for the carbon retained by natural forests, so as to increase the economic costs of deforestation, according to R. Sedjo.

Delaware

THE FIRST OF the 13 original states to ratify the Constitution of the United States, Delaware ranks 45th in population among the states in the United States, although it is the fourth most densely-populated state. Delaware's energy consumption reflects the same pattern. Total consumption is among the lowest in the United States, 47th in rank, but per capita energy consumption is disproportionately high. In 2003, the state ranked 17th highest among the 50 states. Delaware's high consumption of energy can be attributed, in large part, to its energy-intensive industries such as chemical production and paper and plastic products. Ground-level ozone concentrations are at dangerous levels throughout the state.

Delaware, according to records of the Environmental Protection Agency, is one of the nation's leaders in releases of mercury, dioxin, polychlorinated biphenyls, and vinyl chloride, all among the most toxic substances released by industry. Among the companies most frequently named as the leading polluters in the United States, more than 50 percent of them now operate, or have operated, in Delaware. The state spent more than $29 million in 2007 cleaning up contaminated sites.

Carbon dioxide emissions from industry has decreased modestly from 1990 to 2004. Industry continues to be the state's leading consumer of energy, at almost 40 percent, which is nearly double that of the transportation sector. Most of that energy comes from fossil fuels. Transportation, saw only a slight decrease in CO_2 emissions from 1990 to 2004. The state has taken some action to reduce emissions more substantially in the future. Delaware has a vehicle inspection and maintenance program that is in compliance with Clean Air Act policies. The state requires the statewide use of reformulated motor gasoline blended with ethanol, one of the few states to do so. The state's mass transit system is ranked the eighth best in the nation.

COASTLINE AND WETLANDS

Rising sea levels and the accompanying problems are major concerns, as every part of Delaware is within 20 mi. (32 km.) or less of the Atlantic Ocean or the Delaware Bay. Sea level is already rising by 12 in. (30 cm.) per century in some parts of the state, and beach erosion is a growing problem along the state's 381 mi. (613 km.) of shoreline. Delaware made early efforts to respond to the problems of global warming. Legislation to protect shore areas was passed as early as the 1970s, and in 2000, a State Climate Action Plan that placed the state in line with the Kyoto Protocol called for a 7 percent decrease in greenhouse gas emissions from a 1990 baseline. However, amendments weakened coastline protection, and the state has been slow to act upon the recommendations of the Climate Action Plan.

Delaware limits construction on its coastline, and it has spent millions in federal and state funds restoring beaches that have eroded. But shoreline erosion continues, and researchers believe it will only intensify as sea levels rise from global warming. Sand replenishment will become a never-ending and increasingly expensive project. Delaware Bay, the large semi-enclosed inlet of the Atlantic Ocean at the mouth of the Delaware River, is a major spawning ground for horseshoe crabs and the site of the second largest concentration of migratory shorebirds in the western hemisphere, with approximately 1.5 million shorebirds passing through the bay area each spring. The area also supports a number of endangered and threatened species including the bald eagle, the peregrine falcon, and the short-eared owl. Changes to habitat wrought by global warming threaten all these species.

Rises in sea level have already changed the composition of salt marshes and decreased the number of ducks and geese. Between the 1880s and the 1980s, Delaware lost more than 50 percent of its wetlands. The Clean Water Act, combined with the state legislature's measures to protect the wetlands, decreased the rate of loss, but development pressures continue, and rising sea levels could pose an even greater threat to this resource.

GOVERNMENT ACTION

One of the measures that Delaware's 2000 Climate Action Plan called for was a renewable portfolio standard and a strategy to switch to low-carbon fuels. Without this change, the committee felt that the state was unlikely to reach its goal of greenhouse emissions reduction, a goal that required the state to reduce emissions by 15 to 25 percent over what was then a 12-year period in order to meet the 7 percent reduction target based on 1990 figures. In 2003, Delaware, along with Connecticut, Maine, New Hampshire, New Jersey, New York, and Vermont, became one of the original seven states to participate in the Regional Greenhouse Gas Initiative (RGGI), the first cap-and-trade program to control CO_2 emissions in the United States. A primary goal of the collaborative effort is to reduce CO_2 pollution through a mandatory emissions cap on the electric generating companies, the heaviest contributors to pollution.

In summer 2007, Delaware took the state's most decisive steps toward addressing the problems of global warming and climate change. In late June, Governor Ruth Ann Minner signed Senate Bill 18 and created a Sustainable Energy Utility, a state-supervised nonprofit organization. The bill was based on a concept developed, in part, by John Byrne, distinguished professor of public policy, director of the University of Delaware's Center for Energy and Environmental Policy, and a member of the Intergovernmental Panel on Climate Change (IPCC). The plan proposes to cut CO_2 emissions to 2003 levels through conservation and innovative use of renewable energy sources, and save the average Delaware household $1,000 a year in the process.

A month later, Governor Minner signed a bill that increased the state's existing renewable portfolio standard by requiring that 2 percent of the state's electricity supply come from solar photovoltaics by 2019, in addition to 18 percent from other renewable sources by the same date. The other sources may include wind, ocean tidal, ocean thermal, fuel cells powered by renewable fuels, hydroelectric facilities with a maximum capacity of 30 megawatts, sustainable biomass, anaerobic digestion, and landfill gas.

Denmark

DENMARK IS A small, flat, highly-industrialized country with a population of 5.4 million (2006 est.). A member of the European Union, it is situated in the northern part of the European continent and is nearly surrounded by the sea. Denmark normally experiences relatively cold summers and warm winters, which places Denmark in the temperate climate zone. The country's greenhouse gas emissions amount to 62.5 million metric tons of CO_2 equivalents (2005 est.). The primary sources of Danish greenhouse gas emissions are energy (51 percent), transportation (27 percent), agriculture (16 percent), and industry (4 percent).

This windmill in Denmark is part of the country's ongoing effort to cut its CO_2 emissions, which fell 7 percent 1990–2005.

Since 1870, the average Danish temperature has risen by 1.8 degrees F (1.0 degree C), and annual precipitation by 4.33 in. (110 mm.). Scientists expect that the climate of Denmark will become warmer, wetter, and windier; changes that will have consequences for agriculture, an important sector in Denmark. Crops will change and farmers will achieve higher yields. On the other hand, there would potentially be a need for increased fertilizer application, as higher rainfall would lead to higher nutrient loss. Increasing the application of fertilizers would have negative implications for the ecological quality of lakes and watercourses.

Predictions are that before 2100, the temperature of seawater surrounding Denmark will rise 5.4–9 degrees F (3–5 degrees C) and the sea level around the Danish coastline will rise approximately 19.7 in. (50 cm.). If this proves true, improved coastal protection will be required. Furthermore, biodiversity will be affected. Some Danish species will disappear, and new species will arrive. Ecosystems, for example the protected Wadden Sea, may be seriously impacted by rising sea levels.

At the end of the 1980s, environmental matters topped the electorate's agenda for the first time. From 2000 until 2006, both the electorate's and politicians' attention had shifted away from environmental matters. However, a new awakening occurred during fall 2006. Suddenly, newspapers reported that the climate change issue had skyrocketed on the electoral agenda.

A public opinion poll showed that 14 percent of the electorate perceived climate change as the most important political problem to solve, and that 12 percent considered the issue as the second most important political problem. Furthermore, 75 percent of the respondents agreed that Denmark should be a front-runner in solving the climate change problem, even if there are substantial costs involved. Another opinion poll, in February 2007, showed that 80 percent of respondents recognized that they had joint responsibility for climate change problems, and 86 percent believed that every Dane had a responsibility to save energy to reduce climate change problems.

Denmark signed the United Nations Kyoto Protocol in 1998, and ratified the agreement in 2002. According to the Kyoto Protocol and the EU Burden Sharing Agreement, Denmark is committed to reducing greenhouse gas emissions by 21 percent during the period from 1990 to 2008–2012. Denmark has succeeded in cutting total greenhouse gas emissions by 7 percent 1990–2005 (calculated according to the IPCC guidelines), despite the fact that emissions from transportation have increased significantly. The reductions have been reached, for instance, by introducing a CO_2 tax in 1992, which, according to an evaluation, has proven that environmental improvements are possible without sacrificing economic welfare.

Furthermore, Denmark has increased the production of renewable energy from offshore windmills, and Denmark has joined the European Union's scheme for climate gas emission trading. Finally, the Danish government emphasized the Kyoto Mechanisms, Joint Implementation and Clean Development Mechanism projects, as cost-effective means to reach the Danish reduction goal. Therefore, resources have been set aside to buy CO_2 credits through these mechanisms. Denmark is hosting the UN climate summit (COP 15) in 2009 in Copenhagen.

Department of Defense, U.S.

THE U.S. DEPARTMENT of Defense (DOD) is the largest employing organization in the country. It serves in the management and organization the United States Armed Forces and actively works to maintain environmental responsibility while fostering global security. In the United States, the Department of Defense also manages its lands that are federally-owned. As of the mid-1990s, 39,063 sq. mi. (101,173 sq. km.) of U.S. land were owned by the military and, therefore, the Department of Defense.

In an effort to protect the environment, the Department of Defense began cutting back its energy usage in the mid-1980s. Furthermore, it actively reduced the amount of greenhouse gases emitted due to Department activities, in recognition that greenhouse gases have an impact on climate change. The Department of Defense also assisted with research to develop safe alternatives for ozone-depleting chemicals, such as halon. Additionally, by the mid-1990s the DOD had achieved and passed the goal for limited chemical usage amounts as outlined by the Montreal Protocol. The DOD worked with the Environmental Protection Agency (EPA) to reach these goals before the Montreal Protocol's suggested deadline.

In recognition of these extensive efforts to protect the environment, the EPA honored the Department of Defense and Secretary of Defense William S. Cohen, with its Best-of-the-Best Stratospheric Ozone Protection Award. This Award was given at the September 25, 1997, EPA Awards Ceremony. In fact, at the awards ceremony, the EPA Administrator Carol Browner announced that the Department of Defense was the leading world organization in terms of quantity of awards from the EPA, for ozone layer protection. At this ceremony, the Department of Defense and other award recipients were named as "Champions of the World".

In acceptance of the Stratospheric Ozone Protection Award, Secretary Cohen stated that aligning environmental stewardship with national security was a chief priority of the Department of Defense. In fact, out of the 71 awards given at the ceremony, one-fifth went to members of the military community, including military organizations, contractors, and the employees of both. At the awards ceremony, Carol Browner said the following words that outline the EPA's and Department of Defense's stance on global warming; she later stressed that global warming could be fought without economic disaster.

> More than 2,000 of the world's foremost experts on the global environment, internationally recognized scientists, are telling us that there is ample evidence that for the first time in history, pollution from human activities is, in fact, changing the Earth's climate. Modern industrial activity, particularly the burning of fossil fuels, coal, petroleum products, is filling the atmosphere with carbon dioxide and greenhouse gases. These gases trap the sun's heat in the atmosphere and cause the steady, gradual warming of the earth's surface temperature. The average surface temperature is slowly rising, and the scientists tell us that there will be devastating consequences to our environment within the next 100 years. They're predicting more frequent, more intense heat waves; thousands more heat-related deaths; severe droughts; floods will become more common; tropical diseases like malaria will expand their range; agricultural production will suffer; the oceans will rise perhaps by several feet over the next century swamping many coastal areas. This will be our legacy to our children if we do not look for some way to begin reducing our emissions of greenhouse gases.

As of the late 1990s, the Department of Defense was researching new aircraft that would use less fuel, while being more energy-efficient. These aircraft were being researched at many institutes, including the U.S. Army, U.S. Navy, U.S. Air Force, the National Aeronautics and Space Administration (NASA); the Defense Advanced Research Projects Agency (DARPA), and engine companies in the United States.

PIVOTAL AGENDA POINTS

On June 2, 2007, Secretary of Defense Robert M. Gates answered questions at the Shangri-La Security Conference. This conference focused on assisting the development of Asian nations, such as India and the Pacific nations, and connecting them with the rest of Asia. A principal goal of the conference was to foster maritime security in the Asian Pacific. Participating nations came from the Asian Pacific nations as well as Canada, the United Kingdom, and the United States. In an answer to a question regarding the projected key issues in the United States–Asian Pacific (mainly Singapore), relationship for the year 2011, Secretary Gates responded that, in the future, the environment and, particularly, global warming will be pivotal agenda points.

Maritime security and the impacts on it from global climate change are a concern at the Department of Defense.On September 26, 2007, in an article from the American Forces Press Service regarding the increased use of sea transport for trade due to growing shoreline populations around the world, the Department of Defense acknowledged that a Northwest Passage, a maritime route via the northern North American coastline through the Arctic Ocean, had opened. This new passage opened due to climate change.

To advise the U.S. President about current and novel science and technology related to climate change, the Secretary of Defense as well as the Secretary of Commerce alternate in heading a committee known as the

Committee on Climate Change Science and Technology Integration (CCCSTI).

The Department of Defense has had a long history—older in fact than the United States. At the time of the American Revolution in 1775, the group of colonies that would soon become the United States of America established an Army, Navy, and Marine Corps. By 1789, the government recognized the need for a centralized office for these military programs, and thus, established the War Department. The War Department would eventually become the Department of Defense nearly 200 years later.

1790 saw the generation of the Coast Guard, which now acts to maintain homeland security in times of peace. Eight years later, in 1798, a separate Department of the Navy was formed. It was not until the year 1947 that a civilian position was set up by Congress to act as Secretary of Defense, initially intended to serve in the Presidential Cabinet. The War Department became the Department of the Army, and the U.S. Air Force separated from the Army into its own division. The three branches of the new Department of Defense became the Army, Navy and Air Force. In the year 1949, the Department of the Army officially became the official DOD.

Claudia Winograd
University of Illinois at Urbana–Champaign

Department of Energy, U.S.

THE MISSION OF the U.S. Department of Energy is: "to advance the national, economic, and energy security of the United States; to promote scientific and technological innovation in support of that mission; and to ensure the environmental cleanup of the national nuclear weapons complex." To achieve this mission, the Department of Energy (DOE) has outlined five strategic themes: energy security, nuclear security, scientific discovery and innovation, environmental responsibility, and management excellence.

To the DOE, environmental responsibility most generally means responsibly protecting the environment from the impact of production of nuclear arms. Therefore, a chief role of the Department of Energy within the environmental sector is to clean and decontaminate sites of nuclear power production or use. To advise the U.S. president about current and novel science and technology related to climate change, the secretary of defense as well as the secretary of commerce alternate in heading a committee known as the Committee on Climate Change Science and Technology Integration (CCCSTI), not the secretary of energy. Within the Department of Energy, the Office of Fossil Energy manages plans to reduce carbon emissions.

WATCHDOG OFFICE

The Office of Policy and International Affairs, a part of the Department of Energy, is the watchdog office for climate change. Within this Office, there are six initiatives regarding global warming and climate change. These initiatives are the Carbon Sequestration Leadership Forum, the Clean Energy Initiative, Climate VISION, Greenhouse Gas Reporting Guidelines, the Security and Prosperity Partnership / North American Energy Working Group , and the U.S. Climate Change Technology Program.

The Carbon Sequestration Leadership Forum (CSLF) is composed of a group of nations that produces approximately three quarters of the man-made global carbon dioxide emissions. It was established in 2003. This voluntary membership forum was recognized by the G-8 summit in July 2005 as a key mediator of international communication regarding the climate and climate change. This recognition was in the Gleneagles Plan of Action on *Climate Change,* *Clean Energy and Sustainable Development.* By combining economics, industry, and research, the CSLF works to limit the amount of carbon dioxide release into the atmosphere. It does so in accordance with the United Nations Framework Convention on Climate Change. One plan is to store carbon instead of releasing it; carbon would be stored in the spaces left behind by underground oil fields as they are depleted. Initial research carried out by the DOE has suggested that these deep geologic storage chambers could store carbon produced within the next several centuries. Storage could also take place in geologic formations such as unmineable coal seams, global saline reservoirs, and basalt formations.

WORLD SUMMIT

The Clean Energy Initiative is overseen by the Office of International Energy Market Development, within the Office of Policy and International Affairs. The Initiative was announced by the United States at the September, 2002 World Summit on Sustainable Development, which took place in Johannesburg, South Africa. It was led by the United States, with participation from nations around the globe. There are three partnerships to address the chief headings within the Initiative: the Efficient Energy for Sustainable Development Partnership, the Global Village Energy Partnership, and the Healthy Homes and Communities Partnership.

Climate VISION stands for Voluntary Innovative Sector Initiatives: Opportunities Now. It was established on February 12, 2003, nearly one year after President George W. Bush announced on Valentine's Day of 2002 that he would reduce United States greenhouse gas emissions by 18 percent before the year 2012, without harming the economy. Climate VISION has five chief purposes: to develop methods for reducing greenhouse gas emissions and share these technologies, to develop ways to quantify greenhouse gas emission reduction and sequestration, to develop an infrastructure to promote usage of emission reduction technologies in the commercial sector, to develop a means by which energy consumers can reduce their carbon footprints, and to acknowledge voluntary public or private participation in emissions reduction.

A key partnership in the Climate VISION program is called the APP, for the Asia-Pacific Partnership between nations of this global region (Australia, China, India, Japan, and the Republic of Korea) along with Canada and the United States. The APP works to ensure that as these Asian nations develop, they will incorporate clean, environmentally-safe technologies into their public and private industries.

Greenhouse Gas Reporting Guidelines were updated in early 2007 and made accessible to the public on April 2, 2007. The complete name of the document is *The General Guidelines for the Voluntary Reporting of Greenhouse Gases (1605(b)).* These guidelines are under the auspices of the DOE and are part of the Code of Federal Regulations.

The Security and Prosperity Partnership (SPP) /North American Energy Working Group (SPP/NAEWG) is a partnership between the secretaries of energy of Mexico and the United States and the minister of natural resources of Canada. This partnership was first established in early 2001. The SPP was established by the presidents of Mexico and the United States and the prime minister of Canada on March 23, 2005. It works to promote environmental responsibility in policies, as well as protecting the food supplies of North America and preventing the spread of disease. There are three foci of the NAEWG: market facilitation, clean energy, and technology. Within each focus are initiatives and priorities that any country can propose, but all three must approve.

CLIMATE CHANGE TECHNOLOGY

The U.S. Climate Change Technology Program (CCTP) mission is: "to stimulate and strengthen the scientific and technological enterprise of the United States, through improved coordination of multiagency federal climate change technology programs and investments and, in partnership with others, provide global leadership to accelerate the development of new and advanced technologies that would attain its vision." It was established by President George W. Bush.

In September 2007, the secretary of the Department of Energy appointed a new position for a director of a new Office of Indian Energy Policy and Programs. This new office and director were given the responsibility of assisting Native Americans in learning about, establishing, and maintaining efficient energy sources.

Along these lines, the office was set to manage a $2 million grant for promoting renewable energy sources that would be used by 15 pre-selected Native American nations, including Alaskan villages. Of these 15 groups, nine will begin to establish renewable energy sources, while the other six will research the feasibility of such a project on their lands.

The Department of Energy's Solar Energy Technology Program recognizes that burning of fossil fuels releases carbon dioxide and other greenhouse gases that contribute to global warming. This program, part of the Office of Energy Efficiency and Renewable Energy, therefore, works to make clean solar energy available to regions that previously relied on fossil fuels.

Specifically, the program champions photovoltaic (PV) energy converters that transform solar energy into electricity via superconductors. The program also investigates the themes of concentrating solar power to run turbines that would generate electricity, solar heating whereby solar energy is used to heat water or building spaces, and solar lighting which integrates directed natural sunlight into building lighting schemes.

A major initiative of the Office of Energy Efficiency and Renewable Energy is the Solar America Initiative, which aims to bring photovoltaic energy technology up to par with current fossil fuel technologies, so that it will be cost-competitive by the year 2015.

University of Illinois at Urbana-Champaign

Department of State, U.S.

THE AREAS OF responsibility of the Department of State are the United States' foreign policy. Also, how foreign policy may impact U.S. security. Therefore, its interests in global warming and climate change are only to the degree that these phenomena may affect international policy or national security.

According to a June 2007 Report to Congress, called *The Senator Paul Simon Water for the Poor Act 2005 (P. L. 109-121)*, "Climate variability is a measure of the degree to which rainfall and temperature vary across seasonal, annual, interannual and even interdecadal time periods compared with a long-term regional climate mean. Climate change refers to long-term, sustained changes in the climate mean itself." This document states that United States' interests in climate change is strategic because climate change affects water levels, cleanliness, and its availability to poorer nations. The long-term impact of inadequate water in these nations could affect United States' interests, because this could negatively impact their public health which could create unstable governments.

President Bill Clinton strongly supported environmental responsibility. His administration created a new Department of State position to watchdog international environmental conditions, the Undersecretary for Global Affairs. In this way, the foreign policy of the U.S. became concerned with the environment and its stewardship. The position of Undersecretary for Global Affairs was first given to Timothy E. Wirth, a former green senator from Colorado. Wirth served in this position from 1993 until 1997. Following with this environmentalist spirit, Secretary of State Warren Minor Christopher issued a statement on February 14, 1996, stating that U.S. foreign policy would, from that point on, keep the environment and its care in focus, and that Department of State officials must consider this focus when designing international policies or meetings. Like Wirth, Christopher served in his position between the years 1993 and 1997.

A chief concern of President George W. Bush, along with the Department of State, is the reduction of the U.S. dependence on foreign oil. As a fortuitous side effect, through the investigation of other routes of energy generation, science and technology lead towards energy sources that are cleaner and more environmentally responsible than the burning of fossil fuels. In May 2007, President Bush pledged to have a plan by the end of the year 2008, which would encompass an international effort to reduce climate change, with efforts to begin in the year 2012. Countries involved would be major developed and developing countries; in other words, those countries that produce and emit the greatest quantities of greenhouse gases. The United Nations would also be included in this process. To this end, a meeting took place in September 2007 between leaders of the invited nations: Australia, Brazil, Canada, China, India, Indonesia, Japan, Mexico, Russia, South Africa, and South Korea, as well as the United States, the United Nations, and the European Union.

REDUCED EMISSIONS

President Bush stated that the United States will reduce its emissions of greenhouse gases in relation to the size of its economy. Therefore, greenhouse gas intensity was defined as greenhouse gas emissions per unit of economic activity; overall greenhouse gas intensity was to be reduced by 18 percent by the year 2017.

As a member of the Asia–Pacific Partnership on Clean Development and Climate (APP), along with Australia, Canada, China, India, Japan, and South Korea, the United States works to ensure that as these Asian Pacific nations develop, they will incorporate environmentally-responsible technologies into their economies and infrastructures.

The APP is a significant team of nations because it represents approximately one half of the world's population and the same percentage of its economy. The APP has eight task forces: Aluminum, Buildings and Appliances, Cement, Cleaner Fossil Energy, Coal Mining, Power Generation and Transmission, Renewable Energy and Distributed Generation, and Steel.

In 2008, in recognition of the 2007–09 International Polar Year, Under Secretary of State Paula Dobriansky traveled to the dedication ceremony for the Amundsen–Scott Station, a new scientific research unit at the South Pole on Antarctica. The station is run by the United States Antarctic Program (USAP), and is the third of its kind at the South Pole since the first station opened in 1956. Research conducted at the Amundsen–Scott Station will be used to analyze climate change, the ozone layer, glacial dynamics, and the universe at large. Antarctica was established as a protected area for peace and science. in the year 1959, by the Antarctic Treaty. The activities of the United States in Antarctica are managed by the United States Department of State in conjunction with the National Science Foundation.

The U.S. Department of State was established on July 27, 1789, as the Department of Foreign Affairs. It was created by the Senate and the House of Representatives in order to assist the president in maintaining international relations, and for purpose of national security. In September of the same year, the name was changed to the Department of State. It is also commonly referred to as the State Department. Today, the State Department is located in the Harry Truman Building in Washington, D.C., and in 2007 ran on an annual budget of approximately $35 billion.

Desertification

IN THE UNITED Nation's Convention to Combat Desertification (UNCCD), desertification is defined as "land degradation in arid, semi-arid and dry subhumid areas resulting from various factors, including climatic variations and human activities." This land degradation is defined as a:

> reduction or loss in arid, semi-arid and dry subhumid areas, of the biological or economic productivity and complexity of rain-fed cropland, irrigated cropland, or range, pasture, forest and woodlands resulting from land uses or from a process or combination of processes including processes arising from human activities and habitation patterns, such as soil erosion caused by wind and/or water, deterioration of the physical, chemical and biological or economic properties of soil, and long-term loss of natural vegetation.

In a more complex understanding, desertification also involves land-use change in pastoral and agricultural dryland systems, due to environmental pressures.

Many assessments have been conducted on desertification, each as varied as the indicators that they have been based upon. The most recent one is the Land Degradation Assessment in Drylands (LADA assessment) of the Food and Agriculture Organization of the United Nations (FAO). In the World Atlas of Desertification, based on the Global Assessment of Human-induced Soil Degradation (GLASOD) Assessment on human-induced soil degradation: drylands are characterized as the zones having a ratio of average annual precipitation to potential evapotranspiration (P/ETp) between 0.005 and 0.65, which includes semiarid and arid areas. Hyper-arid zones are not part of the United Nations Convention to Combat Desertification (UNCCD) desertification definition because they are presumed to be so dry that human degradation is severely limited unless irrigation is practiced.

Arable land resources of north Africa and west Asia are being pressured by overgrazing, combined with an extension of the cropped area, and by salinization caused by dam and irrigation systems such as in the Nile Delta. Dryland degradation is widespread in sub-Saharan Africa, northern China, Australia, northeastern Brazil, the Carribean islands; many other dryland areas have experienced damage from deforestation and overgrazing in the drylands. Also, in Europe, degradation is significant in the southern Mediterranean zone.

The complexity of definitions make mapping desertification difficult, but according to 2003 data from the UNCCD and WDA, 70 percent of all cultivated drylands are affected by desertification, and 17 percent are already desertified. 24 billion tons of topsoil is lost every year to desertification, which affects the livelihoods of 250 million people. Only 22 percent of global drylands have degraded soils, this figure increases to 70 percent when vegetation degradation is added. The dryland subtype that is most degraded is the arid subtype, whereas in regions with smaller overall dryland area, the semiarid drylands (the Americas), or the dry subhumid ones (Europe), are the most degraded, respectively. However, within these data it is also difficult to distinguish between states and processes. Africa is particularly vulnerable, with around 60 percent of its total area covered by desert or drylands. The United Nations Environment Programme (UNEP) notes that the extent of desertification is increasing worldwide: "desertification currently affects approximately 25 to 30 percent of the world's land surface area. About 1.2 billion people in at least 100 states are at risk."

LINK TO CLIMATE CHANGE

Climate-simulation models indicate substantial future increases in soil erosion. Desertification will be exacerbated by reductions in average annual rainfall and increased evapotranspiration, especially in soils that have low levels of biological activity, organic matter, and aggregate stability. Desertification and climate can form a "feedback loop," with the loss of vegetation caused by desertification reducing carbon sinks and increasing emissions from biodegrading plants.

Soil degradation begins with removal of vegetation. Unprotected, dry soil surfaces are readily eroded by rain and wind, leaving infertile lower soil layers that bake in the sun and become an unproductive hardpan. Sand dunes may form where the blown surface material accumulates. Water is a defining constraint of the drylands. Drought avoidance and coping strategies are imperative, such as choosing drought-tolerant crops, low plant densities, water conservation, and water harvesting. While water shortage is a constant concern, much of the water that is available is not efficiently used. In the Sahel, degraded soils often exhibit impeded water infiltration, so much is lost as runoff.

Given the uncertainty in the models, some models still project other outcomes, such as the regreening of the Sahel zone. Nevertheless, a loss of vegetative productivity can lead to long-term declines in agricultural yields, livestock yields, plant standing biomass and plant biodiversity, changes that reduce the ability of the land to support people. While before, even in adverse areas people in drylands were able to cope with the cycles of droughts without depleting soils, now, with the extension of droughts due to climate change, these systems became vulnerable to breakdown, often sparking an exodus of rural people to urban areas. Breaking the strong connection of people to the land produces profound changes in social structure, cultural identity, and political stability.

Desertification also impacts remote areas, and has silted-up rivers and retreated lake surfaces far away from its origin. Since the early 1950s, 670,000 ha. of arable land and 2.35 million ha. of rangeland, steppe, and grassland were invaded by shifting sands. Dust storms created as a result of destroyed vegetative cover led to air quality problem, and acid, rain elsewhere.

Desert Research Institute

THE DESERT RESEARCH INSTITUTE (DRI) is the nonprofit research arm of the Nevada System of Higher Education (NSHE), with primary research campuses in Las Vegas and Reno and additional campuses in Boulder City, Nevada, and Steamboat Springs, Colorado. The DRI combines the academic world and entrepreneurialism, and faculty members are responsible for securing resources for their salaries. DRI faculty members do not receive state support, nor are their positions tenure-track. The DRI employs more than 500 faculty, support staff, and students who are engaged in one of approximately 300 projects producing about $50 million in total annual revenue. The DRI has an extensive list of private, public, and academic partners and ranks as one of the top 50 recipients of grants in Nevada.

Atmospheric Sciences, Earth and Ecosystem Sciences, and Hydrologic Sciences comprise the principal divisions of the DRI, and the four interdisciplinary centers include those for Advanced Visualization, Computation, and Modeling; Arid Lands Environmental Management; Watersheds and Environmental Sustainability; and Environmental Remediation and Monitoring. The DRI is committed to the effective oversight and management of Nevada's resources, balancing the development of the resources of Nevada with the protection of its environment and meeting the needs for economic expansion and science-based educational programs.

The DRI's educational programs offer environmental programs, including ecology, atmospheric sciences, hydrology, fundamental health and sciences, as well as environmental literature, agriculture, mining, and engineering. The Desert Research Libraries at Las Vegas and Reno maintain collections and services to support the DRI scientific community and other scholars. Resources include archival materials, aerial photographs, the DRI reports, maps, posters, and safety videotapes. One of the academic programs with which the DRI is affiliated is the Academy for the Environment, established in 2004, at the University of Nevada, Reno (UNR), as a multidisciplinary institute aimed at developing, enhancing, and coordinating environmental teaching, research, and service at the university. The faculty of the DRI are integral through teaching in the atmospheric sciences, ecology, evolution and conservation biology, environmental sciences and health, and hydrologic sciences graduate programs.

The DRI, the University of Nevada, Reno (UNR), Sierra Nevada College in California, and the University of California, Davis (UC Davis), have formed a unique partnership offering intensive courses on the environment and sustainability, at the Tahoe Center for Environmental Sciences (TCES). The Storm Peak Laboratory (SPL), constructed during the summer of 1995 and operated by the Atmospheric Sciences Center of the Desert Research Institute, provides an opportunity for students ranging from middle school through graduate school to participate in basic and applied science. The DRI faculty members teach a course in Atmospheric Sciences at the University of Nevada that includes two weeks of field research at the Storm Peak Laboratory. Students gain experience in proposals and project planning.

Students from kindergarten through senior high school have benefited from curriculum development sponsored by the DRI. During summer workshops, kindergarten–12th grade science teachers designed portable instruction modules to be circulated continuously to teachers throughout Nevada for the Desert Research Institute's Science Box Traveling Kits Program. Instructional science topics were based on Nevada's state guidelines for required science education. In 1999, a grant allowed teachers from Arizona, California, Idaho, Oregon, and Utah to participate in the workshop program and return to their states to advocate for similar Science Box programs.

Dr. Joseph R. McConnell, a snow hydrologist from the DRI, received a grant from the National Aeronautics and Space Administration to analyze whether forces other than global warming could be responsible for changes in snowfall and melting in Greenland. McConnell and his colleagues will examine extracted ice cores to determine if recent patterns in Greenland correspond to natural cycles in North Atlantic weather. The study is significant because extreme melting in Greenland has impacts reaching far beyond its own boundaries. Among other priorities of the DRI is research focused on the preservation of Lake Tahoe, Lake Walker, and Lake Mead. Additionally, DRI research efforts have included the investigation of air quality conditions at Ground Zero in the aftermath of 9/11, and working in partnership in west Africa to bring potable water resources to rural villages. Future work includes studying remote sensing to predict environmental change and assist in resource planning.

Deserts

DESERTS ARE AN environmental extreme, characterized by low rainfall that is highly variable intra-annually and interannually, with a coverage of about 27.7 $Mkm.^2$, equivalent to 35 percent of the earth's surface and, thus, representing one of the largest terrestrial biomes. They occur mainly within latitudes between 5–35 degrees north of the equator and are characterized by very high aridity, very little vegetation cover and large surfaces of exposed bare soil, and high adaptations of plants and animals for survival during long droughts. According to bio-ecological definitions, the world's deserts represent all ecoregions of the world that harbor desert vegetation, identified by the xerophilous life-forms and the general desert-adapted physiognomy of the dominant plants.

Desert climate is characterized by precipitation of less than 9.84 in. (250 mm.) with very high variability, high diurnal variations of temperature, and strong solar radiation. Desert air is very dry; incoming solar and outgoing terrestrial radiation are intense, with large daily temperature fluctuations; and potential evaporation is high. Extreme desert systems already experience wide fluctuations in rainfall and are adapted to coping with sequences of extreme conditions.

Deserts can be hot or cold. Among the hot deserts are ones with two rain seasons (Sonora desert, Karoo); with one rainy season (Northern Sahara, Mohave Desert, Middle-Asian deserts); deserts with summer rain (Southern Sahara, inner Namib, Atacama); deserts with few rains at any season (Central Australia); coastal deserts without rains, but with fog (North Chilean coastal deserts, outer Namib); and deserts without any rain or vegetation (Central Sahara). The Sahara in north Africa and the Namib desert in southwest Africa are classified as the hottest deserts in the world, with average monthly temperatures above 86 degrees F (30 degrees C) during the warmest months and extremes above 122 degrees F (50 degrees C). The diurnal temperature range often is large; winter nights in the Namib Desert sometimes are as cold as minus 14 degrees F (10 degrees C) or lower.

Aridity is the most prominent indicator, commonly measured by the Aridity Index, an estimator for the ratio between mean annual precipitation and mean annual potential evapotranspiration, which is less than -40 for arid deserts and -20 for semi-deserts. Aridity is highest in the Saharan and Chilean-Peruvian deserts, followed by the Arabian, East African, Gobi, Australian, and South African deserts, and lower in the Thar and North American deserts. This high aridity, as well as typical pulse-type variations in desert environments, are caused by global atmospheric and oceanic phenomena, such as the position of the jet streams, the movement of polar-front boundaries, the intensity of the summer monsoon, El Niño Southern Oscillation events, and even longer-term ocean cycles, such as the Pacific Decadal Oscillation.

CLIMATE CHANGE

Driven by these large-scale forces, the intensity and frequency of rain pulses at a local scale may vary substantially with time, and future projections indicate an increasing likelihood of even more episodic climate events and inter-annual variability in deserts. Continental deserts could experience more severe, persistent droughts. In the Americas, temperate deserts are projected to expand substantially under doubled CO_2 climate scenarios. About one third of the Sahel was projected to aridify with warming of 2.7–3.6 degrees F (1.5– 2 degrees C) by about 2050, with a general equatorward shift of vegetation zones. Alternative climate scenarios show less pronounced changes, even shifts to wetter climates in the Sahel zone and movement of vegetation zones, accordingly. The potentially positive impact of rising atmospheric CO_2 remains a significant uncertainty, which also could offset current projections, especially because it is likely to increase plant productivity, leading to contrasting scenarios.

Deserts also play an important role in the regulation of climate, air quality, and atmosphere composition of remote areas through wind-blown desert dust; also the desert albedo influences rainfall and biogeochemistry of other terrestrial and marine ecosystems, in this way increasing vulnerability of remote regions to climate change. The 4th Intergovernmental Panel on Climate Change (IPCC) assessment projects increased dust flux rates, which may increase aridity and suppress rainfall outside deserts, with opposite effects under wetting scenarios, associated with a decline of atmospheric burden by soil aerosols of 20–60 percent. Changes of rainfall in deserts are projected to be in the range of 0.2 mm. day-1.

EROSION

Typical desert soils are aridisols, characterized by little weathering of the maternal rocks and low organic matter in the surface layer, formed under the typical influences of desert conditions by strong winds, scattered but torrential rains, and high temperatures. The materials in these soils are often cemented together forming water-impervious hardpans, sometimes containing salts or gypsum. The low soil cover exposes deserts to more wind erosion than any other environment, and to water erosion, as well, if slopes are steep and rain does fall. Desert landscapes come in two categories: shield deserts and mountain-and-basin deserts.

Very low biomass cover is very likely to make some desert dunes susceptible to aeolian erosion, and, with regional warming of between 4.5–6.3 degrees F, (2.5–3.5 degrees C) most dune fields could be reactivated by 2100. About 10–20 percent of deserts are ecologically degraded by an imbalance between demand and supply for ecosystem goods and services. Because of the extremely slow rate of biological activity in deserts, these ecosystems take decades, if not centuries, to recover from even slight damage. Moreover, because traditional livelihoods in deserts require large areas, they are particularly vulnerable to political and environmental changes. Irreversible damages have been caused in previously good agricultural grounds in deserts by large-scale modern developments, such as dam construction for water and energy supplies.

BIODIVERSITY

Previous, present, and future climate regimes structure desert ecosystems in a way that requires a physical and behavioral adaptation to the patch dynamics of primary production, water, and nutrient cycling in space and time. During pulses of bounty, the fragile seedlings of desert plants can germinate, establish, and prepare for long droughts, burying their roots deep into the desert soils and, to a large extent, it is this heterogeneity of pulses that drives the high biodiversity of desert ecosystems. Many organisms in the deserts already are near their tolerance limits. Desert biodiversity is likely to be vulnerable to climate change, especially in biodiversity "hotspots," such as in the succulent Karoo biome of South Africa, where 2,800 plant species face potential extinction as bioclimatically suitable habitat is reduced by 80 percent with a global warming of 2.7–4.9 degrees F (1.5–2.7 degrees C).

Deserts support about 10 people per sq. km. Humans in deserts undergo considerable dehydration, and therefore, have to cope with the dry environment for their survival with a panoply of behavioral, cultural, and technological adaptations. Traditionally, desert-dwellers were of three types: hunter-gatherers, pastoralists, and farmers, whose livelihoods are adapted to the spatial and temporal patchiness of their environment. The movements of pastoralists, for instance, mimic the variability and unpredictability of the landscape and range reserves. Desert agriculture occurs mostly around oases and desert rivers, which often provide silt and nutrients through flooding cycles.

Finally, the specific aesthetic features and atmospheres of deserts, their silence, wideness, beauty, bareness, and emptiness has always created an intimate, spiritual relationship between humans and the desert landscape, leading to the creation of all three monotheistic religions in desert regions. They still remain places of spiritual inspiration and meditation today.

The Namib Desert can range from 14 to above 122 degrees F; such desert variations can be connected to global phenomena.

Detection of Climate Changes

BECAUSE THE ATMOSPHERIC system is dynamic, variations in temperature and precipitation regimes have occurred throughout the Earth's history. Glaciations and deglaciations, for example, show how changeable climate can be. Detecting climate changes shows that climate differs significantly from some previous episode. Detection differs from attribution, which denotes the causes of those changes. While daily fluctuations in weather happen as a consequence of a chaotic atmosphere; climate fluctuations, based on smoothed aggregations of weather events, represent significant shifts in the longer-term averages. To discern these shifts, numerous techniques and methods are employed.

Climate changes, which occur at a variety of temporal scales, are assessed using both directly-observed and proxy data. Directly-observed information refers to meteorological and climate-related variables that have been directly evaluated, such as temperature measured by a thermometer, or cloud tops captured by satellite imagery. Directly-observed data have been used to chart recent increases in air temperature and carbon dioxide (CO_2), concentration, as evidenced by Charles Keeling's famous graph of climbing CO_2 concentrations at the Mauna Loa Observatory.

Proxy data are non-meteorological data, from which climate information is inferred; they serve as a satnd-in for such climate evidence when direct observations are not always available. Examples of proxy data include ice cores, lake sediments, and historical harvest records. Among the information gleaned from proxies are temperature, moisture, sea level, and chemical composition of the atmosphere. These facilitate the reconstruction of past climates.

Although directly-observed data may be preferable, the instrumental record is often too short for all but the most recent evaluations of climate changes. For example, the longest continuous temperature record shows monthly mean temperature only since 1659 (for central England); daily records for the same location extend only to 1772. Many other records are less than 100 years old. Temperature records also require filtering because of biases that may be present in the readings. The effects of urbanization, instrument upgrades, and location changes can result in false changes. Newer technologies, such as satellites, yield even shorter records. However, much climate change research assesses variability at temporal scales up to millions of years, rendering proxy evidence a necessity.

PROXY DATA

Proxy or substitute data extend climate change knowledge beyond the instrumental record, although there is a decreasing resolution and confidence with increasing time. Because climate variability has been identified at various temporal scales, the resolutions of the various proxies differ. Removing the climate signal and reconstructing past climates from them requires the proxy to be related to the climate. Therefore, some link between the two needs to be established; for example, by experimentation or construction of models.

Written historical records, such as harvest yields or military records, as well as diaries and phenological records, have been used to derive information. Temporal resolutions vary, from daily to annual. Farmers' diaries often discuss the weather. Grain harvests, for example, have been linked to precipitation. Dates of cherry blossomings in Japan can provide temperature trends. Historical records may be biased toward significant weather events (such as blizzards), so care must be taken when interpreting them.

TREE RINGS AND POLLEN

The study of tree rings, known as dendrochronology, can yield annual information on climate conditions for the past millennium or so. Every year, many tree species increase the diameter of their trunks by developing concentric rings formed by a layer of wood cells underneath the bark. While each ring corresponds to one year of growth, the spacing between successive rings is usually not uniform. This unevenness is due to differences in annual growth patterns, signifying climatic changes that have either encouraged or suppressed tree growth. Different tree species are sensitive to moisture and/or temperature changes. These environmental conditions can be inferred from the spacing and thickness of the tree rings. Relatively thick rings with a large spacing between successive rings indicate a more optimal growth setting, whereas narrower, tightly-spaced rings point toward climatic stress conditions (such as drought). Dendrochronology is limited to regions that continually support tree growth.

Another form of proxy data, derived from vegetation, comes from pollen and spores produced by plants. Wind can transport pollen grains to nearby water features, where they settle to the bottom and are preserved in sediment layers. Sediment cores extracted from lake beds are analyzed for the amount and type of preserved pollen found in successive sediment layers. Because pollen grains have unique features, plant types can readily be identified and, through techniques such as radiocarbon dating, indicate the time of deposition. Plant growth and distribution is sensitive to environmental conditions, providing an indicator of temperature and moisture trends on time-scales from centuries to millennia.

SEA-FLOOR SEDIMENTS AND ICE CORES

As with lake sediments, the layers or stratigraphy of oceanic deposits and corals can give important clues to paleoclimates. Sea-floor sediments are primarily an accumulation of calcium carbonate- ($CaCO_3$) based shells from organisms that once lived near the ocean surface. These organisms are often sensitive to changes in temperature and salinity, proliferating under optimal conditions and declining in unfavorable conditions.

Because the ocean surface is closely connected to sea-level climate conditions, the amount and type of shells found in the ocean core layers correlates well with atmospheric conditions when the organism died. Coral are small marine organisms that are also made of calcium carbonate, recording oceanic temperature conditions through their growth patterns. Like tree rings, coral thrive under certain conditions; coral are thicker during warmer, and thinner during colder, ocean episodes.

The calcium carbonate shells from ocean cores and coral are also source material for oxygen isotope analysis. This technique examines the ratio between two different isotopes of oxygen that are recorded in the skeletal remains of marine life. Ocean water contains two forms of oxygen molecules, the more common form with an atomic weight of 16 (^{16}O) and the atypical variety with an atomic weight of 18 (^{18}O). Water containing the lighter oxygen (^{16}O) isotope evaporates more readily than its heavier counterpart. This means that during periods of extensive glaciation, the amount of ^{18}O relative to ^{16}O in ocean water increases as more of the lighter oxygen isotope is precipitated out as snow, becoming concentrated in glacial ice. Conversely, the $^{18}O/^{16}O$ ratio decreases during warmer interglacial episodes, when surface runoff returns the ^{16}O previously stored in the cryosphere. Hence, oxygen isotope analysis is also useful for examining the precipitation layers of ice cores.

Taken from glaciated mountaintops and ice sheets, ice cores provide information on past climates in a variety of ways. Oxygen isotope analysis and the depth of snow accumulation in successive layers can give clues on temperature and moisture conditions. Major volcanic eruptions or meteorite impacts are often recorded as a significant layer of dust between ice layers; these episodes adversely impact surface insolation and global temperatures. Ice cores can also provide information on the past chemical composition of the atmosphere from small air bubbles trapped within. Depending on the length, ice cores enable reconstruction of past climates going back thousands of years.

Developing Countries

IN NUNAVUT, CANADA, Inuit hunting is at risk as the ice thins. For many developing countries the danger is from rising sea levels that submerge coastal land or, in the case of some small and low-lying Pacific islands, the country itself. These people have contributed the least to global warming, but they are the most at risk; and the risk is increasing. Seven of the 10 deadliest natural disasters of the past 20 years occurred between 2000 and 2006. Since July 2007, the European Commission has spend £24.5 million aiding victims of disasters in Colombia, the Caribbean, Peru, Kenya, India, Bangladesh, Nepal, North Korea, and the Sudan. The link between climate change and the intensity and frequency of natural disasters is now, finally, recognized.

As well as thinning Arctic ice and rising sea levels, global warming will also bring on heat waves that kill the elderly and sick. It will exacerbate asthma and other respiratory diseases, and heart problems, as body systems work harder to keep cool. And it will bring drought that reduces agricultural output and endangers water and food supplies. The heat will hit the developing world harder than it will the developed world. By 2020, between 75 and 250 million Africans will be without adequate water and sufficient food because crop output will drop about 50 percent. About 130 million Asians may also face food shortages.

A World Health Organization report says that climate change already kills at least 150,000 a year, and that the number will double by 2030. Global warming will increase infectious disease, particularly in tropical areas where increased temperature translates to increased mosquitoes and, thus, increased malaria, dengue, and other insect-borne diseases. Disease also affects the developed world, but richer countries can adjust to increased heat, and thus, reduce heat-stress related illnesses, by using new housing construction and air conditioning technology. Developing countries lack not only the technology, but also the financial resources and the public-health infrastructure.

AGRICULTURE

Global warming, if unchecked, will have, at least, moderate impacts on world agricultural output by late in the 21st. century, but these moderate impacts are more likely to occur in the developed world. The most severe damage will start earliest, and it will hit the areas that can least afford it. Shortfalls in food will also probably create regional conflicts as nations compete for resources.

The developing countries will suffer first because many of them are located in lower latitudes, where temperature thresholds are already close to being reached. Slight rises in temperature can mean loss of already-scarce water and decreased agricultural capacity. These nations have the least economic flexibility, and greatest dependence on agriculture, particularly the subsistence type.

According to William R. Cline, of the Center for Global Development, and Peterson Institute for International Economics, climate change will decrease agricultural productivity 3–16 percent by 2080, but it will cut developing world output by 9–21 percent. Developing countries will lose an average of 9 percent, with Africa losing 17 percent, Latin America 13 percent, south Asia 30 percent, and 20 percent in Pakistan. Without carbon fertilization the percentages will be more severe. China stands to gain 7 percent in the carbon fertilization scenario. India's loss is almost incomprehensible, and could reach 30 percent.

China could have regional losses of 15 percent and a national drop or gain, the range being plus 7 to minus 7 percent. Developed countries in some cases can see increases of 8 percent from warming. Because developing countries are normally closer to the equator, they are closer to the thresholds where increases in warming will cut output, rather than increase output. Cline's numbers do not factor in the increased likelihood of pests, droughts, and floods. Cline notes that technology will allow continuing improvement in yields through the end of the century, but that demand will continue to rise, as well.

Pressures on agriculture are four. To meet population growth, agricultural production must almost double. As incomes rise, the demand for more meat will increase, requiring more food per capita. Increases in yields have been slowing for 20 years and probably will continue slowing. Ethanol will take up to a third of agricultural land from food production.

Developed countries such as the United States, Japan, western Europe, and Australia have moved beyond economic dependence on weather-dependent outputs. Agriculture, fishing, and forestry are less than 3 percent of U.S. gross domestic product. The United States might pay higher prices and lose its agricultural exports, but the Third World will suffer the most. The solution is for the Third World to industrialize, develop as rapidly as possible to free itself of climate dependency.

THE DEVELOPED WORLD'S CONTRIBUTION TO GLOBAL WARMING

Developed nations are responsible for about 80 percent of the current atmospheric carbon dioxide (CO_2). The United States alone has emitted 50.7 billion tons of carbon since 1950. China, with 4.6 times the population, has emitted 15.7 billion tons. India, with 3.5 times the population, has emitted 4.2 billion tons. More than 60 percent of the current industrial CO_2 emissions still come from developed countries, which have about 20 percent of the world's population.

Industrialized nations have caused environmental damage that penalizes developing countries and their poor. It is unfair to expect the developing world to stop trying to provide basic consumption and development needs for the poor, while the developed nations continue to emit greenhouse gases to preserve their luxurious lifestyles. Per capita carbon emissions in the United States are 20 times India's, 12 times Brazil's, and seven times China's. And a portion of the developing world's emissions are due to outsourcing by wealthy nations.

The International Energy Agency (IEA) predicted that in Organisation for Economic Co-operation and Development (OECD) countries, emissions would rise from 11.02 tons per person in 2004 to 11.98 tons in 2030. Emissions for non-OECD nations would rise from 2.45 to 3.55 tons. The developing world may have large overall totals, but it is far behind in per capita pollution. The problem is mostly the responsibility of the developed, industrialized, and motorized OECD nations, and the United States. They have a history of industrialization that dates back to the 18th or 19th century, and their coal-fired industrialization-generated greenhouse gases have not yet dissipated.

EQUITY

Climate change is already having an impact on small island nations. Some of these nations, and other small and poor countries around the world, have been left out of the global warming discussions although the impacts of global warming—and of the solutions that come from the international negotiations—expected to be greater on them than on the developed nations. Equity dictates that these nations attempting to reach the take-off to sustainable development be brought into discussions that affect such things as emissions allowances and other restrictions on economic development.

The issue of equity is usually left out when the developed world and oil producers get together. Their emphasis is on economic effectiveness. Understandably, the United States, consuming 20 percent of the world's resources with 4 percent of its population, and the Organization of the Petroleum Exporting Countries (OPEC) nations, worry about the economic consequences of altering the bases for their economies and way of life. When refusing to sign on to the Kyoto Protocol, the United States claimed that India and China had to endure cuts, too, to keep the economic playing-field level.

Those calling for equity note that the developed world has not provided meaningful assistance to make the transition to clean development. They hold that sustainable development is hampered by the diversion of substantial resources to debt and poverty, that developing countries such as India and China had already made significant cuts in emissions, and that environmental movements in developed countries have frequently pressured dirty industries to relocate to the Third World but provide profits and benefits to the developed world.

In opinion polls, the majority view is that developing countries should limit greenhouse emissions, but should not have to reduce emissions. The majority also back implementation of the Kyoto Protocol, whether or not the developing nations cooperate. Some developed nations back the developing nations in their position that cuts should not be mandatory because emissions per capita are already much lower. In June 2004, a Program on International Policy Attitudes (PIPA) poll found a strong majority wanting limits, but not reductions; the same view held in an earlier PIPA poll in 1998. Other polls have comparable results. Notably, polls show that respondents want the United States to cut emissions, regardless of what others do.

DEVELOPING WORLD SOLUTIONS

Developing countries are becoming more responsible on their own. Even as they develop rapidly, China, Brazil, Mexico, and India are cutting total emissions beyond the levels demanded by the developed world under the Kyoto Protocol. Emissions are still increasing, but the rate is slowing. In late 2005, Reuters reported that a state-owned energy firm in

China committed $2.48 billion over 5 years to alternative energy projects including biomass and garbage treatment. Chinese tariff policy favors non–fossil fuel energy sources. China has a target of 20 percent of energy from renewable sources by 2020, but is currently 70 percent dependent on coal for electricity. The United Kingdom has a goal of 10 percent for energy from renewable sources.

The Pew Center reported, in 2002, that some of the developing nations (Brazil, China, India, Mexico, South Africa, and Turkey) have cut greenhouse emissions by 19 percent, or 300 million tons a year. Additional cuts may reach another 300 million tons by 2010. They used market and energy reforms, energy efficiency, alternative fuels to reduce imports and improve living standards in remote locations, slowed population growth, cut deforestation, and switched away from coal to natural gas and other cleaner fuels.

DEVELOPED WORLD RESPONSES

The United Nations Framework Convention on Climate Change (1992) obligates the developing nations to use clean and sustainable technology, but it also obligates the developed world to assist the developing world in its transition to cleaner technologies. The framework established the principle of common but differentiated, responsibilities. This principle recognizes that developed countries have historically, and currently, create the largest amount of greenhouse gases. Per capita emissions are relatively low in developing countries, but the share will grow as these countries industrialize to satisfy the needs of their people. The convention obligates the rich to help. Christian Aid reports that the developed world owes the developing world $600 billion in compensation for the impacts of climate change. The $600 billion is more than triple the developing countries' debt.

Not all developed nations accept this responsibility. The United States repeatedly protested during the Kyoto Protocol that the agreement did not set the same level of reduction for developing nations as it does for developed ones. The U.S. Senate is on record as refusing to sign any treaty that does not require developing nations to cut their emissions. The counter argument, of course, is that the developing nations have not contributed nearly as much, and should not be expected to reduce equally.

Some developed world leaders attribute global warming, at least to some extent, to overpopulation. That position puts the blame on developing nations with large populations, such as China and India. President George W. Bush is on record repeatedly as refusing to accept limits unless the developing countries do too. Prime ministers Tony Blair and John Howard agree. Critics say that it appears these three leaders would have the world believe that China and India are responsible for runaway climate change and have to be party to any agreement before anything can happen. The developed world fears the impact of large populations developing rapidly; strong economic growth fuels demand for energy and materiel—and demand may exceed supply of resources. But the developed world agreed long ago that development was permissible, even with massive amounts of pollutants. China and India are now being asked to take a different approach, a clean and sustainable way that the old developed countries did not try. This is one view of "common but differentiated responsibilities."

The developing countries produce slightly over a third of greenhouse gases. Their per capita emissions, one fifth those of the developed world, will increase as they develop consumerism, and, by 2100, the developing world will create two to three times the emissions of the developed world. The U.S. government has used this prospect as a rationale for rejecting any agreement, including the Kyoto Protocol, that does not put limits on the developing world. That may be moot because negotiations are taking place on a new agreement that, first, shows the developed world is serious (for instance, Britain has promised to reduce CO_2 emissions by 60 percent), and, second, supports adoption of new technology by the developing world. If this happens, the developing world should skip the dirty-energy phase of industrialization and move directly to clean coal and hybrid cars, for instance. International carbon trading should provide the economic incentive for developed world businesses to help developing industries.

Because of climate change, six years after the adoption of the United Nations Millennium Development Goals, reaching those goals was less than likely. Global warming has finally become most of the world's number one concern. Global warming will have impacts on food, energy, transportation, and make access to healthcare, education, and social services more difficult. The impacts will be greatest in fragile environments, such as mountains and coastal areas.

Africa will be most at risk because African economies depend so heavily on agriculture and natural resources. Drought and flood are major disasters that put life and livelihood at immediate risk. Global warming's unpredictable weather will exacerbate already severe African problems with food, security, and poverty. Africans had great expectations from the first climate summit to take place south of the Sahara, the 12th Conference of Parties (COP 12) of the United Nations Framework Convention on Climate Change (UNFCCC) in Nairobi, Kenya.

THE UNFCCC

Unfortunately, the developed nations persist in seeing climate change and sustainable development as separate issues. The developed nations think globally: a ton of CO_2 is a ton of CO_2 regardless of where it comes from. The developing nations are adapting on a local level, and, sometimes, their local development needs create unwanted CO_2. Also, negative global impacts come from sources other than climate change. Flood and drought occur independently of global warming, although, climate change exacerbates the arbitrariness of weather. The developing nations need development plans that are climate-proof, and the best way to get results is to fight the two problems simultaneously.

Under the UNFCCC, developing nations began creating National Adaptation Programs of Action (NAPA) by 2006, and eight had finished by that time. The plans include such things as Malawi's reforestation as a means of reducing floods, and Benin's project to make people in the rural northwest more capable of adjusting to water scarcity, a high risk in that area. Implementation of the plans, naturally, will require large sums of money. The World Bank estimates an annual cost of $10–$40 billion. The UNFCCC has established a Special Climate Change Fund (SCCF) and a Least Developed Countries Fund (LDCF.) Both the SCCF and LDCF are funded by voluntary contributions from the developed countries. The Kyoto Protocol calls for a third source, an Adaptation Fund, that funds tangible adaptation projects in developing countries. Financing is through a tax on the trade on emission certificates. By the end of 2012, the fund should have $270–$600 million to spend. Disagreement arose at Nairobi over who would manage the fund, with developed country representatives wanting an agency with a global agenda.

The European Commission (EC) proposed a global alliance between the European Union (EU) and developing nations. The solutions include incorporation of new technology and improved communication with the Least Developed Countries (LDC) and the Small Island Developing States (SIDS.) The EU's Spring Council 2007 offered proposals for the next climate change agreement in 2012, when the Kyoto Protocol expires. This council also committed the EU to major cuts in emissions. The Global Climate Change Alliance (GCCA) offers assistance in reducing deforestation-generated emissions, getting developing countries more involved in the global carbon market, helping in preparation for natural disasters, and making climate change part of poverty reduction and development plans. The GCCA acknowledges that development has to be climate proof. The GCCA has funding of £50 million for 2008–10. The EC also appealed to EU states to spend more of their development assistance on helping developed nations cope with climate change.

Diseases

DISEASE IS THE pathological process that presents a characteristic group of symptoms and that establishes the condition as an abnormal entity different from either the normal or other pathological body states. Disease is related to the concept of health, which is broadly defined as a state of dynamic balance, in which an individual or group's capacity to cope with the circumstances of living is at an optimal level. The freedom from disease or the risk of contracting one is only part of the modern concept of health, which involves complete physical, mental, and social well-being. The causes of human disease are varied and result from a combination of environmental, genetic, lifestyle, and socioeconomic factors acting over the lifetime of an individual.

This range of factors and interactions that shape human health have led to a questioning of the classic mechanical model of disease that has dominated the scientific approach guiding research on human health. The mechanical model of disease, as the name implies, only views the organism as a simple machine, instead of a complex system interacting with its environment. In this complex process for preserving health or combating disease, a person or population's environment can shape the behaviors associated with disease.

A changing environment can be a factor in the initiation or spread of disease. Recent research demonstrates the importance of socioeconomic factors in producing disease, and the recognition that these socioeconomic factors, in combination with physical environments (light, temperature, seasonality, and pollution) and biological phenomena, such as pathogens, need to be understood in a holistic way.

The concept of a complex process is key to understanding disease for people inhabiting changing environments, marginal environments, and extreme environments, such as Alaska. Environmental health focuses on the interrelation between human disease and the health of other species in an ecosystem. Contaminated water and air, endocrine disrupters, and even biological terrorism pose important stressors in which human systems have become agents of change that affect rural and natural landscapes, including the movement of organisms and materials. Environmental well-being refers to the ability of the environment to support all life, including human economic and social systems. The efficiency and sustainability of environmental services, the cycling of materials, and the maintenance of organismal balance are needed to reduce the incidence of disease.

Diseases affect homeostasis, which is the feedback that maintains a living organism's body function within limits essential for the body to continue functioning properly, despite external and internal stresses that would move the system away from balance. Diseases that exist in a population for a long time, where they are maintained at a low level, are called endemic. An epidemic occurs when there is a marked increase in the incidence of disease within a region. When an epidemic spreads around the world it becomes a pandemic. For example, the 1918 pandemic is believed to have been related to 30 million deaths. Climate change is expected to increase the spread of disease, especially biologically-transmitted pathogens.

Chronic diseases such as Alzheimer's, emphysema, heart disease, acquired immune deficiency syndrome (AIDS), and cancer are diseases that have a slow onset and last for extended periods of time. Diseases can also be classified by type, such as infectious, developmental, nutritional, radiation, and chemical. Many diseases, such as neoplastic diseases like cancer, involve both genetic components and environmental factors leading to increases in susceptibility. Thermal, chemical, and radiation damage mainly results from a damaging excess of kinetic energy or ionization of molecules in tissues leading to cell death. Free radicals react with molecules in the cell and change their structure, affecting their ability to function. This is the basis for Pauling's molecular theory of disease. Chemical exposure can stimulate or depress metabolic functions, such as homeostasis, by interfering with enzymes or receptors. Some chemicals produce effects that are characterized as a systemic disease. This disease process affects all of the body's organ systems. Most environmental pollutants, such as mercury, lead, cadmium, arsenic, and persistent organic pollutants are systemic toxins. Systemic pollutants, because they are ingested, inhaled, or absorbed, will be more widely distributed during climate change by floods, fires, and winds.

Most public health problems involve diseases caused by pathogens; but environmental molecules, either natural (metals, metal-containing compounds, or plant secondary products) or anthropogenic (pesticides, pharmaceuticals, or industrial waste) can lead to adverse effects on public health. However, some responses are considered to be adaptive and not disease states, such as the induction of a detoxification enzyme.

Human health is also affected by nutrition, contact with allergens and pathogens, and exposure to contaminants in air, water, and foods. Population density, age distribution, mobility, and other demographic variables, as well as the genetic composition, and cultural and behavioral attributes of individuals, influence the incidence of disease. Thus, understanding the relationships between human health and the environment is critical, particularly given the potential for alteration of ecosystems by socio-economic activity, rapid global change, and climate variability. The World Health Organization monitors disease on a global scale.

GLOBAL WARMING AND CLIMATE CHANGE

While high blood pressure in a population can impose a health risk and poor nutrition increases susceptibility to disease, global warming and climate change, alter the temperature, water cycle, and pathogen distributio, posing direct threats to human health. According to the United Nations Intergovernmental Panel on Climate Change, certain regions and populations are more vulnerable than others to increases in disease. As climate changes, regions with high endemicity of malaria, or regions affected by El Niño–linked epidemics may expand. Climate changes will put stress on food and water systems, leading to environmental diseases. Similarly, areas under socioeconomic stress, poor land-use and resource practices, or underdeveloped health infrastructure will have problems combating increases in disease. Chemical hazards related to resource development, such as coal use in the environment, produce a diversity of diseases, ranging from asthma to birth defects and cancer.

Climate change will not only affect exposure to disease vectors and pollutants, but also lower human resistance to disease. Drought is associated with poor hygiene and increases in diarrhea, scabies, and conjunctivitis. Fire smoke carries metals, such as mercury, and fine particles that exacerbate cardiac and respiratory problems, such as asthma and chronic obstructive pulmonary disease. Volatile organic compounds and particulate matter formation can increase at higher temperatures. Once pollutants are formed, climate and environmental change, such as temperature inversions, can increase exposure to toxicants.

Flooding increases waterborne diseases by contaminating drinking water. In marine ecosystems, bacteria such as the vibrio species proliferate in warmer waters. Temperature also increases the incidence of vector-borne diseases. Both malaria and arboviruses are mosquito-borne diseases. Rodent-borne hantavirus infections increase in relation to El Niño's heavy rainfall. Changes in climate will affect food productivity and lead to malnutrition, which may increase disease rates. Inadequate diets also occur in developed nations, as fast food and contaminated food represents an increasing percentage of the diet. Also, fast-food processing and transportation can remove nutritional value from the foods, often increasing the sugar and fat content.

A disease of dietary insufficiency in children known as kwashiorkor needs to be monitored as climate changes. Dietary factors are major components of heart disease and cancer. Increased saturated or trans fat intake may be correlated with increased risks of colon and prostate cancer. Obesity has been linked to endometrial cancer. Cancer is still rare in children, but some types are increasing, such as glioma, a form of brain cancer that has increased by 40 percent in children over the last 40 years. Also, children tend to be more susceptible to environmental toxins because of high relative exposure (with more food intake, lower body weight, and higher internal dose); they have higher rates of cell proliferation and an immature detoxification and cell repair system.

Children of subsistence families are at increased risk from climate change and the global concept of food production as a commodity.

Djibouti

LOCATED IN NORTHEAST Africa, with land borders with Eritrea, Ethiopia, and Somalia, Djibouti was formerly known as French Somaliland, and later as the Territory of Afars and Issas. It has a land area of 8,958 sq. mi. (23,200 sq. km.), with a population of 496,374 (2006 est.), and a population density of 88 people per sq. mi. (34 people per sq. km.). With extremely poor soil, less than 1 percent of the country is arable land, with another 9 percent being used for meadows and pasture, mostly to graze cattle, sheep, and goats.

The electricity for the country is produced entirely from fossil fuels, and all the carbon dioxide emissions come from liquid fuels. As a result, even with the low standard of living and the undeveloped nature of the country, it recorded 0.6 metric tons of carbon dioxide per capita each year 1990–97, with the amount falling slowly to 0.48 metric tons in 2003. This marked decline is far more than that achieved by most other countries in sub-Saharan Africa, in spite of the country still having a poor system of public transportation, with plans for a railway from Djibouti to Addis Ababa, first discussed as early as 1894, never resulting in any construction work.

The government of President Hassan Gouled Aptidon took part in the UN Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, with the Vienna Convention being ratified in 1999. Under President Ismail Omar Guelleh, Djibouti accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on March 12, 2002, and which took effect on February 16, 2005.

Doldrums

DOLDRUMS ARE TECHNICALLY known as the intertropical convergence zone (ITCZ), the intertropical front, the monsoon trough, or the equatorial convergence zone, the doldrums are a belt of low pressure surrounding the earth at the equator. It is formed by the vertical ascent of warm, moist air from the latitudes above and below the equator. The air is drawn into the ITCZ by the action of the Hadley cell, a macroscale atmospheric feature that is part of the Earth's heat and moisture distribution system. It is transported aloft by the convective activity of thunderstorms.

The position of the ITCZ varies throughout the year. Over land, it moves back and forth across the equator following the Sun's zenith. Over the oceans, where the ITCZ is better defined, the seasonal cycle is more subtle, as convection is limited by the relative stability of ocean temperatures. Occasionally, a double ITCZ forms, with one located north and another south of the equator. When this occurs, a narrow ridge of high pressure forms between the two convergence zones, one of which is usually stronger than the other.

The location of the ITCZ can have dramatic effects on rainfall in equatorial locations, resulting in wet and dry seasons in the tropics, rather than the cold and warm seasons characteristic of higher latitudes. Regions in the ITCZ receive precipitation more than 200 days per year. Within the ITCZ surface winds are slight, unlike the zones north and south of the equator where the tradewinds blow. For this reason, sailors named this belt of calm the doldrums due to the stagnation they found their sailing ships in after days of no wind, high heat, and humidity.

The ITCZ's role in the formation of tropical storms depends upon the low-level vorticity as one of its six requirements, and the ITCZ trough fills this role as it is a zone of wind change and speed, otherwise known as horizontal wind shear. As the ITCZ migrates more than 500 km. from the equator during the respective hemisphere's summer season, increasing Coriolis force makes the formation of tropical storms within this zone more possible. In the north Atlantic and the northeastern Pacific oceans, tropical waves move along the axis of the ITCZ causing an increase in thunderstorm activity, and under weak vertical wind shear, these clusters of thunderstorms can become tropical hurricanes.

GLOBAL WARMING

The effects of global warming on the ITCZ could be significant. Given that surface winds over the ocean tend to follow ocean currents, changes in the circulation of ocean currents brought about by global warming will also have a direct influence on the ITCZ, resulting in an intensification of precipitation in the ITCZ, according to S. Nawrath and A. Levermann. A simulation model of global warming (using a general circulation model, or GCM, with enhanced carbon dioxide, or CO_2), indicates an increase in the ITCZ strength and hydrological cycle that accompany global warming, according to U. Cubasch, et al.

A key feature for nearly all GCM simulations of the climate under an enhanced CO_2 is that increases of tropospheric water vapor along with a stronger ITCZ and hydrological cycle are required for any substantial global warming, as described by J.T. Houghton, et al., but once they do occur, these conditions create the potential for the development of more powerful storms, according to K.A. Emanuel. The stronger the ITCZ becomes, the more favorable are conditions for the development of major hurricanes in the central Atlantic. In general, global warming will result in an exaggeration of preexisting conditions, whereby wet areas become wetter and dry areas become drier.

Dominica

THIS CARIBBEAN ISLAND of Dominica, formerly a British colony, has a land area of 290 sq. mi. (751 sq. km.), with a population of 71,727 (2006 est.), and a population density of 272 people per sq. mi. (105 people per sq. km.). Some 9 percent of the land area is arable, with another 3 percent available for use as meadows or pasture. Unlike many other Caribbean islands, Dominica does not rely heavily on tourism, although some 70,000 people do visit the country each year. One major environmental problem for Dominica is that hurricanes hit the island at regular intervals. Although much of the land area of Dominica is higher than many of its low-lying neighbors, the rising sea temperature is threatening the marine life around the island, as well as the coral reefs at Scotts Head Drop and the Pinnacle. Some divers have already noticed the start of coral bleaching, and the ministry of tourism has been worried that this might eventually result in a downturn in the number of tourists that do visit the island.

Traditionally, Dominica has had a low carbon dioxide emission level per capita, with 0.8 metric tons per person in 1990, although this has progressively risen, and was 1.8 metric tons per person in 2003, with Dominica ranking 121st in carbon dioxide emissions, almost entirely from using liquid fuels. The country's agricultural industry has traditionally relied on the heavy use of chemical pesticides and fertilizers, which cause other environmental problems.

With the rising sea levels, there are worries that the flooding of parts of Dominica, that might result, could lead to the spread of malaria and dengue fever, and also damage the water-bottling industry that has become an important part of the local economy. This has led to moves introduced by the Ministry of Agriculture and the Environment in Roseau, the country's capital, to reduce the use of chemicals in agriculture. The Dominican government of Eugenia Charles took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and in April–May 1994, Dominica was represented at the Global Conference on the Sustainable Development of Small Island Developing States held in Barbados. The government of Roosevelt Skeritt accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on January 25, 2005, which went into effect on April 25, 2005.

Dominican Republic

LOCATED IN THE Caribbean, the Dominican Republic occupies the eastern part of the island of Hispaniola, the other part the Republic of Haiti. It has a land area of 18,810 sq. mi. (48,442 sq. km.), with a population of 9,183,984 (2007 est.), and a population density of 474 people per sq. mi. (182 people per sq. km.). The capital, Santo Domingo, makes up for about a quarter of the population of the country, which remains extremely poor, with a Gross Domestic Product per capita of $2,776 per year.

In the Dominican Republic, sugar cane crops are being repurposed to make ethanol to blend with gasoline.

About 21 percent of the land is arable, with a further 43 percent used for meadow or pasture. Historically, the mainstay of the economy has been sugar, with sugar cane now being used to make ethanol to blend with gasoline to reduce greenhouse gas emissions. The carbon dioxide emission per capita for the country has been relatively low, at 1.4 metric tons in 1990, but rose steadily to 2.5 metric tons by 2003. Most of this came from the use of liquid fuels (94 percent), with the remainder from the manufacture of cement (5 percent), and the use of solid fuels (1 percent).

The largest amount of the electricity generated is used for general household consumption, for air conditioning units in houses and businesses, and also for the influx of tourists. There has also been a rise in the number of people who own their own cars, and no longer use the *gua-gua* (buses). Forests cover 13 percent of the country. There is extensive logging by farmers and developers, even though commercial tree cutting has been outlawed since 1967.

To try to combat climate change, the government of Joaquín Balaguer took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention in the following year. The government of Hipólito Mejía accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on

February 12, 2002, which want into effect on February 16, 2005. This, however, has not prevented the destruction of most of the coral reefs off the north shore of the country, which have been badly damaged by hurricanes and by anchors from fishing boats that have heavily overfished that region.

Doris Duke Charitable Foundation

THE MISSION OF the Doris Duke Charitable Foundation (DDC) is to improve the quality of people's lives through grants supporting the performing arts, environmental conservation, medical research, and the prevention of child maltreatment, and through preservation of the cultural and environmental legacy of Doris Duke's properties. Established in 1996, the foundation supports four national grantmaking programs. It also oversees three properties that were owned by Doris Duke in Hillsborough, New Jersey; Honolulu, Hawaii; and Newport, Rhode Island. The foundation is headquartered in New York and is governed by a 10-member board of trustees. The foundation has a specific program on environment that targets the challenges brought about by global warming and climate change.

The DDC's activities are guided by the will of Doris Duke, who endowed the foundation with financial assets that totaled approximately $1.8 billion as of December 31, 2006. The foundation regularly evaluates and modifies its allocation of resources from the endowment to support the programs and properties. Born in New York in 1912, Doris Duke was the only child of James Buchanan Duke, a founder of the American Tobacco Company and Duke Energy Company, and a benefactor of Duke University in his native North Carolina. During an adventurous lifetime lived in the spotlight of media attention, Doris Duke did a great deal of philanthropic work, especially in the areas of medical research, childcare, and environmental preservation. When she died in 1993, at the age of 80, Duke left virtually all her fortune to the DDC. Duke's butler, Bernard Lafferty, was left in charge of the foundation by the heiress, but a lawsuit soon provoked his discharge.

The foundation awarded its first grants in 1997. As of December 31, 2006, the foundation has approved approximately 696 grants totaling approximately $479 million to nonprofit organizations throughout the United States. Grants are awarded in four program areas. The Arts Program supports performing artists by producing their works for public performances. The Medical Research Program supports clinical research to prevent and cure diseases. The Child Abuse Prevention Program promotes the healthy development of children by protecting them from abuse and neglect. The scheme which is most directly related to global warming and climate change is the Environment Program.

Doris Duke was a lifelong environmentalist and had a particular interest in conservation. In her will, she expressed her interest in "the preservation of wildlife, both flora and fauna" and in supporting "ecological endeavors." These became the two main points in the mission of the DDC's Environment Program. The scheme works to reach its aims through two strategic initiatives. Habitat Conservation seeks to preserve essential habitats identified in state wildlife action plans through grants that identify priority habitats for conservation, protect priority habitats, and build conservation knowledge. The DDC regards the wildlife conservation strategies submitted in 2005 by the 50 U.S. states to remain eligible for funding through the U.S. Department of the Interior's State Wildlife Grants Program as a blueprint for protecting the most important areas for our nation's wildlife. Habitat Conservation, thus supports state efforts to develop and implement wildlife action plans that identify priority lands for habitat conservation. It encourages the protection of priority areas identified in state wildlife action plans, the development of new sources of conservation funding, and the integration of state wildlife action plans into local, regional, and national planning efforts. The program also has a series of training, research, and education initiatives that advance the Environment Program's mission.

The second function of the DDC is directly related to climate change. It seeks to help build a clean-energy economy through grants that design optimal pricing policies for greenhouse gases, identify and promote policies that accelerate the development of clean-energy technologies, and suggest ways to adapt to climate change. The DDC recognizes that:

> climate is changing at a rate that jeopardizes our environmental, economic and social welfare, and the choices we make now about how we generate and use energy will either lock us into decades of unmanageable carbon emissions or set the stage for a sustainable future. The Climate Change Initiative focuses on building a clean-energy economy that works for people and the planet.

By devising optimal domestic and international pricing policies for greenhouse gases, especially carbon dioxide, the DDC intends to make existing and new clean-energy technologies competitive in the marketplace. Grants in this strategy fund academic institutions and nongovernmental organizations working at the state, national, and international levels to design optimal greenhouse gas pricing policies. These will encourage the limitation of emissions.

The second strategy of the Climate Change scheme, to promote the development of clean-energy technologies, encourages the development of policies that will make the existing technologies (such as wind and solar power) available to the market more quickly, particularly technologies dealing with energy efficiency, renewable energy, and low-emission uses of coal. This strategy also endorses policies leading to the development of tomorrow's clean-energy technologies.

The third strategy of the Climate Change scheme is intended to suggest ways in which we can adapt to climate change. Initiatives in this area try to assess the likely effects of climate change and identify adjustments that can be made to reduce the impact of those effects on people and the environment. The DDC considers this strategy important as, regardless of whether actions are taken now to reduce greenhouse gas emissions, gases already in the atmosphere will continue to push temperatures higher. This phenomenon will have uncertain impacts on agriculture, forest and freshwater resources, wildlife, and public health.

The DDC regards its Climate Change project as an important part of its work and one consistent with the mandate of Doris Duke's will. It has committed to the formulation of clean-energy policies that can encourage the building of long-term infrastructures. The Climate Change initiative was launched in 2007 for a five-year period, with a budget of $100 million.

Drift Ice

IN THE WORLD'S polar regions, ice that floats on the water's surface is termed drift ice. Drift ice is named for its tendency to be carried by wind and currents. Drift ice that is forced into a single mass is called pack ice. The two major ice pack regions in the world, accounting for the majority of the ocean drift ice, are the Arctic and Antarctic ice packs. Increasing water and air temperatures are causing this ice to melt. The extent of this ice depletion by climate change is unknown. Further, the impact of these changes on ice-dependent species, in the long-term, is not clear.

Drift ice plays a critical role in climate and ecosystem habitats. The ice originates from the freezing of seawater and can be of varying size and shape. The extent of regions that are covered in potential drift ice (sea ice) during the past 30 years has significantly decreased in the Arctic. However, researchers suggest that while some Antarctic areas are decreasing in ice cover, others are actually on the increase. While the

Some of the polar regions' most sensitive macrofauna, including birds, seals, penguins, and polar bears, are dependent on drift ice as platforms for rest and hunting, and as sources of food.

future of drift ice is uncertain, climate models predict a continual decrease in the Arctic regions and a comparable decrease in the Antarctic regions.

The annual fluctuation in Arctic ice ranges from 4.35–9.32 million sq. mi. (7–15 million sq. km.), from the end of summer melt to its peak at the end of winter, respectively. The sea and drift ice area surrounding the Antarctic continent, similarly, range from 1.86–11.18 million sq. mi. (3–18 million sq. km.) during the same seasonal fluctuation. Seasonal ice can range in thickness from 3.28–6.56 ft. (1–2 m.), compared to the typically much thicker permanent ice that does not melt during the summer. The area of ice that does not melt during the summer is gradually decreasing.

Drift ice contributes significantly to the albedo of the Earth's surface, or its reflectivity. High albedo reflects more of the Sun's energy, keeping the Earth cooler, whereas low albedo, particularly with decreasing ice, permits absorption of the Sun's energy by the oceans, which hold the heat and, ultimately, warm the Earth. Snow-covered drift ice contributes even more significantly to a high albedo, but is becoming rare during the summer melt season, when solar energy is greatest.

The contribution of drift ice to the livelihood of humans and animals is significant. Drift ice is a keystone contributor to local and regional food webs. Any changes in ice densities impact tiny microorganisms, including algae and zooplankton, which are dependent on the ice for nutrients and shelter. Ice algae are the primary producers in ice-associated food webs. As primary producers, they are critical to the survival of all higher-level organisms. Ice habitats are critical for the juvenile life stages of many microorganisms, such as zooplankton, which are dependent on these algal and bacterial populations for survival. Fish seek shelter under the drift ice and feast on the abundant zooplankton. Some of the polar regions' most sensitive macrofauna, including birds, seals, penguins, and polar bears, are dependent on this floating ice as platforms for rest, hunting, and a source of food; many feed on the microorganisms and fish found just under the drift ice.

Indigenous Arctic peoples are dependent on drift ice and sea ice for subsistence hunting of whales, seals, and fish. Decreases in, and thinning of, drift ice with climate change and warming trends reduce the time annually that these peoples have to hunt. The macrofauna spend less time in areas that are readily accessible to the hunters, decreasing the opportunity for a successful hunt and the feeding their families. These decreases in drift ice may also be beneficial to humans, however, with the opening of channels for new sea routes and potential future economic benefits. Ease of navigation through these areas may increase trade between indigenous peoples.

From a global climate perspective, melting of drift ice is likely to have a significant impact on ocean circulation patterns. Ocean circulation is driven by water density differences (thermohaline circulation). Ocean surface waters freeze, and as they freeze, salt from that water is transferred to the water below, thereby increasing its salinity (drift ice has very low salt content). This causes the surrounding surface waters of the oceans where ice forms to increase in salinity. The drift ice is moved by winds and currents to far-reaching locales, contributing "freshwater" ice melt to these areas. With increased melting of the drift ice, freshwater inputs to coastal areas are increasing, potentially causing submersion and flooding of these coastal zones.

Scientists predict that as the ice thins, seawater circulation patterns will change, potentially impacting the ocean circulation patterns of the entire planet. Biodiversity of microorganisms dependent on the drift ice for habitat and resources will decrease. If the oceans change from primarily ice-covered to primarily open waters, the productivity (phytoplankton) of the regions will increase dramatically, altering the oxygen and nutrients available for other organisms, and shift the food web structure, as ice-algae would no longer serve as the primary producers. Regional macrofauna may be forced to move to new regions, if drift ice is no longer present, or their populations will be significantly diminished. The potential impact of climate change and warming on the distribution of drift ice (as the foundation of sea ice) is a major focus of the 2007–08 International Polar Year research programs.

Drought

DROUGHTS OCCUR WHEN the rainfall in an area falls below its normal pattern for an extended period of time. If the drought occurs in a region where crops are usually not irrigated, then farmers suffer crop losses that may range from mild to severe. If the drought is extreme, the crop losses may be total, because the plants wither and die without water. The weather, which is the current atmospheric conditions locally or regionally, can develop into a pattern that seems to be stuck. In such conditions, floods or drought may occur. Meteorologists who make long-range weather predictions cannot predict droughts. However, scientists and others who study climatic conditions produced by weather patterns in an area or region over long periods of time have found that there are times in which drier weather than normal occurs and when wetter weather than normal occurs.

By studying the growth patterns of tree rings, seasons of significant growth in wet years can be seen in comparison with years in which drought occurred and as a consequence the tree grew little. When the pattern of wet and dry year growth is observed in tree ring patterns, it is not unusual to find multi-year periods when trees grew rapidly followed by little growth in multi-year times of drought. Weather over a long time period becomes patterns of the climate flowing in irregular repeated cycles. These may be cycles that occur occasionally every 50 or 100 years, or they may occur somewhat more frequently.

Droughts are caused by a lack of rainfall or snowpack. If water vapor is not in the atmosphere, then rising temperatures causes warm air to rise and, in the case of warm moist air, to condense in the cooler upper atmosphere and to shed its moisture as rain or other forms of precipitation. If rising air or water vapor is not present in combination, then drought results.

Meteorological droughts are due to changes in climatic conditions over vast regions. Conditions that can cause a drought include shifts in the jet stream in the presence of an El Niño, which signals changes in the temperature of vast areas of ocean water that contribute moisture for rainfall or other changes.

Agricultural droughts are usually produced by meteorological droughts. They occur when the average precipitation is insufficient to support agricultural activity at its normal levels. In agricultural droughts, crops die or produce only a small portion of their normal yield. Livestock must be fed with imported food, sold, or turned loose to forage for themselves. Deforestation also affects local conditions that cause or retard rainfall. Many scientists believe that it is still too soon to determine whether the rise of average global temperatures in the last 100 years is sufficient to create global warming conditions that are causing droughts in areas where droughts have historically been rare.

EFFECTS OF DROUGHT

When droughts occur, they can have a number of negative effects. The drought can cause the destruction of plants and animals, and the deaths of vast numbers of human beings. Droughts can be the result of a failure of winter rains and snows. The absence of winter moisture can affect plants, animals, and humans. In many areas, water supplies are dependent upon winter moisture that is stored for use by farmers and cities, and may, if the drought is prolonged, create immense problems for humans. For example, Los Angeles, California, is dependent for much of its water supplies on snowmelt from the snowpack in the high Sierra Mountains in northern California. If there is a winter snow drought, it is a threat, because water supplies have to be managed very carefully and alternative supplies sought.

The failure of the winter snows or rains, the spring rains, or even summer showers to come can also be accompanied by weather patterns that are damaging. Warm winter temperatures may trick plants into blossoming as if the warm seasons of the year have arrived. The sudden return of cold weather can then bring freezing temperatures that damage or kill plants that have emerged from a wintertime dormant state.

Global warming as a likely cause of the destruction of glaciers is of enormous concern to many scientists, the United Nations, and others because their destruction may greatly affect the rivers of India, China, and Southeast Asia. The Himalayan glaciers are the sources for the largest rivers in Asia. The Indus River, especially in its Punjab area, feeds millions. The Ganges and the Brahmaputra are also the sources of water for 500 million Indians. If the Himalayan ice pack were to disappear because of global warming, then the Yellow, Yangtze, Mekong, and Salween rivers would probably disappear or be reduced to only a trickle of their former flow volumes. The effects could be deadly for billions of people.

Droughts are often accompanied by higher than normal temperatures. The higher temperatures cause plants to suffer heat stress. The heat stress from temperatures that may be 10, 20, or more degrees above normally occurring temperatures dry out plants so that not only crops, but also grasses, brushes, trees, and other plants are vulnerable to dehydration. They may become dormant to endure a drought. Diseases may then successfully attack plants that would not have normally been vulnerable.

The longer a drought continues, the drier the vegetation, including dead-fall and the decaying leaf matter on the ground in wooded areas. The possibility of forest fires, or of fires in more open country, begins to grow at an exponential rate. It is not unusual for drought to be accompanied by many forest fires or brush fires.

HISTORICAL EXAMPLES OF DROUGHT

Short-term drought occurred in many places in the world during the 20th century. western Europe, including England, experienced years of drought on a number of occasions, as did parts of the United States. South America, Africa, and Asia have also known years in which drought conditions occurred. In the 1960s, drought appeared in the northeastern United States. Winter snows failed in the western United States 1975–77. In 1976, western Europe suffered a summertime drought. In the late 1960s and in the early 2000s, parts of Africa suffered from drought.

There are regions of the world where drought is normal. Some areas, such as the northeastern area of Brazil or other semi-arid regions, have regularly reoccurring patterns of drought. Drought in some areas of the Amazon basin, in 2005, was recorded as a 100-year drought. Some Brazilian scientists argued that it was due to deforestation that was pushing the Amazon rainforest to a tipping point where it would never recover as a rainforest.

In areas of the Mediterranean, or where a Mediterranean climate occurs (California, Central Chile, South Africa, and south and southwestern Australia) drought in the summertime is normal because there is less than 4 in. (2.54 cm.) of rain that falls during the summer months. The winters in areas with a Mediterranean climate are cooler and wetter than the summers. The rains of the non-summer months cause plants to grow profusely. However, the long dry summers expose the plants to fire hazard. Southern California is well known for brush fires that destroy the vegetation in many thousands of acres. People who have built homes in fire-prone areas may lose them to these wildfires. Plants in such regions are adapted to drought and to depend upon periodic fires for renewals. Fires that occur in drought conditions can be so severe that great expanses of timber and grassland are destroyed. With the cover crops and vegetation removed by fire, hot, dry winds can pick up soil and further damage soil productivity.

One reason for the concern over the loss of glaciers is that they feed rivers like the Indus, which sustains millions of people.

During the 1930s, a period of drought (1931–38), afflicted the states of the Great Plains. The 1920s had been a wetter time. It had also been a time in which farmers used the plowing techniques of the eastern United States. The deeper soil in the east was improved by plowing deep to bring up minerals from under the soil. However, in the drier conditions of the Great Plains, plowing deep broke the water table's contact with surface plants. The conditions were created for the terrible dust storms that occurred in the famous Dust Bowl.

RECENT DROUGHTS

Droughts occur in other parts of the United States with some frequency, but on an irregular schedule. They may be mild and last only a year or two. Other droughts can be prolonged and last for five, six, or more years. They range from mild, to severe, to extreme. During 2007, Georgia, Alabama, and areas of Florida suffered an extreme drought that was unprecedented. Lakes, ponds, and streams ran out of water and became dry. Wells and other sources of water were depleted, causing significant political turmoil.

Besides a meteorological and an agricultural drought, the area was experiencing a hydrological drought. The water resources had not been husbanded with sufficient stewardship to make them last well during the drought. Some areas of the world, such as the Aral Sea, and a lesser extent the Caspian Sea, have experienced hydrological drought because water resources have been used beyond the limits of precipitation needed to restore them to normal levels in wet years.

Political disputes, in 2007, over the distribution of water by the U.S. Army Corps of Engineers from Lake Lanier in north Georgia into the Chattahoochee River involved many parties. The politics of drought, in this case, involved not only the federal government, but also the governments of the states of Alabama, Florida, and Georgia, as well as many of their cities and counties. In addition, power companies that use riparian waters in the generation of electricity were involved in the controversies that the drought evoked.

The drought also brought ecologists, state environmentalists, and others concerned about the survival of plants and animals into conflict with businesses and developers. Species of mussels in the lower Chattahoochee could become extinct if water levels drop too severely. They are a harbinger species, like canaries in coalmines in earlier times, which were used to detect the presence of dangerous quantities of gas that threatened life. Their loss could be much more important than just the loss of an inedible species that plays a role in cleansing impurities from river water, aiding the survival of fish species.

The drought in the southeastern United States in 2007 is believed to be connected with global warming. It may just be a cyclical shift in the positioning of normal summertime high-pressure air masses usually centered westward over Bermuda. Most scientists believe that the drought conditions in the United States may be the result of global warming, but in order to state that climate has changed, long periods of weather activity must occur, be recorded, and then examined for permanent changes in patterns.

In other parts of the world, droughts have caused famines resulting in the deaths of those who live a subsistence life in arid lands at the edge of deserts. The people of Mongolia, of the Sahel, which is the arid transition zone between the Sahara Desert and the savannah lands to the south, of the southwestern United States and northwestern Mexico, Australia, the Middle East and Central Asia, and other places have long lived with recurring periods of drought.

Historians have concluded that periods of drought also stimulate mass movements of people. When drought occurred in Mongolia, the weakest tribes were driven out to rampage westward across the steppes and became civilization-changing forces. It is likely that severe droughts caused by global warming will cause movements of peoples and will also contribute to political instability in many parts of the world. The instability may also lead to wars and the deaths of many people, just as the lack of water during droughts has often caused deaths from heat, famine, and consequent diseases.

Conflicts in the late 20th century and the early 21st century in the Horn of Africa and in the Darfur region of Sudan are directly related to prolonged drought conditions that exacerbated conflicts between tribes and peoples. Other conflicts are also connected to competition for scarce resources that are directly related to water shortages caused by droughts. Drought conflicts can bring nomads into a struggle with farmers of marginal lands. The farmers, or the nomads, if defeated, may well overrun their neighbors, causing disruptions among peoples who were not as severely affected by a drought. Drought is normal in many parts of the world, but it may be that global warming is contributing to an increase in droughts, or a shifting of the locations of droughts. Regardless, with the great increases in world population during the 20th century, it is prudent to create drought mitigation and survival plans.

Dynamical Feedbacks

A DYNAMICAL FEEDBACK is a relationship within a system in which the effects caused by one part of the system on another part eventually come back to affect the first part. The easiest such relationship to envision might be a tug of war, in which each side has to pull harder, causing the other side to pull harder, causing the first side to pull harder still. In the study of global warming and climate change, these feedbacks are especially critical.

In a more general sense, a feedback is a relationship found in most complex systems: the output of that system is returned to the input. Negative feedback reduces that output (cancels out some of the effect), while positive feedback increases it. In climate change, as in many complex systems, both negative and positive feedbacks exist; just as with credits and debits in a bank account, the net effect is determined by the strength and magnitude of those multiple gains and losses.

Where global warming is concerned, positive feedbacks are easy to identify: they are all relationships where global warming encourages a trend, which itself contributes to further warming. An oft-cited hypothetical from Earth science classes is the use of chlorofluorocarbon-emitting air conditioning: as summers get hotter, such air conditioners run longer, releasing more CFCs into the air contributing further to the greenhouse effect,and the next summer is hotter still. There are plenty of observable expamples of dynamical feedback. In recent years, there have been more forest fires than usual. Global warming and dry weather contribute to this. In turn, the fires impact the climate, not only through deforestation, but by releasing large amounts of carbon dioxide.

Similarly, warmer temperatures have meant the thawing of permafrost, in the high-latitude soil that has been below the freezing point for at least two years (and often much longer). In western Siberia, areas of permafrost peat bogs that have remained frozen for thousands of years—since the last ice age—have begun to thaw, releasing considerable amounts of methane, which will worsen the greenhouse effect. Methane hydrate—ice containing dissolved methane—exists in enormous deposits on the cold ocean floor, and warming sufficient to melt it would release a great deal of methane all at once—at, it is believed, a much faster rate than has been seen in the past, even from industrial pollution. Methane is a greenhouse gas with an effect on global warming five times that of carbon dioxide.

The carbon cycle, too, can work as a positive dynamical feedback for global warming. As anthropogenic causes increase the total amount of carbon passing through the carbon cycle, more of it remains free in the atmosphere, as the carbon load exceeds what the other phases of the cycle can take in. Various models have found that global warming increases the amount of anthropogenic carbon dioxide remaining in the atmosphere, which, in turn, accelerates global warming; the models disagree only on the extent to which this happens.

The ice-albedo feedback is another clear example. As temperatures near the Earth's polar regions increase, more and more ice melts—either permanently or for the summer—leaving land and water in its place. Ice is a highly reflective surface, that reflects more sunlight back into space does than land or water—and the difference in reflectivity is relevantly high. Over time, as the polar ice retreats, more Sunlight is retained by the Earth's surface, and with it, more heat. Though popular discussion of the polar ice caps melting with regards to global warming focuses on rising sea levels, many models implicate the ice-albedo feedback in their predictions of future catastrophe and major climate change.

Perhaps the greatest feedback is the evaporative feedback. Just like carbon dioxide and methane, water vapor is a greenhouse gas. Higher temperatures lead to greater evaporation of the Earth's surface water. At the same time, the amount of moisture the air can hold increases exponentially with the temperature—as anyone has noticed in a southern summer, the hotter it is, the more humidity or the more water vapor can be held in the air. So globally, as temperatures rise, not only is more water vapor produced, but less of it is forced to condense or precipitate, and the absolute water vapor content of the atmosphere increases—and with it, the temperature rises again.

Earth's Climate History

CLIMATE IS NOT a static set of weather conditions, constant over eons; rather it varies, sometimes in dramatic ways, over time. The hot climate of the newly-formed Earth gave way to glaciers in a little more than a billion years, an immense time by human reckoning, but not nearly so long by geological standards. Earth's climate has alternated many times between hot and cold periods of varying magnitudes. Radiation from the Sun, the ocean currents, rainfall, wind, continental drift, the concentration of greenhouse gases in the atmosphere, volcanic activity, radioactivity in the Earth's core, the eccentricity of Earth's orbit around the sun, the tilt of Earth's axis, and photosynthesis all affect climate. Climate has not one, but, rather, myriad causes. Disentangling these causes is not easy, but it is necessary to understanding why climate changes over time. The current climate is warming. The culprit, carbon dioxide, has been increasing in the atmosphere, driving up temperature, and prompting speculation over Earth's future climate.

The interlocking scientific theories of the 19th century—Darwinism and uniformitarianism—implied that climate changed little, and then only gradually. uniformitarianism held that the climactic conditions prevailing today are very similar to the conditions that prevailed centuries and even eons ago. Charles Darwin matched his theory of evolution to the dictates of uniformitarianism. Darwin posited that species evolve gradually in response to slow and small changes in the environment. Climate might change, but neither abruptly nor by a large magnitude. In contrast, the advocates of catastrophism asserted that Earth has been racked by sudden changes. Modern geology has retained the kernel of catastrophism. The climate has changed quickly by geological standards, and by large swings in temperature and precipitation.

EARTH'S EARLY CLIMATE

Earth is roughly 4.5 billion years old. Its early climate was the hottest in the planet's long history. Temperatures were hot enough to liquefy rock, a circumstance that accounts for the absence of rock from the early geological record. The mass of radioactive elements in Earth's core was the maximum at the origin of Earth. The radioactive elements generated heat and pressure as they decayed, pushing molten rock toward Earth's surface. Volcanoes were active, bringing molten rock to the surface, where it liberated its heat. Volcanoes spewed carbon dioxide (CO_2) into the atmosphere, causing the greenhouse effect. Sunlight passed through the atmosphere and struck Earth, which absorbed some sunlight as heat and radiated the rest into space as infrared radiation. Rather than disappearing into space, the infrared radiation was absorbed by CO_2, heating the atmosphere. The amount of CO_2 in the atmosphere of the newly-formed Earth was 1,000 times higher than it is today, more than making up for the fact that the young Sun burned with only 70 percent the luminosity of its mature, current phase. At its origin, Earth received only as much sunlight as Mars receives today. The young Earth was too hot for water to liquefy. Instead, the atmosphere held all of Earth's water as vapor. Like CO_2, water vapor traps heat in the atmosphere, intensifying the greenhouse effect.

As the mass of radioactive elements in Earth's core diminished, the climate cooled, and the first rock formed roughly 3.8 billion years ago. The cooling of the atmosphere liquefied water vapor, which fell to Earth as rain. The deluge was greater than any rainfall since, filling Earth to a depth of 2 mi. (3.2 km.) and forming the primordial ocean. The origin of life around 3.5 billion years ago enhanced the cooling of the climate, for among the first life were single celled photosynthetic algae. Like modern plants, these algae consumed CO_2 and exuded oxygen. The reduction of CO_2 in the atmosphere weakened the greenhouse effect. Rainfall also diminished the amount of CO_2 in the atmosphere. CO_2 dissolves in rainwater to form carbonic acid, a process that removes carbon dioxide from the atmosphere. With the reduction in CO_2, temperatures dropped below freezing, causing the planet's first ice age roughly 3 million years ago.

The retreat of the glaciers one million years later inaugurated a long period of warm climate. The sun, burning steadily brighter, bathed Earth in its heat. Warm inland seas covered Earth, moderating the climate. Ocean currents circled the globe, spreading warm water from the equator to the poles. The warm climate persisted until 800 million years ago, when a series of ice ages and interglacials alternated the climate between cold and warm cycles.

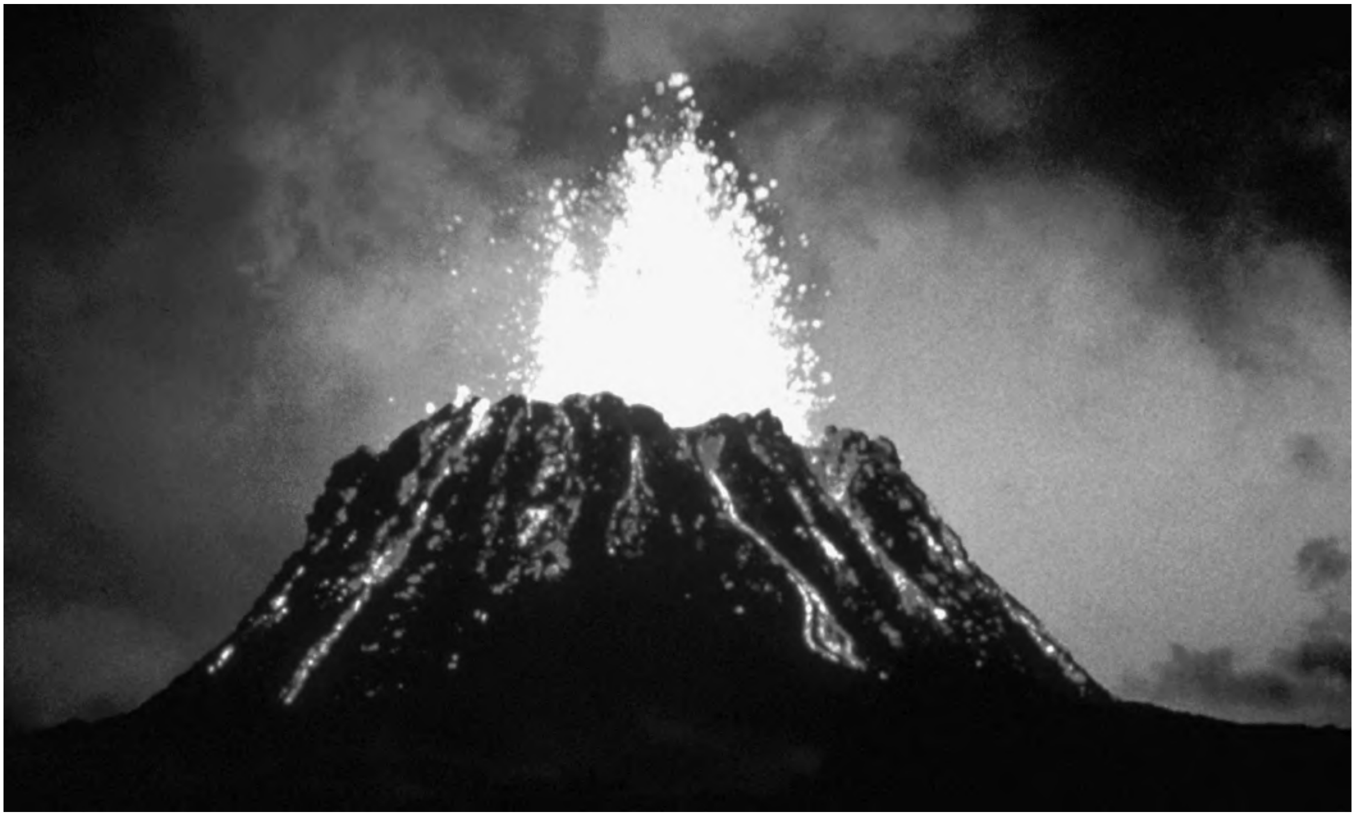
The multiple changes in climate may have an astronomical cause, in addition to terrestrial ones. Earth's orbit around the Sun is not constant, but changes its geometry. The orbit traces an ellipse that puts Earth far from the Sun at its greatest distance and near the Sun at its shortest distance. Because Earth's distance from the Sun varies, the amount of heat that Earth receives from the Sun fluctuates. Under these circumstances, Earth's climate alternates between hot and cold extremes, accounting for the advance and retreat of glaciers. At other times, Earth's orbit is nearly circular. Earth, at roughly a constant distance from the Sun, receives nearly the same amount of heat from it. Under these conditions, Earth's climate is uniformly warm, as it was during the Cretaceous Era.

EARTH WARMED

During the last Ice Age, glaciers covered the ocean as well as the land, killing photosynthetic algae that lived in the ocean. With algae in small numbers, they were able to remove only a fraction of CO_2 from the atmosphere. With no check on its accumulation, CO_2 increased in the atmosphere, causing the greenhouse effect. The greenhouse effect ended the Late Proterozoic Ice Age roughly 550 million years ago, inaugurating a new warm period. The lush plant growth of the Carboniferous Era (350–280 million years ago) confirms that the climate was warm and that CO_2, essential for plant growth, was abundant. Around 230 million years ago, the continents gathered into a single landmass called Pangea. Being near the equator, Pangea's climate was tropical. Even warmer was the Cretaceous Era (135–65 million years ago). Temperatures soared 20 degrees F (11 degrees C) warmer than in the current era. Forests covered Antarctica. Ocean currents again carried warm water to the poles. The transit of warm water to the poles caused polar water to be only 40 degrees F (4 degrees C) cooler than equatorial waters. The difference today is 75 degrees F (24 degrees C). The water at the bottom of the ocean, now near freezing, was then 25 degrees F (14 degrees C) warmer. Coral reef, which requires warm water to survive, grew 1,000 mi. (1,609 km.) closer to the poles than it does today. Antarctica was warm enough to support the growth of forests.

EARTH COOLED

The end of the Cretaceous suddenly reversed the climate. The consensus among scientists holds that an enormous meteor impacted Earth 65 million years ago. The meteor ejected a gigantic cloud of debris and dust and ignited widespread fires, which pumped ash into the atmosphere. The debris, dust, and ash blocked out much of the Sun's light, chilling the climate. So severe was the reversal in climate that the dinosaurs and a large number of marine species, unable to cope with the new conditions, perished.



Roughly 4.5 billion years ago, active volcanoes spewed carbon dioxide into the atmosphere, causing the greenhouse effect. Earth's early climate was so hot that all water vaporized, trapping heat in the atmosphere and intensifying the greenhouse effect.

The sudden reversal in climate has had a lasting, if erratic, effect on Earth. During the past 55 million years, temperatures have declined 20 degrees F (11 degrees C). Around 35 million years ago, the climate grew cold enough for glaciers to form on Antarctica. Yet, by 4 million years ago, the glaciers had melted and forests had returned to Antarctica. The forests were transitory: within one million years glaciers had once more spread across Antarctica and had begun to grow in the northern hemisphere.

The warmth of the Cretaceous returned briefly 130,000 years ago, when the climate was again warmer than it is today. The water from melting glaciers flowed to the oceans, raising the sea level 60 ft. (18 m.) higher than it is today. Approximately 30,000 years later, the climate cooled yet again, and glaciers once more spread across the continents, plunging Earth into its most recent Ice Age. Between 16,000 and 10,000 years ago, the glaciers in retreat, temperatures rose nearly 15 degrees F (8 degrees C). Toward the end of this era, and extending to 6,000 years ago, rain was plentiful. Africa had no deserts. Rather, Lake Chad, swollen with rain, was 10 times its current size. Salt Lake, in what is today Utah, was likewise several times larger than it is today. Variations in temperature were greater than they are today, because the tilt of Earth's axis was extreme. If Earth did not tilt on its axis, there would be no seasons, because the northern and southern hemispheres would receive the same amount of sunlight year round. However, Earth tilts on its axis 23.5 degrees. As a consequence, the northern and southern hemispheres receive differing amounts of sunlight during the course of a year, accounting for the seasons. The greater the tilt, the greater the amount of sunlight falls in summer, and the greater the darkness in winter. About 10,000 years ago, Earth tilted on its axis 25 degrees. The northern and southern hemispheres received 7 percent more sunlight in summer than they do today, and 15 percent more sunlight in summer than in winter. By contrast, the differential in sunlight between summer and winter is only 8 percent today.

Temperatures peaked 7,000 years ago at 2–3 degrees F (1–1.5 degrees C) above current temperatures. The climate remained warm and wet another 3,000 years. There was then no desert in the American Southwest, which received enough rainfall to sustain the growth of trees. Between 6,000 and 4,000 years ago temperatures rose 5 degrees F (2.7 degrees C) , melting parts of the glaciers that remained in Antarctica and Greenland. The water from these glaciers flowed to the ocean, raising sea level 300 ft (91 m.). The end of the rainy epoch 4,000 years ago turned the climate arid. Rainfall in the American Midwest fell 25 percent, even as July temperatures peaked 4 degrees F (2 degrees C) above current July temperatures. Deserts formed in the American Southwest, Africa, Asia and Australia. Along the Atlantic coast of North America, the climate remained warm and humid.

EARLY HUMAN RESPONSE TO CLIMATE CHANGE

Originating in Africa with a body adapted to warm weather, humans thrived in the moderate climate of antiquity. Inventing agriculture at the end of the most recent Ice Age, humans settled in the warm latitudes that sustained the growth of crops. At the margins, however, the climate was inhospitable. The Near East had long been arid. Around 4,000 years ago the Akkadians relied on rainfall, scant as it was, to irrigate their crops. When the rains failed, their civilization collapsed. Drought likewise extinguished the Mayan civilization of southern Mexico and Guatemala 1,200 years ago. In Europe, however, the Medieval Warm Period between 1,000 and 1,300 C.E. rewarded peasants with bountiful crops. They seldom went hungry, and landlords grew rich on the proportion of the harvest that they commandeered from the land. The favorable climate allowed Europeans to finance the crusades and the building of cathedrals.

Yet after 1300, the climate turned against Europeans. In only a generation, summers went from warm to cold and wet, and crops rotted in the fields. Having enjoyed a surplus of food, peasants were now on the verge of starvation. They clashed with landlords over who had a right to what little harvest there was. Malnutrition left Europeans vulnerable to disease, and the Black Death killed between one third and half the population. Climate had conspired with disease to inflict misery on a scale that is difficult to imagine. The cold climate intensified between 1645 and 1715 when the Sun, shedding one percent less sunlight than it does today, chilled Earth, cooling it 2 degrees F (1 degree C) . The diminution of sunlight corresponded with the low number of sunspots during these years. Sunspots are a measure of how much heat the Sun radiates into space and indicate, in this instance, that a small diminution in the sun's activity suffices to cool Earth. The eruption of Mount Laki, a volcano on Iceland, in 1783 spread volcanic ash and debris across the Northern Hemisphere, blocking out sunlight and cooling Earth. The eruption of Mount Tambora in Indonesia had a similar effect. By 1816, temperature had fallen 7 degrees F (3.8 degrees C) in New England and 5 degrees F (2.7 degrees C) in Europe. History records 1816 as the year that had no summer.

Although temperatures, with some fluctuation, have declined during the past 55 million years, they are beginning to rise again because of the greenhouse effect. Since 1750, the amount of methane, a greenhouse gas in the atmosphere, has risen 2.5 times. Fortunately, methane does not persist in the atmosphere, but breaks down in a few years. More worrisome is the amount of CO_2, which since 1750 has risen 31 percent. Unlike methane, CO_2 does not deteriorate, and has the potential to remain in the atmosphere for centuries. Since 1900, temperatures have increased 1.3 degrees F (0.7 degrees C) and the sea level has risen 6 in. (15 cm.) from the melting of glaciers in Greenland and Antarctica. Since 1973, the polar icecaps have shrunk six percent. The snow is melting from Mount Kilimanjaro in Africa and the Himalayan Mountains in Asia. Adding to the Greenhouse Effect is an increase in the number of sunspots since 1985. The increase in temperatures may intensify the climate, causing hurricanes in the Caribbean and Gulf Coast, and droughts in Africa and North America.

Curiously, temperatures and the amount of CO_2 in the atmosphere were higher 130,000 years ago than they are today; yet, the earlier warm climate was followed by an ice age. Therefore, scientists may not be able to predict if the current temperatures will spiral upward or will end in yet another ice age. Unsure of the future, humans are increasingly aware that their activity affects the climate. The burning of fossil fuels at a prodigious rate pollutes the atmosphere with more CO_2, threatening to raise temperatures still further. In the developed world, progressives talk about renewable energy, but despite their rhetoric, countries continue to pump CO_2 into an already crowded atmosphere. In Central and South America, people are chopping down the rainforest, removing the trees and plants that would have consumed some fraction of the CO_2. Earth, and with it the climate, may be in crisis.

Earthshine

THE *WORLD BOOK* defines albedo as "the ratio of light reflected to light received by a planet or other heavenly body." Earthshine arises from sunlight reflected from the Earth to the dark of the moon and back to the nighttime Earth. The albedo is due to the Earth's cloud cover and the diversity of landscapes. Leonardo da Vinci (1452–1519) first explained Earthshine in the 15th century. A simple technique was developed to measure the amount of sunlight that bounces off the Earth's surface and is subsequently reflected by the moon. Earthshine is faintly visible to the naked eye on the darker side of the crescent moon as an ashen glow. For many phases of the moon, Earthshine is easily visible by the naked eye.

André-Louis Danjon (1890–1967) performed the first rigorous Earthshine measurements in 1926. He captured 200 data points over a period of five years with his cat's eye photometer, and using a technique he pioneered called the Danjon scale. Danjon found it was important to take the measurements well after and well before a full moon or a new moon. Having an even area of bright and dim light when observing the moon's surface is needed to gain an accurate reading of Earthshine. After then, few measurements were taken, until NASA funded Project Earthshine in the 1990s to obtain albedo numbers. A value of 0.297 was obtained from the study. The research team used a 6-in. refractor telescope housed at California's Big Bear Solar Observatory. Earth's albedo decreased 2.5 percent during a period of five years. Satellite measurement of solar irradiance reported a variation of no more than .1 percent during an entire 11-year solar cycle. Some experts believe this deviation is too small to change climate or leave a terrestrial footprint of the solar activity cycle. Thus, Earth's reflectivity may be what is magnified in an indirect role of the Sun in climate change. If this ability to reflect light is degraded, by even as little as 1 percent, global warming could be accelerated.

Earthshine measurements using low-power Earthbound telescopes are practical since they are cost-effective, easy to conduct, and immediately cover a large portion of the Earth's surface. Satellite determinations of the albedo, however, are costly and require precise calibration to obtain good results. In addition to capturing measurements when there is a clearly-defined moon crescent, it is important to average a large number of data points. This is to remove the effects of a single measurement location where a nighttime measurement would see more light reflected by a large landmass on the opposite side of the planet, or where less light would be reflected by an ocean. This process of averaging provides a more accurate reading of a changing albedo. Modern techniques enable a measurement accuracy of 2 percent for each reading, which is equivalent to measuring Earth's emission temperature to within 0.8 of a degree C.

Earth's cloud cover dominates the "shininess" feature of the planet. Clouds reflect around 50 percent of incoming sunlight. Snow and ice reflect even more sunlight, usually from 50–90 percent. The melting of polar ice and disappearance of Greenland's ice cover leaves more water, which reflects only 8 percent of sunlight, and uncovers more land, which is also a poor reflector of sunlight, usually with a reflectivity of 10–25 percent. The darker the surface, the lower the albedo, and the more solar energy absorbed. The dark side of the moon usually refers to the side of the moon that the human eye cannot see from Earth, even with the aid of a telescope. In the controversial world of climate change and the use of Earthshine as a tool to gauge global warming, the dark side of the moon now refers to the dim side of the moon in its crescent configuration. The moon's surface provides astronomers and climatologists another means for measuring both sunshine and Earthshine, and to assess the global warming phenomenon.

East Timor

FORMERLY A PORTUGUESE colony, East Timor (or Timor Leste) occupies the eastern half of the island of Timor, along with the enclave of Oecussi, on the northwest coast of the island. It has a land area of 5,743 sq. mi. (15,007 sq. km.), with a population of 947,000 (2005 est.), and a population density of 166 people per sq. mi. (64 people per sq. km.). Forests, with a small timber industry, cover much of the country. Much of the arable land is used for subsistence farms and small coffee plantations, and coconut, cloves, and cocoa are also grown commercially. Because of the undeveloped nature of the country, and the low standard of living, the rates of carbon dioxide emissions are extremely low, measured at 0.2 metric tons per person in 2002 and 2003.

During a visit to the island around 1901, an Australian chemist, traveling to find new pharmaceutical products, spotted deposits of oil, but attempts to locate oil on land during the 1930s never found any substantial supplies. However, during the 1980s, vast oilfields were found offshore in the Timor Sea between East Timor and Australia. Jointly developed by Australia and Indonesia, East Timor lay claim to these fields after its independence in 1999. The oilfields are now jointly owned by East Timor and Australia. As a result, East Timor has become a petroleum exporter, contributing to climate change and global warming. The major effect of global warming on East Timor is likely to be increased damage to coastal areas, including Dili, the capital. Some problems with agricultural production may also begin as the temperatures rise, making it harder to grow some crops that normally grow in more temperate climates.

Ecological Footprint

THE ECOLOGICAL FOOTPRINT is a metaphor for ecological impact, regardless of where that impact occurs. The ecological footprint is also an ecological accounting tool, a measure of the environmental impact of consumption and subsequent waste discharge. Consumption items are divided into food, shelter, transportation, and consumer goods and services. The consumption impact is measured by converting impact variables into the single unit of land, measured in hectares or acres. This includes land appropriated by fossil energy use, the built environment, gardens, cropland, pasture, managed forest, and land of limited availability, including untouched forests and non-productive areas, such as deserts and icecaps. The major strength of the ecological footprint as a way of measuring the sustainability of cities is that it enables a picture of the flow of materials into and out of the city.

Bill Rees and his students, particularly Mathis Wackernagel, developed the concept of Ecological Footprints (EFs) as a way of ascertaining sustainability at the University of British Columbia in Vancouver, Canada. Most analyses of sustainability, whether radical or mainstream, recognize that major concentrations of human consumption generate impacts far beyond a nation or a city's formal boundaries. Prior to the invention of the concept of EFs, very few policy, lobby group, or academic analyses successfully moved beyond highlighting these external impacts as issues that needed to be addressed. Ecological footprint analysis managed to put forward a way of both measuring and vividly demonstrating how ecological impacts extend far beyond the official area of cities or countries.

The EF approach is similar to the idea of "ghost acres" developed by the Swedish academic Georg Borgstrom in 1965. The focus of Borgstrom's work was adequate nutrition for a growing population. The ghost acres were comprised of fish acreage and trade acreage. Jim MacNeill and colleagues extended the concept in the lead-up to the Earth Summit in Rio de Janeiro in 1992. The metaphor of ghost acres for food production was extended to include other consumption concerns, and repackaged as "shadow ecologies." More recently, William Catton discussed the idea of "phantom land." This concept refers to how humans currently use the ecological productivity of ecosystems that no longer exist. For example, nature cannot replace fossil fuels such as coal and oil at the rate that humans are diminishing the stock of nonrenewable resources. The goal of ecological footprints is to document "overshoot," which refers to the excess global demand over global supply, of nature's resources for human use.

Since the original EF methodology was developed, a number of different approaches have emerged. At the Footprints Forum in Siena, Italy, in June 2006, an international standard for footprinting was introduced to ensure consistency. This standard was divided into application standards and communication standards. Standard number 15 attempts to clarify the relationship between EFs and sustainability; that ecological footprinting is a necessary criterion for sustainability, but it is not an absolute indicator of sustainability. This point is crucial because the EF is a tool that may be used to inform choices and policy development, but it is not a predictive tool, nor can it be a surrogate for environmental policy.

Although the national scale is used as a benchmark in the 2006 Footprint Standards, the EF approach can be used at a variety of scales that have been labeled sub-national. These include cities, regions, states, counties, and organizations. In the case of a city, the approach can be used to calculate the equivalent amount of land consumed for a city to function. This equivalent amount of land is influenced by changes in both population and per capita material consumption.

Critiques have been made about the ecological footprint concept. These include questioning the desirability of converting everything into a single unit, called land. Although the goal may be deciding how best to limit the footprint. However, reducing the size of the ecological footprint does not equate to reducing environmental impacts if the uniqueness of nature, the cultural values associated with particular sites, and so on, are lost in this quantification process.

There is also the problem of boundary definition for comparing ecological footprint scores. It is easy to achieve a smaller EF where the boundary around a city is drawn wide enough to include agricultural land. There have been studies of many cities around the world using similar methodologies, which make it possible to compare the results and arrive at some logical, but erroneous, conclusions. Areas with a high population and with little or no agricultural land within their borders will inevitably generate a higher EF, unless there is a huge difference in the material consumption between areas.

The high ecological footprint for many places is primarily due to the use of "energy land." This land is calculated as the amount of land and water required as carbon sinks to sequester the greenhouse gas emissions generated by human activities, including energy production, agriculture, and transport. This carbon component now comprises about half the total EF. It has increased approximately nine fold since 1961 because of reliance on fossil fuels.

Critics of the ecological footprint methodology question the assumption that land is used only for single functions, or that land uses only meet one particular ecological service. While footprint advocates claim that the ecological footprint tends to underestimate humanity's demands on the available resources of the planet, critics claim that one implication of ignoring the potential of land to be used for multiple purposes simultaneously is to bias the ecological footprint upwards.

The concept of the ecological footprint as a way of measuring sustainability and as a catalyst for positive changes has become increasingly popular in environmental policy and environmental planning work. While it can be applied at a variety of scales, the concept has been very important in encouraging urban planners and environmental managers to look beyond the traditional scales of planning and environmental management to consider the regional and international environmental impacts of urban activities.

Economics, Cost of Affecting Climate Change

THE MAJOR PROBLEM with determining the economics of affecting climate change is the number of variables involved and the inability, even using advanced modeling theories, to accurately project these variables for more than a few years. Projecting the economic costs of doing nothing to combat climate change, or the costs of attempting to do something, are hampered not only by understanding the effects of the climate change on national, regional, and global economies, but also by the infinite variables that must be incorporated into the economic models. These variables are contingent on the infinite variables incorporated into the currently evolving and competing climate change models.

MODELING DIFFICULTIES

Even if the climate change model of the United Nations Environment Programme (UNEP)/World Meteorological Organization (WMO) Intergovernmental Panel on Climate Change (IPCC) is the accepted model, the IPCC model itself is evolving at such a rapid rate that any economic projections based on it are outdated in no more than five years. The 2001 IPCC data used to create most current climate change models and to extrapolate economic projections was already out of date before the spring 2008 IPCC report updated the data and created a model synthesized from the competing models. As the data and modeling of climate change evolves, the economic projections based on them evolve, making the economic projections less reliable because their assumptions and infinite variables are built on the changing assumptions and variables of climate change models that are themselves evolving.

Variables include policy and regulatory shifts, population growth and densities, the pace and type of climate changes, agricultural and forestry losses, changes in governments, changes in regional alliances, wars, damage from catastrophic storms, the impact of climate change on human health, technological change, utility costs, changes in energy use and generation, savings from efficiency improvements, and water shortages. Modeling these variables is made even more daunting by the need to project the range of potential changes in these quantifications and then amalgamate them into a coherent economic model that itself rests on the range of projected quantifications of the evolving climate change models. Additionally, any projection becomes outdated if massive policy changes are introduced. If, for example the four major greenhouse gas (GHG) emitters, the United States, China, Russia, and India, adopted the Kyoto Protocol, the costs of adoption, estimated at $350 billion (2001–10) if Kyoto was universally accepted, would have to be integrated into future economic projections. These future economic projections would then have be readjusted once the climate change models were remodeled integrating the universal acceptance of Kyoto or another policy shift

Another challenge in projecting the economic impact of climate change or in affecting climate change is that there is no standard format for making these projections. Some of the studies use annual projections, some five-year projections, some decade projections, some 100-year projections, and some 200-year projections. The longer the projections, the more assumptions must be made to create the projections, making the projections more subject to variances in the original projection and, thus, less reliable. This difficulty is seen in the competing projections of impact and mitigation based on the 2001 IPCC data and correlative climate change models.

CURRENT ECONOMIC MODELS

The median projection based on the 2001 IPCC data is that inaction will reduce global Gross Domestic Product (GDP) by 5 percent annually, resulting in an annual global loss of $3.341 quadrillion using a rounded World Bank 2006 global GDP projection of $67 quadrillion (in 2006 values). Assuming that emissions can be stabilized by 2025, the projected annual reduction in the global GDP due to climate change will be one percent annually, resulting in an annual global loss of $670 trillion (in 2006 values) using the World Bank 2006 GDP projection of $67 quadrillion. This study asserts that the costs escalate radically if the cost of feedback loops is integrated; that is, changes in one variable can lead to changes in another variable, such as the melting of the permafrost releasing more carbon dioxide into the air. This study assumes a net social cost of carbon dioxide of $85/ton, but other studies assert that the cost is less, perhaps as little as $2.50/ton. This study also does not offset the mitigation savings ($2.68 trillion annually) with the cost of mitigation.

Chris Hope's University of Cambridge PAGE (Policy Analysis of the Greenhouse Effect) model estimates the cumulative cost of climate change approximates a much smaller estimate of $74 trillion (in 2000 prices from the then value of the Euro) by 2200, and asserts that if mitigation efforts are begun immediately that the estimate would be reduced to less than half that amount. These projections vary from those of the IPCC report partly because different economic and climate change models and modeling assumptions, the inclusion of different variables in the models, and different means of calculating the variables that are in common.

Claudia Kemfert's World Integrated Assessment General Equilibrium Model (WIAGEM) from the German Institute for Economic Research estimates the cost of inaction to be $20 trillion annually by 2100, approximately 6–8 percent of the projected 2100 GDP. This estimate assumes the implementation of climate change mitigation policies limiting the increase in the average global temperature to 3.6 degrees F (2 degrees C). WIAGEM estimates the annual cost of mitigation to be $3 trillion annually. The WIAGEM cost estimate rises to $32 trillion annually if no mitigation is undertaken. The WIAGEM estimates assert that the net loss of abating the rise the average global temperature by only 3.6 degrees F (2 degrees C) until 2100 results in a net savings of $9 trillion annually. The WIAGEM study asserts that if mitigation does not begin until 2025 that this underestimate the costs of climate change by 2100, and correlatively the sooner, the more widely, and the more actively that mitigation is pursued, the more this figure overestimates over project the cost. The IPCC Third Assessment Report (TAR) *Climate Change 2001* projects annual mitigation costs of $78–$141 billion. Other studies assert that at present values, the cost of mitigation exceed $2.5 trillion annually, in agreement with the WIAGEM study.

ASSUMPTIONS OF CURRENT ECONOMIC MODELS

All of these studies make assumptions about future data. For example, each study makes assumptions on the future costs of money. The IPCC TAR assumes certain economic offsets, through tradable emissions permits, and makes additional assumptions within projected ranges for monies generated or saved through taxing structures, incentive sector tax cuts rewarding greater fuel efficiencies or encouraging alternative forms of energy, incentive sector tax increases reducing carbon fuel consumption, the costs of labor, market conditions, the value of technological innovation, and recycling methods. Assumptions are also made about the rate of regulatory and policy changes and the impact of these changes. For example, different studies make different reduction projections of carbon intense energy by assuming different lengths of possible life extensions of existing nuclear power generation plants, different lengths of time to get new nuclear plants producing energy, and different lengths of service for the new and refurbished nuclear plants.

Assumptions are also made concerning the net return on new technology created to meet all of the new policies and regulations aimed at mitigation. For example, it is assumed that money, jobs, and new businesses will be generated by researching and creating alternative forms of energy, hybrid cars and their support systems, new power plants using energies such as wind or geothermal, and other, as yet unforeseen, technologies. Conversely, however, the expenditures for these new technologies will draw monies from other existing sectors costing loss of jobs, revenue, and taxes that could offset the economic advantages of the new technologies. The WIAGEM study projections are made assuming some value to technological change and assuming no value to technological change.

Though it is difficult or even impossible to quantify the real monetary costs of affecting climate change, climate change will have great impact on society, population densities (out migration and in migration), agriculture, infrastructure, manufacturing, and intergovernmental relations. These effects will bear more intensely on the poor than those wealthy enough to adapt and prosper from climate change. The cost of doing nothing is high. This can be seen in the cost of catastrophic natural disasters that pale in comparison to the potential catastrophes that even the most conservative climate change models project. The total cost of catastrophic storm damage in the United States 1980–2005 is estimated to be in excess of $560 billion, with Hurricane Katrina alone causing between $150–$200 billion in economic damage. Worldwide natural catastrophes cost another $220 billion.

Economics, Impact From Climate Change

THE ECONOMIC IMPACTS of climate change are the net costs or benefits from such climatic change on the global economy relative to a prior world with constant climate. Economic impacts are usually measured relative to a pre-industrial average climate (1750–1850). Climate change will directly and indirectly affect people's lives, the physical environment, as well as the economic growth of developing and developed countries. The economically most significant physical changes brought on by climate change are shifted temperature, rainfall, and radiation patterns, because these factors serve as inputs to production and affect human well-being directly or indirectly through socioeconomic and ecological systems. The largest effects are likely to occur through impacts on the global water balance, the food production system, human health, land, and ecosystems. In addition to gradual changes in the geographic distribution of temperature and rainfall, extreme and catastrophic events occurring with greater frequency are expected to cause much damage. Economic impacts of climate change are also predicted to differ greatly between developing and developed countries.

MODELING THE ECONOMICS OF CLIMATE CHANGE

Translating changes in future climate into economic impacts measured in monetary terms is a challenging task for a number of reasons. First, in order to understand how climate will affect the global and regional economies, a solid understanding of how the economically relevant dimensions of climate are going to vary at these spatial scales is required. Global climate models (GCMs) provide predictions of the main variables of interest, rainfall and temperature, at increasingly finer temporal and spatial resolution. However, there is much uncertainty remaining over the predicted spatial and temporal distribution of climate across GCMs and emission scenarios. In economic impact evaluation, this uncertainty is amplified by the uncertainty about how individuals, firms, and governments respond to the changing climate directly, and are affected by it indirectly through its impacts on ecosystems.

The economy is a complex system, whose response to a changing climate must be studied using models because, unlike physical scientists, economists lack the opportunity to conduct controlled experiments on this system. Agents in this complex system will sometimes respond in offsetting directions to climate changes. Individuals, for example, respond to incrementally hotter summers and milder winters by cooling more during the hot months and heating less during the cold months, resulting in increased energy consumption in the summers and decreased energy consumption in the winters. Further, responses to the changing climate may be gradual and small or abrupt and sizable. For example, farmers may respond to slightly drier and hotter growing seasons by planting and harvesting earlier in the season. If, however, summers become significantly drier and hotter, farmers may switch crops and/or install irrigation equipment. More households may purchase air conditioners or run existing ones not only during the day, but also during the night. Such adaptions make it extremely difficult to predict impacts on humans and the economy as a whole, because individuals respond to exogenous changes in often-unpredictable ways.

One aspect that is especially difficult to predict is the investment in successful research and development of new technologies. The energy intensity of most industrialized economies has dropped significantly since World War II. This is partially due to improved energy efficiency of capital, but also due to a structural shift of these economies away from manufacturing toward the production of services. Much of manufacturing, which is thought to be more carbon intensive, has shifted to the developing world. Predicting the future path of energy efficiency and structural composition of the worlds' larger economies is a difficult task. This is especially true for technological innovation, which often progresses in discrete leaps that are virtually impossible to predict.

The timespan used to assess the economic impacts of climate change is much longer than that for many other environmental problems, due to the long atmospheric lifespan of many greenhouse gases. While there is evidence of climate change impacts at the beginning of 21st century, many of the potentially larger effects are expected to occur after mid-century. In order to evaluate the potential costs of climate change, economists discount its future costs and benefits. Discounting essentially recognizes that a dollar today is worth more than a future dollar, because investments are productive and, therefore, resources today are more valuable than resources tomorrow. This implies that if there are two equally damaging outcomes 10 years apart, the second bad outcome would be judged to have lower current dollar damages. There is a much debate over the practice of discounting and the choice of discount rate. Some advocate a discount rate of zero. The choice of discounting method and discount rate has a significant impact on the calculated damages valued in present-day currency.

There are several classes of models used to simulate the economic damages from climate change. Statistical/econometric models are used to estimate the benefits/damages from climate change on, for example, agricultural yields and net profits at the farm or county level using historical data. The estimated relationship between yields or net profits and climate based on observed data is then coupled with GCM output to provide estimates of future yields and farm profits. The advantage of the econometric approach is that it uses actual observed data, which reflects individuals' responses to already-observed changes in climate. The disadvantage of this approach is that these studies deal with specific sectors at the country or a lower level of spatial aggregation. Therefore, many studies are required to obtain global estimates of impacts. Finally, these models are sensitive to estimation technique and the choice of variables used to explain variation in yields/net profits. Several econometric studies have been conducted to estimate the impact of climate change on agriculture, mortality, energy demand, water demand, ecosystem damage, and stream flows.

One alternative to modeling the potential damages from climate change is the use of large-scale simulation models. This computer-based modeling approach represents the different sectors of the global or national economy individually, and assumes specific climate sensitivities for the relevant sectors. As in reality, the economic sectors are interlinked; thus, climate-change induced damages, for example, in the agricultural sector may affect labor markets, which may affect wages in the agricultural (and potentially, other) sectors. Some of these simulation models have built in the fact that economic growth is directly linked to the amount of greenhouse gases emitted into the atmosphere.

Through this feedback loop, climate change impacts in the model depend on emissions, which are dependent on the state of the economy. The advantage of these simulation models is their ability to represent spillover effects across sectors and the feedback between the economy and the climate system. The disadvantage of these complicated computer models is the need to make a assumptions concerning how individual sectors of the economy are linked, as well as how they respond to changes in climate. Results from econometric studies are often used to inform these simulation models, yet the necessary number of parameters needed in these simulation models is much greater than what our current knowledge from econometric models. The simulation models do have the crucial advantage of simulating the impacts of different policy tools on emissions, as well as on the economy as a whole.

DIRECT EFFECTS OF CLIMATE CHANGE

The direct effects of climate change that are best understood are the impacts of temperature, the hydrological cycle, and sea-level rise. The increase in globally-averaged temperatures by mid-century will potentially boost production in temperate climates by expanding arable land, lengthening growing seasons, and increasing yields. Negative impacts are likely to affect the world's poorest countries, where plants are already suffering from temperature and water stress. Due to their geography, low incomes, and importance of the agricultural sector, developing countries are more exposed economically to the risks from climate change.

Sub-Saharan Africa stands out as an already famine-stricken region, with the potential of putting an additional 10 million people at famine risk, increasing stress on already fragile political and economic systems. Some shortfalls during periods of famine could be met by imports, assuming functioning markets (not always be a valid assumption). Parts of South Asia responsible for a major share of global rice production are expected to experience drier, warmer climates, although these effects are expected to be significant only after 2050.

Rising sea levels increase the risk of coastal flooding. The largest flood risk and saltwater intrusion potential is in south and Southeast Asia. Vegetable production, aquaculture below sea-level, and coastal fisheries are going to be most severely affected. The effects from rising sea levels are amplified by increased anticipated short periods of extreme rainfall, as well as on and offshore storm episodes. Rising sea levels will negatively impact food security in south Asia, coastal zones in Africa, as well as island-states worldwide. Major affected food production centers in delta regions are found in Vietnam, Bangladesh, India, and Thailand. In some areas, coastal land can be replaced by converting upland areas with increased temperatures to agricultural land, although population movement towards urban centers at coasts and in delta regions may result in large negative impacts for the small farm production sector. Saltwater intrusion may further negatively impact irrigation systems in coastal areas. Rising sea levels may displace as many as 200 million people by mid-century. By the end of the century, 20 percent of Bangladesh could be flooded, if sea levels were to rise by 39 in. (100 cm.).

INDIRECT EFFECTS OF CLIMATE CHANGE

A major indirect effect of climate change on agriculture will be the lower availability of irrigation water.

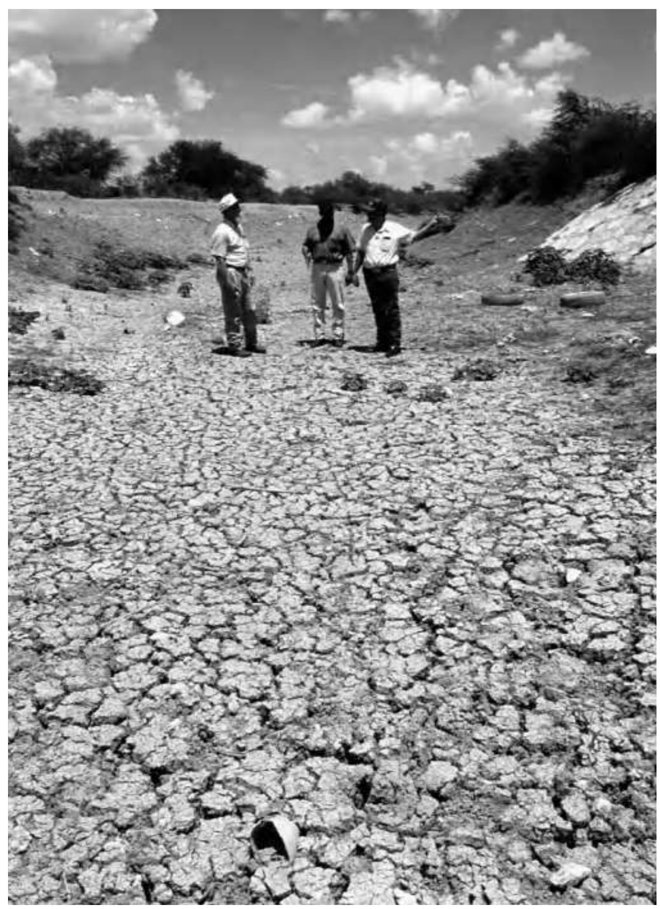
The main mechanisms through which climate change has an impact on irrigation water are less runoff and groundwater recharge, combined with increased rates of extraction in many parts of the world. The main geographic areas of concern are India, which in the recent past has seen a slowdown in the growth rate of rice yields, southern and North Africa, some of Latin America, and parts of Europe. Droughts and the lack of water may spark or reignite political and military conflict between countries whose water systems are interdependent. The indirect impacts of decreased rainfall and the increased frequency of droughts will drive up wildfire risk and, even in the short-term, change the distribution of pests. Decreased frequency of winter frosts will also affect the spatial distribution of pests. Historically, famines were caused by pests, which are becoming an increasing concern. In addition, marine ecosystems, home to the world's fisheries, will be affected though climate-induced acidification of the oceans.

Impacts on human health due to global warming will come directly from increased heat stress and malnutrition. Additionally, vector-borne illnesses such as malaria will become more widespread in areas near the Equator, whereas deaths from extreme cold may decrease at high latitudes. Further, climate change has already and will further impact ecosystems leading to devastating species loss. The loss of these species affects the global economy through their loss as measured by their existence value and their potential uses in the pharmaceutical and ecotourism sector.

MONETARY IMPACTS OF CLIMATE CHANGE

While it is very difficult to reliably estimate the monetary impacts of climate change, one study estimates that climate change may lower India and Southeast Asia's gross domestic product by 9–13 percent by the end of the century, compared to what it would be in the absence of climate change. An estimated 145–220 million more people may have to subsist on less than $2 a day, resulting in 165,000–250,000 additional annual child deaths in south Asia and sub-Saharan Africa attributable just to lower income. Lower farm profits will increase rural poverty rates, preventing farmers from investing in the necessary capital to expand and secure future production.

A few developed economies will benefit from moderate global warming in the short term, yet are at risk under scenarios predicting greater warming toward the end of the century. Canada, Russia, and Scandinavia may see higher crop yields, fewer cold-related deaths, lower heating fuel needs, and an influx of winter tourists, initially. However, warming in these countries is predicted to progress faster, requiring ecosystems to adapt more quickly. Lower latitude high-income countries are more vulnerable to consequences from climate change. Even a 2–3 degree increase in temperatures may lead to significant decreases in water availability in southern Europe and California. Regions relying on snow packs for agricultural water storage are predicted to experience a more volatile water supply throughout the century. Predictions for the world's largest economy, the United States, are a gain or loss in GDP of one percent at moderate increases in global temperatures, with potentially negative consequences at higher temperature increases.



If summers become significantly drier and hotter, farmers may switch crops and/or install irrigation equipment.

A major concern are the economic impacts of extreme events, such as the shutdown of the thermohaline circulation, extreme shifts in regional weather patterns, shifts in El Niño–Southern Oscillation (ENSO), changes to the monsoon, as well as the potential melting or collapse of major ice sheets. It is estimated that costs of extreme weather events could be on the order of 0.5–1 percent of global GDP by 2050, and higher as the globe gets warmer. Even moderate increases in hurricane wind speed of 5–10 percent could double annual economic damages from hurricanes. In addition, costs of flooding in Europe could triple or quadruple, unless flood management actions are taken. Extreme heat events, such as summer 2003, which killed 35,000 people and caused $15 billion in agricultural damages, could be quite common by mid-century. More large-scale shocks could potentially disrupt global financial markets and trading patterns, if they interfered with transport and communications infrastructure.

MITIGATION POLICIES

One unknown that will greatly affect the impacts of climate change on the economy is the degree and type of mitigation policy chosen by the international community. Global government action on climate change began with the Rio Earth Summit in 1992, which resulted in the Kyoto protocol of 1997. Ratifying industrialized countries agreed to cut back their emissions by a collective average of 5 percent of 1990 level emissions. Successor agreements require even more stringent cutbacks to achieve stabilization at roughly double pre-industrial concentrations of CO_2 in the atmosphere. Even though carbon-containing fuels have served as one of the main inputs to the production of goods and services since the Industrial Revolution, decreasing their use does not necessarily imply decreasing the amount of goods and services produced.

The use of substitute fuels with lower life-cycle carbon content, or the more efficient use of existing fuels by improving combustion technology, or switching to hybrid technologies can be encouraged. In order to decrease the amount of carbon emitted into the atmosphere, governments can use command and control regulations, which prescribe the technology used or the total amount of carbon emitted by each source. An alternative would be to employ flexible instruments, which may reach the same emissions reductions, but at a lower cost. Two examples of such flexible instruments are carbon taxes and cap-and-trade systems. Cap-and-trade systems rely on the trading of so-called carbon permits, where the regulator determines the total emissions of carbon by all sources through the number of permits issued. A carbon tax essentially imposes a per unit fee on each ton of carbon emitted. Under certain assumptions, these methods provide reductions at least cost. The choice of policy instruments also has implications for technological innovation. It has been shown that taxes and cap-and-trade programs provide much stronger incentives for technological innovation than command and control strategies such as emissions or technological standards.

Ecosystems

ECOSYSTEMS ARE DEFINED as communities that involve dynamic interactions among living elements (such as animals, plants, and microorganisms), and the inanimate elements of their environments. All parts of an ecosystem need to work together to maintain the proper balance of the system, and it is necessary for all ecosystems to function in conjunction to maintain balance.

The term ecosystem was first used in 1930 by Roy Clapham (1904–90), an appointee to the Demonstratorship in Botany at England's Oxford University. At the time, Clapham was studying plant ecology under the guidance of Botany Department Chair Arthur Tansley (1871–1955), a pioneer in the field of ecology. Two decades after Clapham and

Tansley first articulated the concept of ecosystems, ecologists began including the study of ecosystems as a distinct field of study within the discipline of ecology. Scientists have since identified eight major ecosystems: the temperate forest, tropical rain forests, deserts, grasslands, the tundra, the taiga, the chaparral, and the ocean.

An ecosystem may be as small as a puddle or pool of water, or as large as the Sahara Desert or the Atlantic Ocean. The ecosystems of the tropical forests provide a classic example of the extent of ecosystems. In these forests, thousands of vegetable and animal species that live in the air and on the ground interact with millions of surrounding organisms. Within each ecosystem, the habitat is a physical element that combines the natural and adaptive conditions of particular species. All ecosystems are dynamic. Changes may be temporary in response to outside events such as forest fires or natural disasters, or they may occur according to established cycles. Commonly occurring factors that affect changing ecosystems are nutrient availability, temperature, light intensity, grazing intensity, and species population density. Six ecosystems are identified as most necessary for supporting life on Earth; agroecosystems, forest ecosystems, freshwater ecosystems, grassland ecosystems, coastal ecosystems, and urban ecosystems. The integral relationship between these ecosystems and human life is demonstrated by the fact, half of the world's jobs are dependent on agriculture, forestry, and fishing. In the poorest sections of the world, 70 percent of all jobs are derived from these industries.

BIOMES AS GROUPS OF ECOSYSTEMS

Biomes, sometimes confused with ecosystems, are in reality composed of a number of similar ecosystems that work together to maintain the critical balance of the environment. The Earth itself is a biome, as are the Great Basin, the High Plains, and the Kalahari Desert. Through global warming and climate change, human behaviors are altering vital ecosystems throughout the world, including those that make up the food chain, the carbon cycle, the nitrogen cycle, and the water cycle. The critical nature of this dilemma is evident in the well-documented loss of species, their habitats, and ecosystems as a result of human pollution and overexploitation of resources. Particular attention is being paid to the ecosystems of Antarctica, the Arctic, the Bering Sea, and the Greater Yellowstone Ecosystem. In the Arctic, scientists have identified two major climate and ecosystem changes during the past 50 years, in part as a response to warming temperatures, that have precipitated a transition from primarily cold Arctic ecosystems of the pre-1970 period to the to sub-Arctic conditions during 1970–2000. The Bering Sea provides the vast opportunities for studying the ecosystems of various bird and marine mammal populations.

In 1992, at the Earth Summit in Rio de Janeiro, member nations negotiated the Convention on Biological Diversity, popularly known as the Biodiversity Treaty. The treaty, which was signed by 196 countries, became international law on December 29, 1993. The treaty formally recognizes the interrelationship between human life and various ecosystems and encourages universal commitment to conserving biological diversity and using all biological resources responsibly. It also calls for equitable sharing of genetic resources among developed and developing countries.

In 2001, 1,300 scientists from 95 nations began working on the Millennium Ecosystem Assessment (MA) under the auspices of the United Nations. The assessment team is charged with identifying the effects of global warming and climate change on various ecosystems and determining ways to employ conservation and sustainable development to check the pace of ecosystem failure and environmental degradation, while improving human well-being. Between 2001 and 2005, the MA published five technical volumes and six summary reports. Scientists involved in the MA have concluded that 60 percent of the 24 ecosystems under investigation are being degraded as a result of human behavior. MA scientists have learned that this degradation is leading to the emergence of new and old diseases, abrupt alternations in water quality, the presence of dead zones in coastal waters, the collapse of fisheries in many sections of the world, and shifts in regional climate. While agreeing that the ecosystems of tropical forests and coral reefs are particularly vulnerable to global warming and climate change, the MA has identified degrading dryland ecosystems as the most significant threat to human health because of these are the areas where poverty is greatest.

Ecuador

LOCATED ON THE Pacific Coast of South America, Ecuador is located on the equator (from where it takes its name), and has a land area of 98,985 sq. mi. (256,370 sq. km.). It has a population of 13,850,000 (2005 est.), and a population density of 122 people per sq. mi. (47 people per sq. km.). Six percent of the land is arable, 18 percent is used for meadows and pasture, mainly for cattle and sheep, and 40 percent of the country remains forested. Hydropower generates 75 percent of its electricity, with the remainder from fossil fuels. These contribute to a relatively low rate of per capita carbon dioxide emission, 1.6 metric tons per person were generated in 1990, rising slightly to a peak of 2.2 metric tons in 1993, and falling gradually to 1.8 metric tons per person by 2003. Some 84 percent of the carbon dioxide comes from liquid fuels, with 9 percent from gas flaring, and 5 percent from the manufacture of cement. With the heavy use of hydroelectric power, electricity production only accounts for 10 percent of these emissions, with 41 percent made by the transportation sector.

While Ecuador has contributed little to cause global warming and climate change, the country has seen a rise in annual temperature by about 0.18 degrees F (0.1 degrees C) per decade since 1939, with the rate of warming doubling in the last 40 years, and tripling in the last 25 years. The effects of global warming are noticeable on the Galapagos Islands, located in the Pacific Ocean. Temperatures have risen steadily. In March/April 2002, a study showed repeated bleaching of the coral reefs, with disastrous effects on the marine environment.

The Ecuadorian government of Rodrigo Borja Cevallos ratified the Vienna Convention in 1990, and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. In October 1997, Yolanda Kakabadse the vice president of the World Bank, and adviser to the Global Environment Facility addressed the Fifth World Bank Conference on Environmentally and Socially Sustainable Development at Washington, D.C. The government of his successor, Jamil Mahuad, signed the Kyoto Protocol to the UN Framework Convention on Climate Change on January 15, 1999; it was ratified on January 13, 2000, and took effect on February 16, 2005.

Edison Electric Institute

THE EDISON ELECTRIC Institute (EEI) is an association or a trade group representative that seeks to represent people and organizations owning stock in power companies. The stock companies represented by the EEI directly represent 95 percent of the power consumers served by stock companies generating electric power in the United States, which produce about 70 percent of the total power produced in the United States. The other 30 percent is produced by member cooperatives, by the Tennessee Valley Authority, or other government-owned generating facilities, or by privately owned companies. All of the companies that are members of the EEI are American-owned. In addition, 65 international electric companies are affiliate members. The 170 industry suppliers and related organizations are associate members.

The chair, president, and CEO of PNM Resources, Jeff E. Sterba, was chosen as the chairman of the EEI in June 2007. PNM is the parent company for Public Service Co. of New Mexico. In 1998, he was chosen as executive vice president of USEC, a global energy company headquartered in Maryland. In 2000, he returned to PNM as CEO. At the same time, Sterba was chosen to lead the EEI, its member associations chose David M. Ratcliffe and Anthony F. Earley Jr. as first and second vice chairmen, respectively. David Ratcliffe is currently chairman, president, and CEO of Atlanta-based Southern Company, which is a holding company that owns Georgia Power, Alabama Power, Gulf Power, Mississippi Power and other operating power and service companies. Anthony F. Earley Jr. is chairman and CEO of Detroit's DTE Energy.

Serba recognized that he was chosen to lead the EEI in a time of great changes in the power industry, saying in a prepared statement, that the Energy Policy Act of 2005 would be implemented soon. Although its provisions deal with matters that can override environmental concerns and interests, Serba was also aware of great challenges involving climate change and the need for energy efficiency. The EEI was organized in 1933. It works with all of its members, affiliates, and associate members, as an advocate of their interests. This means that the EEI promotes the development and adoption of equitable public policies before legislatures and before regulatory bodies.

Because the EEI is an industry association, it has command of the industry's critical data, reports, problems, and needs. With this information on the industry and its contacts, it can effectively lobby the U.S. Congress, state legislatures, federal and state government agencies, or including opinion leaders. The EEI stock analysts who advise investors may also be called upon to provide information to the news media to counter the claims of opposing consumer groups or environmentalist groups. Lobbying activity of EEI is extensive. It is the advocate for its numerous members, and has lobbied on legislation concerning the use of renewable fuels, energy efficiency, power plant security (especially against the threat of terrorism), and on environmental issues, including climate change.

A subject of particular interest has been its lobbying for the use of power lines as a medium for high-speed internet service and communications. Some internet media providers such at AT&T have lobbied for net neutrality, for all of the providers and users of the internet to be treated the same. In opposition have been some phone companies and cable companies that want to charge for internet traffic. By the end of 2007, the EEI had spent over $5 million to lobby various agencies of the federal government on the subject of climate change. Organizations lobbied included the White House Budget Office, the Environmental Protection Agency, the Energy Department, the Federal Energy Regulatory Commission, and the Federal Communications Commission.

The EEI is a long-term participant in debates over climate change science and its assessments. It has been an active observer to the Framework Convention on Climate Change sessions of the Conference of the Parties and the Subsidiary Body for Scientific and Technological Advice, and the Intergovernmental Panel on Climate Change sessions. The EEI, through its members, is an expert on the power industry and on some aspects of climate change. The EEI has recognized the problem of greenhouse emissions, especially by its industry members, and since at least 1994 has engaged in a number of activities to reduce and eliminate these power plant emissions as a cause of climate change.

Education

GLOBAL WARMING EDUCATION is part of environmental education, and varies from raising awareness of the phenomenon, to a deep civic implication and political engagement, depending on the strategies and the goals that are adopted. Global warming education follows some principles of environmental education, and, more specifically, education of complexity, as proposed by French sociologist Edgar Morin. Morin advocates redefining the relationship to scientific knowledge, to understand sciences as carriers of uncertainties, leading to a particular reading of the world and climate, a reading that is interesting, but not sufficient to join the aims of environmental education regarding global warming.

In order to educate for the environment, combining the scientific analysis of the climate with other disciplinary and cultural analysis, is recommended, according to Gerard Fourez. Global warming education must teach ways to decode the dominant tendencies of Western analyses regarding global warming and their consequences, to minimize the consequences of catastrophic scenarios, and move toward greater social justice and rethink our relationship with nature and others.

ENVIRONMENTAL EDUCATION AND SUSTAINABILITY

The fourth report of the Intergovernmental Panel on Climate Change (IPCC), published in February 2007, confirms the reality of global climate change. Some scientists have pointed to the uncertainties and the inevitable limits of the climatic modeling, and other researchers question the ascendancy of scientist's analyses of the question in the public sphere. They assert that sociopolitical analyses should lead scholars to question the neo-liberal model of society, with its faith in technical progress, as well as the inequitable sharing of the wealth which ensues from it, according to Scott Lash, et al. The consensus of the IPCC experts has strengthened over the years, and concludes that the production of greenhouse gas of human origin is an important cause of global warming.

For more than 30 years, various arguments have fed the debate: scientific, economic, ethical, and sociopolitical. From the 1970s, environmental education became the subject of a succession of international conferences of United Nations Educational, Scientific and Cultural Organization (UNESCO) and the United Nations Environment Programme (UNEP). It began with the United Nations Conference on the Human Environment held in Stockholm in 1972, followed by the Earth Summit in Rio de Janeiro in 1992, and the World Summit on Sustainable Development (WSSD) in Johannesburg in 2002. The shift from environmental education to education for sustainable development is clear in the titles of these conferences.

The defining principles and orientations of environmental education found their inspiration in this type of consensus and the reports that followed, such as Tbilisi's in 1977, following the Intergovernmental Conference on Environmental Education that took place there. Such reports underline the necessity of lifelong learning, which prepares individuals for the analysis of the fundamental problems of a contemporary world in constant evolution. The complexity of the environmental question and the importance of interdisciplinarity require analysis of the environmental questions using social, political, economic, and scientific dimensions, while underlining the necessity of redefining our value system to renew the relationship between nature and human beings.

Since the early 1990s, environmental education has been defined as education for sustainable development: UNESCO launched the International Decade of Education for Sustainable Development in 2005, which will last until 2014. This is contested by many academics. Some see a legitimate proposal to reinforce the institutionalization of environmental education, and recognize some of the principles of deep ecology. Others, notably the team of Lucie Sauvé from Université du Québec à Montréal (UQAM), point out that education for sustainable development is defined in an instrumental way, as being at the service of a development for economic purposes, as the key to solving environmental problems. The idea is above all considered a resource to exploit for economic development. Education seems miles away from the initial critical aims of social transformation that should characterize environmental education, according to many authors of the domain, such as: Joel Spring, Ian Robottom, John Fien, Noel Gough, and Annette Gough. These critical goals should also be considered and provide a direction for global warming education.

A NEW NATURE-HUMAN RELATIONSHIP

A critical environmental education consists of developing, not only among youth, but the population in general, the capacities to analyze educational propositions regarding the environment and dominant environmental discourses to decode hidden ideological orientations, the beliefs and interests that direct them, and which implicitly tend to reproduce the practices that are nevertheless the ones that would be necessary to shift to a different kind of relationship between nature and human beings. The reference to science and technological transfers as the main answer to defining and correcting the problem is insufficient to correct a situation that requires that humans also question the philosophic foundations, sociological, political, and economic dimensions of the regulation of climate. To reproduce the same economic logic is denounced by many as incapable of correcting the shameless exploitation of nature and human beings that are at the heart of the environmental crisis.

Edgar Morin proposes principles and a philosophy for complexity, the consideration of the other, and acknowledgement of uncertainty in the scientific domain. This approach offers a vision of the world rethought concerning connections with nature. These principles provide different educational aims than the principles of education for sustainable development, prescribed in many educational ministerial programs on the international level. Education for sustainable development might reproduce a narrow vision of nature as just a resource for better management of economic development of the world.

Environmental education is different, and strives for different goals, geared to the age of the target audience, the pupil. In many North American school systems, environmental education generally begins with science education, the learning of scientific knowledge and principles, such as biology, chemistry, physics, or ecology. Many teachers rely on the idea that a better understanding of sciences can lead to better protection of the environment. That postulate is of interest, but it is not enough. Environmental education must be institutionalized to reach its aim of social transformation.

STUDENTS AS SOCIAL ACTIVISTS

Environmental education implies a critical pedagogy that gives pupils a role as social actors and considers them to be competent interlocutors, capable of logical argumentation, reasoning, and of being informed about complex questions. This type of environmental education can use interdisciplinary pedagogies, such as those proposed by the Belgian team of Gérard Fourez, and should lead to questioning the principles of the free-market economy and the dominant ways of thinking that are at the origin of the Western relationship to nature. For instance, the exploitation of natural resources for purposes of short-term profit; faith in technical progress, which allows scientific analyses and technical solutions to settle the imbalance that the more developed societies tend to print in the ecological regulations of the planet. For instance, such reasoning legitimizes nuclear energy to renew the modes of energy production and decrease greenhouse gas emissions. This position strengthens the dependence of societies on very expensive and risky technologies, as well creates an international balance of power to the detriment of the countries of the south; rather than promoting an analysis of the foundations of the systems of over-consumption, and decreasing energy and natural resource consumption. A more critical environmental education engages youth in concrete action and civil citizenship, toward another vision of the world, in a quest for more social justice.

Some approaches to science education also suggest engaging pupils as young citizens in community projects to assist in restoring ecosystems. It is the case, most notably, in the works of researcher Wolff-Michael Roth. Thus, pupils learn scientific notions while learning about the analysis of history and the local culture, and about their impact on the studied ecosystems from various disciplinary specialists (for instance, a biologist and a water quality technician). Science education and environmental education are then anchored in a sociocultural and critical analysis, aimed toward concrete actions and political pressure. The students, having analyzed the quality of water, explain their results to the group

Global warming education should teach general principles and scientific knowledge, as well as the limits of science.

and exert political pressure to change the ways people conceive of and consume water.

Global climate change shows up often in the media and political discourse. In a more political context, some politicians support the urgency of taking measures to reduce the production of greenhouse gases. The carbon exchange has become a new player on international economic markets. The Kyoto Protocol, intended as the first step in the international regulation of this issue, is already considered behind to some, in front of the scale of the phenomenon. This topic is part of secondary school curricula in many countries in North America and Europe. Researchers in science and environmental education analyze the pupils' and teachers' conceptions of this issue and plan educational strategies for the study of climate changes in classrooms.

These strategies go from the enrichment of pupils' scientific knowledge to improving the pupils' capacities of debate, critical analysis, and civic action, according to Jonathan Osborne and his colleagues. Frequently, popular magazines on science and nature (such as *Green Teacher*, or *La Recherche*) dedicate special issues on global warming. Magazines and documentary books for youth also address the question and can serve as documentary resources and references in class, but always with developing critical reading by pupils. It is sometimes necessary to consult various sources and to critique the information that is presented, and understand the author's ideological orientations. Some science museums organize exhibitions on this question for the public and schools.

Global warming education can take various forms, from simple awareness of the scale of the phenomenon with young children, and the understanding of some elements of climate regulation, and the presumed impact of consumer habits on the rates of carbon dioxide (CO_2) in the atmosphere (according to the conclusions of scientists), to more critical analysis and citizenship participation with older pupils. The information can be oriented differently according to educational goals. In an interdisciplinary way, this question can also lead to a more critical reflection on the complexity of the problem, including political, economic, or ethical analyses. According to the educational goals, the type of pedagogy selected can vary in the degree of critical analysis of the discourses and practices related to the Western system of society and its globalization, and engage pupils in more or less civic action.

Educators can seek a better understanding of the scientific notions that contribute to define this complex climatic phenomenon: physics, chemistry, climatic zones, functioning of the water and carbon cycles, understanding sources of greenhouse gases and their contribution to the climatic regulation. Understanding climate regulation models can be taught to older students. An interdisciplinary reading of this question should be integrated into such education, which, besides teaching scientific notions, will include analyzing the history of contemporary societies linked with their models of energy production and consumption and their contribution to global warming. Energy consumption of the concerned pupils and that of their teachers, for example, would also be analyzed to compare it to energy consumption and consumer habits in poorer countries.

The importance of the automobile in wealthy societies and its consequences should be documented and analyzed, both by reading technical and sociological data, for awareness, changing habits, and definiting the main aspects of the problem, to recommend concrete attempts of social transformation. In so doing, the pupils feel engaged and capable of changing things in society, even if only at a local level, so they learn to involve themselves actively in the democratic debates by knowing the decision-making authorities to whom they can address their point of view. Global warming education contributes directly to citizenship education, which can lead to the analysis and the commitment of the young people concerning other environmental questions, while enriching their knowledge of the sciences and the society.

It is also important to denounce ambient catastrophism, especially that conveyed by the media. Education should instead cultivate hope and optimism, logical and critical reasoning, and provide knowledge, without shying away from explaining elements of debate within the scientific community and the scale of the challenges to be surmounted. Science education should prepare young people to argue about contemporary social and environmental questions that contain a scientific dimension. The climatic question lends itself well to this type of exercise.

To teach global warming is also to get acquainted with certain research practices and to recognize the complexity and the limits of sciences, to enrich the current image of science that is popularized in school sciences and media, to make it more accurate and open to discussion. If Bryan Wynne's proposals are followed, education will update school sciences and to move them closer to their public. It is a matter of forming future scientists and informed citizens, who have an open and critical attitude when facing the contemporary scientific developments. Thus, global warming education should try to teach pupils and people, in general, certain principles and scientific knowledge, and also the different issues debated on this question. Teachers must remain aware of the limits of current approaches that would only lead to replacing obsolete technology with another, without questioning the overconsumption society model, which remains individual and always competitive.

Egypt

DOMINATING NORTHEAST AFRICA, the Republic of Egypt has a land area of 386,660 sq. mi. (1,001,449 sq. km.), with a population of 80,335,036 (2007 est.), and a population density of 192 people per sq. mi. (74 people per sq. km.). Some 7,933,000 people live in Cairo, the capital, the 14th largest city in the world population, with a population density of 91,900 per sq. mi. (35,420 per sq. km.). Alexandria, the second largest city, has a population of 3,917,000 and a population density of 3,575 per sq. mi. (1,378 per sq. km.). Egypt is heavily reliant on the Nile River, and droughts over many centuries have caused severe food shortages in the country. However, there have not been enduring shortages, and the population of has Egypt grown steadily. Temperatures in recent years have been high, however, reaching 105.8 degrees F (41 degrees C) on August 6, 1998, the warmest August day on record.

With many areas of Egypt undeveloped, the rate of per capita carbon dioxide emissions has been low, at 1.4 metric tons per person in 1990, rising to 2.0 metric tons by 2003. The country's electricity production is heavily dependent on fossil fuels, which account for 77 percent of total production, the remaining 23 percent comes from hydropower, much of it from the hydroelectricity plant at Aswan. The development of this hydroelectric plant also led to the creation of Lake Nasser, which allows some 400,000 hectares of cropland to be cultivated throughout the year.

Electricity generation and heat production account for 31 percent of the country's carbon dioxide emissions; 5 percent come from other energy industries, and 28 percent from manufacturing and construction. In Cairo and many other urban areas, considerable traffic congestion has resulted in transportation contributing to 17 percent of the carbon dioxide emissions; liquid fuels contribute to 67 percent of the emissions, 2 percent come from solid fuels, 22 percent from gaseous fuels, and 9 percent from cement manufacturing. Pollution in much of urban Egypt has been bad for many years. There are more than a million automobiles in Cairo, many poorly maintained, which contribute to the world's highest level of lead and suspended solid particles in the world. This accounts for an estimated 10,000 to 25,000 premature deaths per year, and has contributed considerably to the environmental pollution, and to the regions greenhouse gas emissions.

The Mubarak government of Egypt ratified the Vienna Convention in 1988, and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, which was ratified in 1994. In October 1997, M. El-Ashry from the World Bank addressed the Fifth World Bank Conference on Environmentally and Socially Sustainable Development at Washington, D.C. The Egyptian government signed the Kyoto Protocol to the UN Framework Convention on Climate Change on March 15, 1999, which was ratified on January 12, 2005, and took effect on April 12, 2005.

Ekman Layer

THE EKMAN LAYER (EL) is a boundary near-surface layer in the low troposphere and upper ocean, in which the vertical turbulent friction plays a crucial role in the balance of governing forces. Ekman drift is to the right of the wind in the Northern Hemisphere, which causes upwelling along the equator and certain coasts.

As Ekman showed in his classic paper, the basic steady balance within EL (in the ocean where depth can be considered infinite) occurs between vertical friction and the Coriolis force. Such balance leads to the generation of the Ekman spiral of drift current (wind), that is the turning and weakening of the Ekman current (or wind) to the depth (upper boundary of Ekman layer in the atmosphere). The vector of the Ekman current (wind) is rotating clockwise/counterclockwise to the depth (in the atmospheric boundary layer) in the Northern/Southern Hemisphere. The angle between vectors of surface Ekman current and surface wind is equal to 45 degrees, if the coefficient of vertical turbulent exchange (mixing) does not depend on the depth, as was postulated in the classic Ekman theory. In fact, this angle is usually close to 30 degrees, because the coefficient of vertical turbulent mixing decreases to the depth.

In deep ocean, EL thickness (or Ekman scale) is determined as a depth, where the current direction is opposite to the surface one. Speed of drift current at the low boundary of EL is smaller than surface speed by e^{π} times. Thickness of EL in the homogeneous fluid (gas) is controlled by two parameters, namely, turbulent stress (or dynamic velocity depending on the wind speed) at the sea surface and Coriolis parameter. Wind in the mid-latitudes, which speed is about 33 ft. (10 m.) per second, generates the surface drift current of about 12 in. (30 cm.) per second. The corresponding Ekman scale is about 98 ft. (30 m.). In the ocean with intermediate depth (ocean depth and Ekman scale are the same order), the Ekman spiral is modified and rotation of the current vector to the depth decreases. Typical temporal scale of steady Ekman spiral development is equal to local inertial period. For instance, classic Ekman balance in the mid-latitude interior of the upper ocean is established in about one day after the beginning of wind forcing.

There is also bottom EL in the ocean, which should be taken into account in the global circulation models if the ocean's depth is not too large in comparison with the Ekman scale, or for super high-resolved models with typical size of vertical grid in the bottom layer of about 33 ft. (10 m.). Special care should be taken for the case of a shallow sea, where the depth is much smaller than the Ekman scale. In this case, surface and bottom ELs create a unique EL in which turbulence is well developed, while the Coriolis term is small. As a result, the rotation of drift current to the depth is negligible, and directions of surface wind and drift current in the shallow ocean coincide.

From comprehensive analyses by Eric Kraus, Andrey Monin, and Alexander Yaglom, in the stratified fluid (gas), a depth of mixed turbulized layer may be much smaller than EL thickness because turbulent stress is working against buoyancy force. In this case, a profile of velocity within the mixed layer looks like a drift current in the shallow sea. Transport of drift (Ekman) current in the ocean's interior (that is, in deep ocean) does not depend on the coefficient of vertical turbulent exchange. It can be calculated accurately if surface wind stress and latitude are known. For instance, from the assessment of Eric Kraus and Sid Levitus, integral meridional volume transport of drift current across a latitude circle in the world ocean associated with the trade winds reaches about 50 Sverdrups (one Sverdrup = 10^6 cu. m. per second) and it accounts for a significant proportion of meridional overturning circulation within the tropics and at the boundary between the tropics and subtropics.

El Niño and La Niña

THE WATERS ALONG the barren coast of Peru are cold and flow northward during most of the year, but around Christmas time, they are warm and flow southward. The latter current was originally given the name El Niño, Spanish for "the boy." Because of its timing, and because it is associated with refreshing rains, the name also refers to Child Jesus.

Every few years the current is exceptionally intense and persistent, bringing very heavy rains that transform parts of the coastal desert into a garden. At such times the fish (such as anchovies) that usually are abundant in the cold water, disappear temporarily. Today, the term El Niño is reserved for these interannual events which now are perceived as disasters even though they originally were welcomed as blessings. El Niño was originally regarded as a regional phenomenon, confined to the shores of Peru, but is now recognized as part of the changes in oceanic conditions across the entire tropical Pacific Ocean.

Furthermore, El Niño is not a sporadic departure from "normal" conditions, but is one phase of a continual oscillation with a period of 3 to 5 years; the complementary phase is known as La Niña. (This oscillation is evident in a record of sea surface temperature variations in the eastern equatorial Pacific over the past century. The figures show the spatial structures of El Niño and La Niña.)

The fluctuations in oceanic conditions are in response to fluctuations in the trade winds, which are intense during La Niña, weak during El Niño. Why do the winds change?

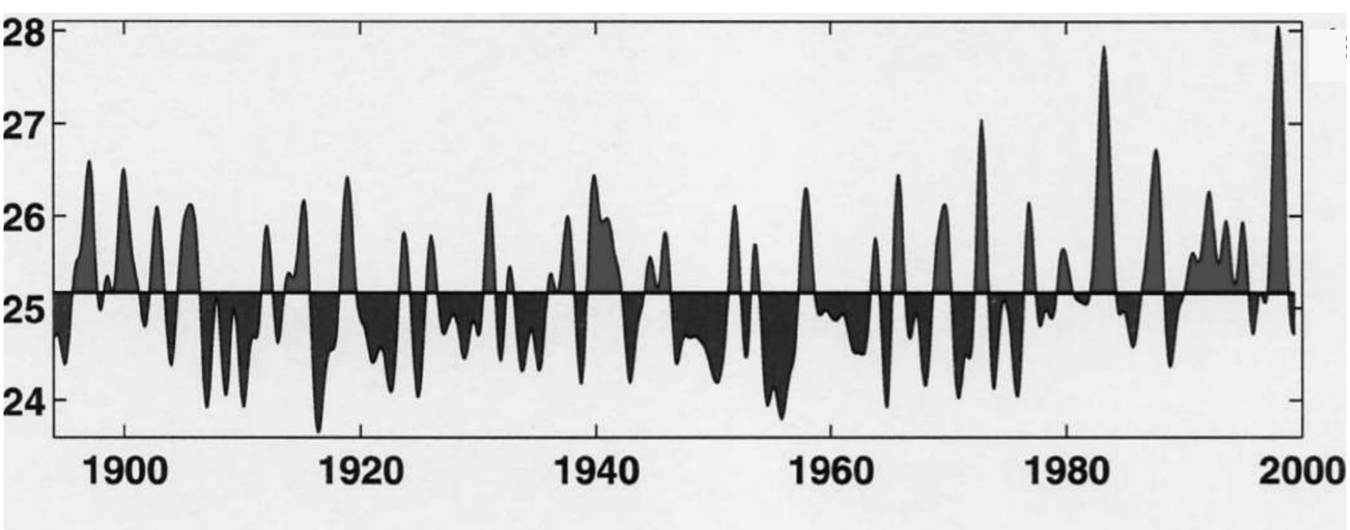
Early in the 20th century, Gilbert Walker's attempts to predict failures of the monsoons in India led to his discovery of the Southern Oscillation, which includes oscillations in the intensity of the trade winds over the tropical Pacific. Those oscillations, it turns out, are the ones that induce El Niño and La Niña. From a meteorological perspective, the changes in the wind patterns are a consequence of the changes in the sea surface temperature patterns associated with El Niño and La Niña.

This circular argument—sea surface temperature changes are both the cause and the consequence of changes in the winds—implies that interactions between the ocean and atmosphere are at the heart of the matter. Those interactions are unstable, capable of amplifying small, random disturbances, such as a burst of strong winds, into a major climate fluctuation.

To ask why El Niño (or La Niña) occurs is as meaningless as asking why a pendulum swings. It is more interesting to inquire about the factors that determine the period of the oscillations—the width of the ocean basin is an important one—and to explore the predictability of El Niño.

THE NIMBLE ATMOSPHERE

Forecasters take into account that the interactions between the ocean and atmosphere are not symmetrical: the nimble atmosphere swiftly responds to changes in sea surface temperature, but the sluggish ocean adjusts slowly to changes in the winds. The ocean has the "memory" of the system and needs to be monitored to anticipate El Niño. The large array of instruments that oceanographers have deployed across the equatorial Pacific enabled them to anticipate the intense El Niño of 1997 several months in advance.



Oscillations in sea surface temperatures (in degrees Centigrade) over the past century, in the eastern equatorial Pacific Ocean (after removal of the seasonal cycle.) El Niño conditions prevailed during the periods in lighter gray above the 25 degree C line, La Niña during the periods in darker gray below the 25 degree C line.

The impact that global warming will have on El Niño is a matter of debate. The properties of El Niño, its intensity and frequency of occurrence, for example, depend on the background state, which includes the time-average intensity of the trade winds, and the spatially averaged depth of the thermocline. The factors that determine those conditions today are poorly understood.

El Salvador

LOCATED IN CENTRAL America, El Salvador has a land area of 8,124 sq. mi. (21,040 sq. km.), with a population of 6,948,073 (2007 est.), and a population density of 823.6 people per sq. mi. (318.7 people per sq. km.). It is the only country in Central America that does not have a Caribbean coastline. Pacific hurricanes occasionally affect the country, as was the case with Hurricane Mitch in 1998. Some 27 percent of the land is arable (the highest percentage in Central America) much of it in coffee plantations; 29 percent of the land is used for meadows and pasture, with only 5 percent forested.

One of the poorest countries in the region, electricity generation in El Salvador comes largely from fossil fuels (42.3 percent) and hydropower (35.5 percent). The country has a very low rate of carbon dioxide emissions per capita, at 0.5 metric tons in 1990, rising to one metric ton in 1997, and 0.99 metric tons in 2003. Most of the carbon dioxide emissions come from the use of liquid fuels (91 percent), with the remaining 9 percent from the manufacture of cement.

Global warming and climate change are expected to lead to flooding in some low-lying parts of El Salvador, with the threat of more insect-borne diseases such as malaria and dengue fever. The right-wing government of Alfredo Cristiani ratified the Vienna Convention in 1992, and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and the government of his successor, Armando Calderón Sol, signed the Kyoto Protocol to the UN Framework Convention on Climate Change on June 8, 1998. The Kyoto Protocol was ratified on November 30, 1998, and took effect on February 16, 2005.

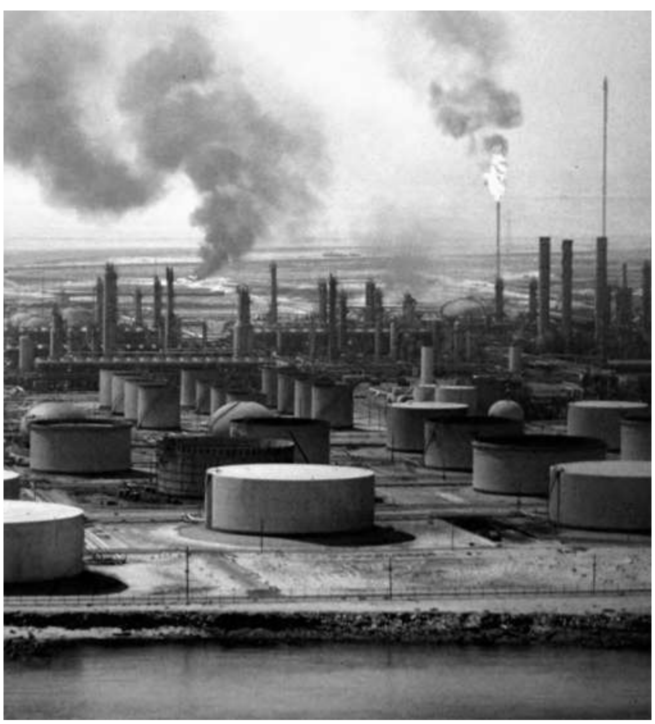
Emissions, Baseline

THE EMISSION BASELINE represents the starting point or reference level from which increases and decreases in emissions are measured. The intergovernmental action through which national governments have coordinated their response to the threat of human-induced climate change is based on the United Nations Framework Convention on Climate Change (UNFCCC), adopted in 1992, and its Kyoto Protocol, negotiated since December 1997. In 2001, the so-called Marrakech Accords marked the shift from negotiation of an intergovernmental framework to cope with climate to a phase of implementation. Setting a baseline for greenhouse gases emissions is part of this shift towards implementation.

Under the terms of the UNFCCC, all signatory countries have common, but differentiated, responsibility to reduce their greenhouse emissions. Yet, only the Annex I Parties were subject to a specific commitment to adopt policies and measures with the aim of returning their emissions of CO_2 and other greenhouse gases to 1990 levels by 2000. This was not a legally-binding emissions target; the commitment of Annex I Parties was simply to aim to return their emissions to 1990 levels by 2000, not necessarily to achieve that goal. In addition, the approach of the UNFCCC, stressing as it does the common, but differentiated, responsibility among the signatories, takes into account national diversity in addressing climate change. The UNFCCC calls for special consideration for least-developed countries (LDC) and economies in transition (EIT) and has granted them a certain degree of flexibility in implementing its targets. Several EITs have taken advantage of this flexibility by choosing a baseline earlier than 1990, prior to the economic collapse that led to dramatic cuts in their emissions.

During the first Conference of parties, the signatories launched the AIJ (Activities Implemented Jointly) phase whereby parties could implement emission mitigation projects in the territories of other Parties, including developing countries, but without gaining credit for the emissions reduced. Many of the projects during the AIJ pilot phase were concerned with the establishment of baselines and their results have contributed to negotiations on the rules for the project-based flexibility mechanisms under the Kyoto Protocol, such as the Clean Development Mechanism and joint implementation with EITs. Unlike the AIJ phase, these mechanisms allow crediting.



An emission baseline represents the starting point from which increases and decreases in emissions are measured.

The negotiations among the parties of the UNFCCC led to the adoption of the Kyoto Protocol. Article 3.1 of the document sets a collective emission reduction target for all Annex I Parties of at least 5 per cent by 2008–2012, from the baseline 1990. In the same vein of differentiated responsibility that also characterized the Framework, the Protocol divides this collective target among the Annex I Parties, giving each of them an individual commitment listed in Annex B. Each Annex I Party chose its individual emission targets in Kyoto. The Protocol's targets deal with the six main greenhouse gases: CO_2, methane (CH_4), nitrous oxide (N_2O), hydrofluorocarbons (HFCs), perfluorocarbons (PFCs) and sulphur hexafluoride (SF_6). Article 3.8 allows parties to use a baseline of 1995 for the latter three gases, in recognition of their increased use since 1990. Article 4 of the Protocol contains the so-called bubble provisions. According to this article, the European Union (EU) is permitted to redistribute its 8 per cent reduction target as it wishes among its member states. An important difference between the targets of the UNFCCC and those of the Protocol is that the Protocol's ones are legally-binding. The Protocol clearly states that Annex I Parties "shall ensure" that they do not exceed their targets, indicating obligation to achieve the targets, not just attempting to meet them.

During the negotiations, ambitious emission reductions were proposed, such as minus 15 per cent by 2010 by the EU and –20 per cent by 2005 by The Alliance of Small Island States (AOSIS). Yet, in the end, more modest targets were adopted. These do not represent a sufficient measure to stabilize the concentration of greenhouse gases in the atmosphere at a safe level. Yet, the Kyoto Protocol's legally-binding emission baselines represent a landmark reversal of the persistent upward trend in emissions. In most of the industrialized world, this trend has been developing since the industrial revolution. The emissions of many industrialized countries continued to rise since the adoption of the UNFCCC and meeting their own Kyoto Protocol targets will require them to make considerable efforts. The targets of the Russian Federation and Ukraine to simply stabilize emissions at 1990 levels are widely considered as extremely generous, since their emissions declined dramatically in the early 1990s: by over 35 per cent from 1990 to 1998 in the case of the Russian Federation

Emissions, Cement Industry

HYDRAULIC CEMENT IS the binding and strength-contributing agent in concrete and most mortars. The cement is hydraulic because it sets and develops strength through the hydration (chemical combination with water) of its component minerals or compounds. Among hydraulic cements, the most common are Portland cement and similar cements having Portland cement as a base.

Concrete is a very common construction material and is a proportioned mix of fine and course aggregates (such as sand and gravel or crushed stone), hydraulic cement (only about 10–12 percent by volume, or about 11–14 percent by weight), and sufficient water to fully hydrate the cement.

In 2006, hydraulic cement was manufactured in about 150 countries and world output was about 2.5 billion metric tons (Gt) per year, enough for about 20 Gt per year of concrete (including mortar) or about 3 tons of concrete per year per person on the planet. The most important environmental issue with respect to global warming stems from cement rather than concrete manufacture: nearly one ton of carbon dioxide (CO_2) is emitted for every ton of Portland cement made. Although generally well below the total CO_2 emissions from fossil fuel-fired power plants and motor vehicles, the cement industry is overall the world's largest single industrial source of CO_2 emissions.

Portland cement is made by finely intergrinding Portland cement clinker (about 95 percent by weight) with about 5 percent calcium sulfate (mainly as the mineral gypsum). The CO_2 emissions come from the clinker's manufacture. The chemical composition of clinker is fairly uniform worldwide, and averages about 65 percent calcium oxide (CaO), 22 percent silicon dioxide, 6 percent aluminum oxide, 3 percent iron oxide, and 4 percent other oxides. These oxides are derived by the high-temperature breakdown in a kiln of a variety of (mostly geologic) raw materials. The clinker is then formed by chemically recombining these oxides into certain hydraulically reactive compounds (mainly calcium silicates).

The dominant CaO component of clinker is chiefly derived from limestone, an abundant rock made up primarily of the mineral calcite (calcium carbonate, or $CaCO_3$). In the kiln, the calcite is broken down by the calcination reaction: $CaCO_3$ + heat CaO + CO_2. Calcite is 56 percent CaO; thus, it takes 1.16 tons of calcite per ton of clinker of 65 percent CaO content, assuming no other source of CaO.

This amount of calcite yields 0.51 tons of CO_2; this emissions factor is commonly boosted to 0.52 tons to account for some loss of calcined raw materials in exhaust dust from the kiln, and the possible presence of small amounts of other carbonate minerals in the raw materials.

Although calcination occurs at temperatures 1,292–1,832 degrees F (700–1,000 degrees C) below those needed for the subsequent formation of the hydraulic calcium silicates in clinker 2,562–2,642 degrees F (about 1,350–1,450 degrees C), it is calcination that consumes much the largest share of the total heat energy requirements.

Depending on the kiln technology and factors such as heat loss through the kiln shell, about 3–7 GJ of heat energy is required per ton of clinker manufactured. This enormous amount of heat is supplied by burning large quantities of fuels (typically coal and/or petroleum coke), which also releases CO_2, typically about

0.43–0.48 tons of CO_2 per ton of clinker, depending on the fuel's overall carbon content.

Thus, counting calcination and combustion, total CO_2 emissions are about 0.95–1.0 tons per ton of clinker, or about 0.90–0.95 tons per ton of Portland cement. Based on typical issues affecting the accuracy of clinker and cement production data, estimates of CO_2 output using the foregoing emissions factors accurate to about plus or minus 5 percent. Other fairly high-volume emissions from cement plants (such as kiln dust, sulfur oxides, and non-N_2O nitrogen oxides) are not significant to the issue of global warming.

There are four main strategies to reduce CO_2 emissions from cement manufacturing. The first involves reducing overall fuel (heat) consumption by upgrading the kiln technology (for example, conversion or replacement of wet kilns with preheater-precalciner dry kilns). The second involves switching among fossil fuels and/or incorporating a proportion of waste fuels; the latter reduce primary fossil fuel consumption, commonly have lower carbon contents, and may offer carbon emissions credits. The third strategy is to source some of the requisite CaO from non-carbonate materials such as iron and steel slags, or coal combustion ashes; these not only do not directly involve calcination emissions, but also require far less heat in the kiln to process.

The fourth strategy is to encourage the use of blended cements rather than straight Portland cement. Blended cements are integral mixes of Portland cement and pozzolans. Pozzolans are siliceous materials that have little initial cementitious character, but which become hydraulically cementitious when reacted with calcium hydroxide (such as that released through the hydration of Portland cement). Although the first three strategies can reduce plant-level CO_2 emissions, the main emphasis (of four strategies) is to reduce the emissions per ton of cement produced by keeping the kilns working at full capacity (their most efficient condition), to make more cement using less raw material and fuel.

Emissions, Trading

EMISSIONS TRADING IS a method of controlling harmful carbon emission by creating a system of economic incentives for reduction. Since the creation of the Kyoto Protocol in 1997, where all signatory nations agreed to implement caps on the six major greenhouse gasses and reduce emissions to 1990 levels by 2012, emissions trading has become one of the most popular tools in controlling industrial pollution. Critics argue that it does little to get to the root causes of that pollution and, ultimately, has a negligible impact on global carbon emissions. The process is relatively simple: a regulatory authority sets a limit, or cap on the amount of emissions a company can produce in a year. The company is given a certain number of credits per metric ton of emissions. If that company comes in under the cap, they can keep unused credits and sell or trade them on the open market; if they exceed the cap, they are required to purchase credits from another company with lower emissions.

The most popular form of this system is called cap-and-trade, where a limit is set with an eye toward overall reduction of emissions. Under baseline and credit programs, there is no cap, but companies are required to stay under a baseline level set at a given year. Project-based, or offset credits are programs that reward emitters for implementing changes that reduce emissions well below the regulatory caps.

The largest experiment in emissions trading is the European Union Emission Trading Scheme (EU ETS). All 27 EU member nations are part of the scheme, and participation is mandatory. Each nation is allocated an amount of carbon tonnage relative to their total industrial output: for example, heavily-industrialized Germany was given an initial cap of 499 metric tons (mt) of carbon emissions, while tiny Malta was allocated 2.9 mt. Individual companies, which are required to report their emissions with the EU ETS, are then allocated credits. Phase I was launched in January 2005. Early reviews are mixed, with many believing that the caps established by the European Union were too lenient and have not resulted in a lowering of emissions.

The United States has utilized cap-and-trade to a limited extent, most notably in the reduction of sulfur dioxide (SO_2) emissions, the main pollutant in acid rain. This program, begun under the Clean Air Act of 1990, proved so successful that the European Union used the American model when setting up the ETS. However, the United States is not a signatory to the Kyoto Protocol, and does not have a single, unified program like the ETS. Individual states and regions are creating their own cap-and-trade programs, some of which are showing early success.

Supporters of carbon-emissions trading argue that this is a prime example of free-market environmentalism that creates a politically and economically viable way to control pollution. Rather than forcing industries to implement often-costly changes in infrastructure, it reduces overall carbon emission, while giving each industry time to develop cleaner alternatives. It also creates a new and potentially lucrative market in carbon-credit trading; giving value to something that was previously just waste. During the EU ETS's first year, 362 million tons of CO_2 were traded for €7.2 billion on this new carbon market. Cap-and-trade programs require little investment by regulatory agencies and have been credited with reducing emissions far beyond what was originally expected.

Critics say that cap-and-trade programs represent a capitulation to market forces at the expense of the environment, and ultimately do little to reduce global emission rates. Most schemes give credits to companies freely, rather than auctioning them off, meaning the companies have no investment in the program at the outset. Many programs allocate too many credits at the outset (this is one of the main criticisms of the EU ETS). Cap-and-trade does not encourage polluters to find greener alternatives or invest in upgrades, because it is usually less expensive to purchase credits from other emitters. These critics also believe that the system relies too much on self-monitoring by industry, and does not have strict fines or punishments for failure to meet regulatory caps. This fosters a sense of business-as-usual that does not address the long-term impact of continued high emissions. They argue that other remedies, such as a carbon tax, would do far more to force compliance with reduction goals.

Energy

ENERGY IS TYPICALLY defined as the ability to do the work. According to the First Law of Thermodynamics, energy is always conserved, so it cannot be destroyed nor created, it only can be transformed from one form to another. Examples of different energy forms include thermal, radiant, potential, and kinetic energy. In particular, thermal energy or heat is energy transported across the system boundary by temperature difference. The energy transfer in the Earth's atmosphere defines the energy cycle of the planet. The fundamental mechanisms for energy transport are radiation, convection, conduction, and evaporation/condensation.

Radiation is energy transfer due to the oscillations of electromagnetic fields or photons that have properties of both particles and waves. The properties of radiation are defined by its wavelength (λ), which represents a distance between two successive wave crests. Atmospheric science is usually concerned with wavelengths that fall into ultraviolet, visible, and infrared parts of the electromagnetic spectrum. All objects radiate energy, as long as their temperature is higher than absolute zero. The Stefan-Boltzmann law defines the total emitted energy in terms of a power law based on the object's surface temperature. Furthermore, Plank's law defines the inverse proportion between the surface temperature and the peak wavelength, which is characterized by maximum energy output. Typical wavelengths for the Sun's radiation are in the range of 0.15– 3.0μm, which is called short-wave or solar radiation, while Earth emits radiation in the wavelength range of 3.0–100μm, which is called long-wave radiation. The incoming solar radiation first encounters the atmosphere, which reflects, absorbs, and transmits this energy to the Earth's surface. The composition of the atmosphere plays an important role in reflectivity, absorptivity, and transmissivity. The atmosphere also emits energy to the surrounding environment, which is characterized as atmospheric emissivity.

Convection, also know as advection, represents heat transfer via bulk, or microscopic, motion of fluids, which can be liquids or gases. There is no convection in solids. For convection in the vicinity of solid surfaces, a boundary layer forms at the interface to reduce the velocities of the unobstructed fluid motion to the velocity of the solid surface, which is typically zero. Also, a temperature boundary layer forms in the vicinity of solid surfaces that have temperatures different than the bulk fluid. The connective transport due to the different densities of fluid is called natural convection. An example of natural or free convection would be vertical movement of the air masses heated at the warm Earth's surface, which receives energy via solar radiation. When free convection is the dominant motion for the air mass, the atmosphere is called unstable. A stable atmosphere has forced convection to take over the fluid motion. This forced motion is mechanically-induced by terrain roughness or pressure differences, and the atmosphere has a predominantly horizontal motion. In nature, the most typical mode of convection is mixed convection, which combines natural and forced convective heat transfer regimes.

Conduction is associated with random molecular motion. It represents an effective heat-transfer mechanism for solids, because of short molecular distances, while it is less effective for fluids and gases. For conduction, there is no bulk motion of molecule characteristics as for convection. Fourier's Law describes this process by relating the total heat transfer to temperature difference and the distance or length of the system under consideration. Conduction is important for heat transfer beneath the Earth's surface, but for atmospheric science conduction is negligible, except at the very thin laminar sub-layer in direct contact with the Earth's surface.

The evaporation/condensation process is a heat-transfer mechanism that involves a phase change of the matter in the system. Evaporation occurs when energy is added to the system during the heat transfer process, while condensation is characterized by energy release to the surrounding environment. The total energy necessary for the phase change from fully-saturated liquid to fully saturated vapor is called latent heat, and represents material property dependent on the temperature and pressure of the system. For example, the latent heat would be different for the same matter, such as water, at different elevations in the Earth's atmosphere. Furthermore, the water cycle is defined by the water evaporation at the ocean surface and condensation that forms clouds and rain. Another important contributor to the water cycle is plant life that releases water vapor to the atmosphere by evapotranspiration, because it combines evaporation and transpiration.

Energy, Renewable

GLOBAL WARMING IS the increase in near-surface air temperatures from the emission of greenhouse gases and particulate black carbon. Greenhouse gases result mostly from fossil fuel burning to produce energy. For industrial and household energy needs, humans compromise on greenhouse gas production, and endanger the future. However, the advent of renewable energy would reduce the production of greenhouse gases. Therefore, renewable energy is considered clean energy.

According to the International Energy Agency (IEA), renewable energy "is derived from natural processes that are replenished constantly. In its various forms, it derives directly from the sun, or from heat generated deep within the earth. Included in the definition is electricity and heat generated from solar, wind, ocean, hydropower, biomass, geothermal resources, biofuels, and hydrogen derived from renewable resources." The use of renewable energy is an old concept. More than a century ago, wood supplied up to 90 percent of the world's energy needs. The use of wood as an energy source has fallen in the last century because of low prices for fossil fuels and their conveyance advantage. With climate change concerns, the rising cost of fossil fuels, and increasing government support, renewable energy production is increasing. The disposal problem of biomass, such as manufacturing wastes, rice hulls, agricultural wastes, and black liquor from paper production is encouraging biomass burning to produce electricity and biofuels. Presently, about 13 percent of the world's primary energy comes from renewable sources such as the burning of traditional biomass. Hydropower provides 2–3 percent, and modern technologies such as geothermal, wind, solar, and marine energy meet less than one percent of world demand.

RENEWABLE ENERGY TECHNOLOGIES

There are many proven technologies available to produce renewable energy, and some new technologies are under development. One of the most promising renewable energy technologies for electricity generation is wind energy that uses airflows to run wind turbines. In good wind regimes, cost-wise, wind power is comparable to fossil alternatives, particularly when economic or environmental concerns are considered. Modern wind turbines range from around 600 KW to 5 MW of rated power. Most common wind turbines for commercial use are of a rated capacity of 1.5–3 MW. Wind energy is the fastest-growing renewable energy in the world. Since 1993, it is growing on average 30 percent a year. Windmills typically run at 25–35 percent of their capacity over the course of a year.

A photovoltaic module composed of multiple photovoltaic cells or arrays is used to convert sunlight directly into electricity. Photovoltaic power is also widely viewed as cost competitive, like wind power. As energy from the Sun is free and the cost of the photovoltaic cells is dropping, a solar energy boom is likely in the near future. Solar energy is good for many grid-connected and building-integrated uses. They are widely used for off-grid applications ranging from telecommunications, to village power in remote and rural areas. In general, solar energy is of two types: solar thermal and solar electric. Solar thermal technologies provide heat and hot water for residential, commercial, and industrial end uses. Solar electric technologies or concentrating solar power (CSP) creates heat to produce steam and/or electricity. At present, producing a few kilowatts to hundreds of megawatts of electricity is feasible through commercial solar electric technologies, but a hybrid application of the technology with fossil fuel would be more economically competitive.

Hydropower is another clean energy source and is the most mature form of renewable energy. It has a significant share of electricity generation worldwide. Because water is denser than air, water has more energy producing ability than wind. Hydropower units not only provide electricity, but also help in flood control, irrigation, pisciculture, navigation, and recreation. Energy from the ocean in the form of tidal forces, ocean currents, wave power, and thermal gradients can be feasibile to produce electricity. It can be harnessed using technology similar to underwater windmills. It is being deployed in many countries, although it is a new concept. Portugal has the world's first wave farm. It generates 2.25 MW of initial electricity using three Pelamis P-750 machines.

Geothermal technology obtains energy by tapping the heat of the Earth. It is expensive to build a power station, but operating costs are low, resulting in low energy costs for suitable sites. Geothermal electricity generation is a base load technology. It can be a low-cost option if hot water or steam from geysers is at a high temperature near the surface of the Earth. This technology contributes positively towards global warming as its taps some of the greenhouse gases emitted through geysers.

Biofuel is another renewable resource that is produced from biomass. It is not as clean as the other renewable energies. Biomass can be directly burned to produce heat energy or steam to run turbines for electricity generation. Liquid biofuel can be produced indirectly from biomass that is available worldwide in a variety of forms: wood, grasses, crops, and crop residues. These are converted to energy through thermal or biological conversion or as feedstock to produce liquid or gaseous biofuels. Biomass itself is carbon neutral, but when used for biofuel production, the emission of methane is blocked, thus helping the environment. Unsustainable ways of biofuel production are not environmentally friendly. However, the Roundtable on Sustainable Biofuels is working to define criteria, standards, and processes to promote sustainably-produced biofuels to positively impact global warming mitigation.

Biogas is produced through biogas plants. These plants operate using waste from paper and sugar production, sewage, animal waste, and other biodegradable wastes. These wastes are slurried together and allowed to ferment with bacteria to produce methane gas. This methane gas is a renewable natural gas used for cooking, heating, and electricity production. In Asia, many developing countries such as India, Nepal, Bangladesh, Laos, Cambodia, Vietnam, Bhutan, have individual household biogas plants to meet household energy demands. There is immense viability to having commercial biogas plants. Current sewage treatment plants can easily be converted to biogas plants. Once the methane gas is extracted from waste, the remaining sludge can be used as a fertilizer. It is five times higher in nitrogen than compost produced from the same biomass.

Hydrogen can act as a crucial storage medium and carrier of renewable energy. According to the IEA, hydrogen, along with renewable energy technologies, is a major potential contributor to the sustainability of the energy sector. Over the longer term, if costs can be dramatically reduced, hydrogen can act as the crucial storage medium and carrier of energy produced from renewables. Hydrogen is already being used in some vehicles. With proper research and development, hydrogen, battery-powered electricity, and solar energy will fully replace fossil fuels as energy source for vehicles.

RENEWABLE ENERGY POTENTIAL

Although renewable energy technologies are unreliable for the world's present energy demand, the market is growing for many forms of renewable energy. Approximately 74,223 MW of power is generated from windmills worldwide. Several European countries and the United States produce the largest percentage of wind energy. Denmark is the world leader in this technology. The present worldwide manufacturing output of the photovoltaics (PV) industry is more than 2,000 MW per year. Japan, Germany, and the United States contribute 90 percent of all photovoltaic installations in the world. Solar energy use is also growing at a faster rate in developing countries, such as Kenya and India. Worldwide, approximately 8,000 MW capacity of geothermal power plants are in operation. A 750 MW geothermal power plant, The Geysers in California, is the largest in the world. Brazil has one of the largest renewable energy programs in the world. It produces ethanol (biofuel) from sugarcane, contributing 18 percent of the country's automotive fuel demand. Ethanol fuel is also widely available in the United States and many other countries. Most countries are mandating using more than 10 percent ethanol or other biofuel as a mixture with fossil fuel. Renewable energy production and its use is very popular in rural settings without grid-based electric supply. Thus, renewable energy is popular among both the poor and rich countries of the world.

According to IEA, the potential of bioenergy is 200-300 EJ/a (Exajoules per annum) compared with the current potential of 50 EJ/a. The potential is so high because of the abundant resource base in all countries. Bioenergy crops and municipal wastes would be better used for producing bioenergy. Theoretically, wind energy is capable of supplying a large percentage of global energy needs as wind is ample everywhere. However, the practical potential is limited due to cost, variability, intermittency, and siting factors. However, researchers believe that these concerns are exaggerated, and that contributions of more than 1,000 percent of total electricity supply are possible without compromising grid reliability. It is estimated that total long-term wind energy potential is five times total current energy production.

Solar energy potential is immense. In Europe, this growth is anticipated around 20 percent per year. China has the highest potential growth of solar

One of the most promising renewable energy technologies is wind energy, which uses airflows to run wind turbines.

energy production and use. Solar heating and drying potential worldwide is estimated to be 600–900 PJ. Some estmates suggest that the worldwide potential installation capacity of PV systems for grid purposes might be 4,001,000 MW by 2010. The potential for large hydropower plants are hampered by environmental concerns. However, there is tremendous potential for small hydropower plants. There are potential geothermal resources in more than 80 countries in the world. The potential energy from these is estimated at 600,000 EJ. Ocean energy systems offer the promise of low-cost reliable electricity, principally to coastal regions, but technology must be improved to be economically viable. Hydrogen energy potential is promising due to serious research and development programs.

In 1983, physicist Bernard Cohen proposed that uranium is effectively inexhaustible, and therefore, can be used as a renewable energy source. Cohen believed that fast breeder-reactors fueled by seawater-extracted uranium could produce and supply energy for billions of years. Nuclear fusion technology is in the development stage; it would be very efficient and have a large potential for long-term energy production. Nuclear fusion technology produces less nuclear waste and has less containment issue than nuclear fission technology.

Energy Balance Models

ENERGY BALANCE MODELS represent the First Law of Thermodynamics applied to a system. In climatology, energy balance models are used for the Earth-atmosphere system. This is a closed thermodynamic system because it does not exchange matter with the surrounding environment, or space. Energy balance models can be applied to the Earth-atmosphere systems for different timescales such as a year, day, or hour. Depending on the timescale, the models would produce an annual, daily, or hourly temperature of the Earth-atmosphere system. Also, the energy transfer processes, the energy cycle, could be either steady-state or transient processes. For steady-state models, the energy input is equal to the energy output in the system, resulting in a steady temperature that does not change with time. This assumption is simple, and results in an energy balance model that can be easily solved. More complex models use transient assumptions and give more informative results, but their solution requires numerical simulations.

The simplest energy balance models assume that the incoming solar radiation, called the solar constant, is equal to the radiative energy lost by the Earth-atmosphere system over the period of one year. These simple balance models can calculate an average constant temperature, and cannot account for the climatic shift defined by the change of the Earth-atmosphere temperature. To study more realistic natural problems, these models can take into account more complicated energy-transfer processes, such as thermal storage of the energy in the upper layer of the ocean, which makes the model inherently transient. Another modeling improvement includes atmospheric energy transfer by convection and radiation. These models enable studies of the climatic shift by decoupling the incoming solar radiation, forcing, climatic shift, and response.

In terms of spatial distribution, the simplest are zero-dimensional models that assume the Earth-atmosphere system to be a single, uniform point. Dividing the Earth-atmosphere system into zones can refine this assumption. One-dimensional models divide the system into latitude zones to allow for latitude-dependent solar flux, albedo, and emissivity. Two-dimensional models create zones in both latitudinal and longitudinal directions.

Energy balance models can be coupled with mass balance models for the atmospheric air and species conservation models for particulate matter or CO_2. These comprehensive models are called Global Climate Models (GCM). With GCMs, the calculations become much more numerically complex, and provide results for weather forecasting and climate change predictions.

Energy Efficiency

ENERGY EFFICIENCY PROVIDES an immediate answer to an energy crisis because it can significantly reduce energy consumption, which further decreases greenhouse gas emissions. For example, during the first energy crisis during the 1970s, popular energy-efficiency measures included fuel-efficient cars and well-insulated buildings. With climate change considerations, the technological solutions to improve energy efficiency are much more diverse and more widely supported than the solutions from the end of the 20th century. To evaluate the performance of energy-efficient devices, products, and engineering-system solutions, an index called energy efficiency can be used. The definition of energy efficiency as an index depends on the thermodynamic system under consideration. In general, energy efficiency is defined as a desired output divided by a required input, and it represents a ratio of energy or work output to energy or work input for a particular thermodynamic system.

For systems that convert energy or work from one form to another, the values of energy efficiency are between zero and one. The maximum value is one, because the useful output cannot be larger than the costly input according to the First Law of Thermodynamics. For heat pumps that are transferring energy between outdoor and indoor environments, the efficiency is called Coefficient of Performance (COP) and can be larger than one. Adoption of energy efficient devices in households is enabled by the U.S. Energy Star and the European Union Energy Label to distinguish devices that produce more useful output for the same input as devices without these certifications. These marketing efforts are aimed at the faster adoption of energy-efficient technologies. Even though energy-efficient technological improvements are welcomed, they are not always adopted in the marketplace because of associated costs. In general, energy-efficient products cost more, but over their lifetime, they save energy and make their up-front investment worthwhile. This phenomenon is called the energy-efficiency gap, and can significantly slow or prevent adoption of these innovations. This gap can be bridged with appropriate government policies and economic incentives to stimulate technology invention, innovation, diffusion, and use of energy-efficient technologies.

Environmental and Societal Impacts Group

THE FORMER ENVIRONMENTAL and Societal Impacts Group (ESIG) is now called the Institute for the Study of Society and Environment (ISSE). ISSE has a three-part motto: Integrative Research, Service to Society, and Education for the Future. Integrative research refers to ISSE's multi-disciplinary research groups, which includes members of different Laboratories in the National Center for Atmospheric Research (NCAR). ISSE is part of NCAR, itself part of the University Corporation for Atmospheric Research (UCAR). Within NCAR, there are five Laboratories: the Computational & Information Systems Laboratory, the Earth Observing Laboratory, the Earth & Sun Systems Laboratory, the Research Applications Laboratory, and the Societal–Environmental & Research and Education Laboratory. ISSE is part of the Societal–Environmental & Research and Education Laboratory (SERE).

The Integrative groups within ISSE are the NCAR Geographic Information System (GIS), the North American Regional Climate Change Assessment Program (NARCCP), a collaborative project with the National Oceanic and Atmospheric Administration (NOAA)'s Regional Integrated Sciences and Assessment (RISA) Program (RISA–NCAR Collaboration), the Collaborative Program on the Societal Impacts and Economics Benefits of Weather Information, and the NCAR Climate and Weather Impact Assessment Scientific Program.

The GIS works to combine data describing climate and weather with other sciences such as the geosciences, and physical, and social sciences. In this way, GIS aims to provide an infrastructure that allows a greater sharing of information between these fields in order to benefit all researchers involved. The NARCCP is a joint project with Canada and northern Mexico. This Program integrates regional data with global climate models and time-slice experiments to predict the weather-related needs of these countries and better prepare the available support services. The RISA–NCAR Collaboration aims to accomplish three goals: to work with the NARCCP to downscale the climate predictions; to further understand the interrelations among climate, water, and weather; and to understand the relationship between scientists and stakeholders.

The Collaborative Program on the Societal Impacts and Economics Benefits of Weather Information, also called the Societal Impacts Program (SIP), is funded by the U.S. Weather Research Program. The SIP works to determine how weather information can impact society and the economy. Finally, the NCAR Climate and Weather Impact Assessment Scientific Program aims to tackle three ambiguous fields in climate research: characterizing uncertainty, extreme weather and climate events, and how climate affects health conditions.

FOCUSED RESEARCH

In addition to its integrative research teams, ISSE also maintains research groups focused on five themes: Assessment Methods, Products and Tools; Climate–Ecosystem–Human Interactions; Use of Scientific Information in Decision Processes; Vulnerability, Adaptation, Thresholds and Resilience; and Integrated Science and Regional Applications.

UCAR collaborates with universities to manage the National Center for Atmospheric Research (NCAR) and the UCAR Office of Programs (UOP). The goal of these three organizations is: "Understanding our changing Earth system, Educating about the atmosphere and related sciences, Supporting a global community of researchers, and Benefiting society through science and technology."

Environmental Defense

ENVIRONMENTAL DEFENSE (ED), an environmental advocacy group headquartered in New York, began when a group of scientists teamed up with a lawyer, went to court, won a battle to ban the pesticide DDT, and incorporated as the Environmental Defense Fund in 1967. Environmental Defense now prefers to work creatively, without confrontation, for solutions to environmental challenges, the most serious of which it views as global warming, "through partnership with powerful market leaders."

ED prides itself on having on staff "more Ph.D. scientists and economists than any similar group" and is noted for its "rigorous scientific approach." It seeks not only to oppose policies that it deems detrimental to the environment, but also to propose workable, innovative alternatives. In 2007, Environmental Defense was a founder and organizer of the U.S. Climate Action Partnership (USCAP), a coalition of environmental organizations and corporations advocating legislative action to address global warming.

Most of ED's more innovative solutions have been market-based. According to ED's chief economist, Dr. Daniel Dudek, market competition "has always been the most powerful engine of American innovation." Solutions reached using this approach have included a 1989 Environmental Defense plan in which Southern California's largest urban water district encouraged and financed farm water conservation by buying the conserved water. This followed the creation of a market for water rights in California in the 1970s, that gave farmers an incentive to conserve water and sell it to cities, thus avoiding the construction of new dams. As another example, the cap-and-trade mechanism for curbing emissions, which was designed by ED and introduced in the 1990 Clean Air Act to reduce sulfur dioxide emissions that cause acid rain, is viewed by the group as "the centerpiece of international plans to reduce global warming pollution."

ED has also proposed innovative solutions to wildlife conservation issues. Its Safe Harbor program assures landowners that protecting endangered species habitat will not result in burdensome restrictions on the use of their land. Its Catch Shares program advocates the creation of limited-access privilege programs that place control of specific marine fisheries in the hands of local fishing cooperatives, providing fishermen with incentives to limit their catch and restore depleted fisheries.

ED has also helped develop agreements among multiple stakeholders to set aside marine protected areas that allow fish stocks to recover. When working with McDonald's in 1991 to convince the fast-food chain to reduce packaging waste and introduce biodegradable food containers, the group used the market incentive approach to not on appeal to altruism, but to point out benefits to the corporation of improved efficiency and reduced waste. McDonald's Vice President Bob Langert commented, "Environmental Defense is probably the best non-governmental organization to find the intersection between profit and planet."

The group also spurred Federal Express's 2003 use of hybrid electric delivery trucks in Sacramento, California, New York City, and Tampa, Florida, which not only reduced emissions by up to 90 percent, but also cut fuel use, and thus costs, by up to 57 percent. More examples include an incentive program in California that encourages residents to purchase energy-efficient air conditioners and refrigerators, a joint air-quality management district on the U.S.-Mexico border to improve local air quality, a sulfur dioxide permit program in the electric-generating sector in China, and a program of incentives in Russia used to measure and reduce greenhouse emissions. Environmental Defense has convinced Petróleos Mexicanos (PEMEX), Mexico's state oil company, to promise to reduce greenhouse emissions, and has convinced the Texas State Environmental Agency to set strict pollution limits on backup electricity generators.

In February 2007, ED helped broker a major climate-related deal. Texas Pacific Group and Kohlberg Kravis Roberts & Co., two private equity investor groups, wanted to take over energy giant TXU Corporation, which had sought permission to build 11 new coal-fired power plants. These plants would add more than twice as many greenhouse emissions as would be reduced by California's enacted, but not yet implemented, climate change legislation. Environmental Defense had helped other environmental groups organize strong opposition to the TXU plans. The investment firms recognized that the success of a takeover largely depended on the reaction of environmentalists to their decisions regarding the TXU coal plants.

Realizing a deal had to made, William Reilly, former U.S. Environmental Protection Agency administrator and an executive at Texas Pacific, contacted Environmental Defense President Fred Krupp. As a result of the subsequent negotiations, the two investor groups scrapped plans for eight power plants, agreed to upgrade the environmental performance of the remaining three, committed to a $400 million efficiency and renewable energy program, including a commitment to wind energy, and promised to join USCAP. Fred Krupp saw this as a "watershed moment in America's fight against global warming" and ED endorsed the plans, but reactions from other environmental groups highlight the difference in approaches to global warming solutions.

A Greenpeace spokesperson said that, from their perspective, there was "no deal to cut" and that the only acceptable solution was a moratorium on any new coal plants.

Environmental Defense educates the public via internet and broadcast media campaigns. In September 2003, it created the Undo It campaign to stress the urgency of action to curb global warming. At the site, flightglobalwarming.com, there are lists of actions to take in the home, in relation to transportation, and in terms of neutralizing bad choices individuals might make. Viewers can find information on the dangers, science, and myths of global warming, plus a tool for calculating personal environmental impact.

Environmental Defense spends 78.9 percent of its budget on programs and services. It uses 5.3 percent of its total functional expenses on management and general administrative expenses. Fundraising expenses account for 15.6 percent of its total expenditures, and it costs ED $0.11 for every $1 it raises.

In fiscal year 2005, Fred Krupp received compensation of $357,057, which amounted to .71 percent of Environmental Defense's total expenses. The organization has 104 staff specialists working in 10 U.S. offices, with 25 of them experts in climate and air pollution issues.

Environmental Development Action in the Third World

ENVIRONMENTAL DEVELOPMENT ACTION in the Third World (ENDA-TM) is an international nonprofit, nongovernmental organization based in Dakar, Senegal. Founded in 1972, on the occasion of the United Nations (UN) conference on environment held in Stockholm, ENDA is an association of autonomous entities coordinated by an executive secretariat. ENDA's representation is disseminated throughout the world and includes 24 thematic teams at the Dakar headquarters, each working on development and environment themes, 21 sections in southern countries (14 in Africa, five in South America, and two in Asia), a European delegation, and a Japanese representation to be established. The organization has about 100 staff members in Senegal and about the same number abroad.

Funding for the organization's activities mainly come from the governments of Switzerland, Austria, and the Netherlands, as well as from the United Nations. Community groups and multilateral organizations, both in Western and developing countries, also support the nongovernmental organization. The European Union also increasingly contributes to the support of the organization. The government of Senegal bestowed several facilities to the organization, which also has an extensive network of volunteers in developing countries. ENDA cooperates with grassroots groups in search of alternative development models based on the experience and objectives of marginalized peoples. It is one of the core members of the Climate Change Knowledge Network and shares its interest in climate change, and in sustainable models of development.

ENDA has stated its concern for acting on initiatives and on popular action. It has lent support to individual and collective initiatives for poverty relief and sustainable development. These initiatives have centered mainly upon the mobilization of inner-city inhabitants. The organization has backed community-based associations and community movements such as rural and urban associations, which bring together youth and women with professionals, consumers, and local or national federations.

The focus of ENDA is to provide socioeconomic, sanitary, and social services to serve the poor. ENDA took part in the 2005 World Social Forum at Porto Alegre, Brazil, in January 2006, joining focus groups on the right to the city, popular responses to privatization, youth, violence, urban segregation, Afro-descendants in Latin America, urban architecture and sustainable development. The organization also supports the activities of the African Social Forum. Participation in these events is part of ENDA's commitment to information exchange with other nongovernmental organizations and to awareness-raising among intellectuals and decision-makers. Communication and education are important sectors of ENDA, which produces films, video, and radio broadcasts, and publishes books and brochures.

ENDA closely works with grassroots groups to contribute to the search for alternative possibilities for development. It also aims to facilitate the access of intellectuals and trained personnel to development programs. ENDA favors integrated action, reflection, and training. Thanks to these actions, the organization seeks to prioritize local, technical, human, and national resources. ENDA particularly targets the area of human rights. This primary objective has led ENDA to support culturally-threatened peoples, to fight against socio-spatial disparities, to assist children and youth in the face of unemployment, and to favor a sustainable development respectful of ecology. ENDA also fights against "imported consumption patterns and production models" and supports actions against acquired immune deficiency syndrome (AIDS). All of ENDA's activities are based on the principle of making the positions of Third World countries in international debates visible and effective.

ACTION TEAMS

Within its different thematic groups in Senegal, ENDA has specific teams working on environmental schemes that highlight the effects of global warming in developing countries. The organization's Energy Program is centered around the use and development of energy in Africa. The program builds on the principles of research-action and training to contribute to the implementation of the UN's conventions on climate change and desertification in Africa, and to develop alternative energy technology, which will allow increased respect for the environment. The team is involved in collecting information on energy and carrying out projects on local, as well as regional, levels. Natural Plant Protection (PRONAT) is another action program concerning the environment, aimed at developing an African system of agriculture adapted to local resources. The scheme plans to raise awareness among farming groups and local authorities about the dangers linked to abusing chemical agricultural products, such as fertilizers and pesticides. PRONAT works with farming communities to develop and promote an alternative approach to rural development, which takes the environment into account.

Environmental Financial Products, LLC

ENVIRONMENTAL FINANCIAL Products, LLC (EFP) is a company that offers legal and financial services to businesses interested in the environmental management sector. EFP is based in Chicago, Illinois. A chief role of the company is to assist in designing and mediating arrangements between parties looking to develop business relations in environmental commodities trading, as well as other environmental or financial markets.

Richard Sandor, chair and chief executive officer, founded the principles driving EFP. Sandor earned his Ph.D. in economics from the University of Minnesota in 1967. He went on to play a large role in developing the idea of emissions credit trading after the Congressional Clean Air Act of 1990. Emissions credit trading began in an effort to reduce acid rain-causing emissions, by trading allowances for sulfur dioxide emissions at the Chicago Board of Trade, where Sandor served as nonresident director 1991–94. He later acted as second vice chairman of strategy 1997–98.

The concept of emissions credit trading is as follows: company that exceeds sulfur dioxide emissions allowances can sell its extra allowance credits to another company that cannot meet the standards. These extra credits will be at a lower cost to the purchasing company than the restructuring needed to meet the standards. The principle behind this trade is that the selling company is rewarded for exceeding standards, and the purchasing company is given extra time to meet those standards without being penalized. Overall, the same net amount of emissions is effectively released as if both companies had met standard allowances. In 2001, Sandor formed the Chicago Carbon Exchange, modeled after the original emission allowances trading for sulfur dioxide. This trading would be for emissions credits for carbon-based greenhouse gases (GHG).

EFP representatives have played a number of roles in assisting various institutions in meeting global GHG emissions standards. For example, they have consulted, advised, or acted as board members for various sectors, such as government, corporate, and nongovernmental organizations. Some examples include the Brazilian states of Amapá, Amazonas, and Paraná; the New York Mercantile Exchange; the U.S. Agency for International Development; the Toronto Stock Exchange; Lloyd's of London; the Hong Kong Futures Exchange; the Chicago Board of Trade; the United Nations; the Australian Greenhouse Challenge Office; and the Stock Exchange of Singapore.

EFP has given seminars and risk management programs at the University of Notre Dame in South Bend, Indiana; the Berkeley Program in finance at the University of California at Berkeley (where Sandor was once a faculty member); the Kellogg Graduate School of Management at Northwestern University in Chicago, Illinois (where Sandor works as a research professor); and the INCAE (Instituto Centro Americano de Administración de Empresas) business schools throughout Central and Latin America.

Environmental History

ENVIRONMENTAL HISTORY IS the study of the interactions between human cultures and nature through time and space, examining how the natural environment has influenced the historical processes and, conversely, how people have recognized and transformed their environment using technology. This bilateral approach was designated by Christopher Smout. The goal is to place the natural world as an actor of history, an approach that social history has neglected. The object of study is ecological, where humans develop their habitat, examined from a historical perspective.

The emergence of modern environmental history as a field of study took place between the 1960s and the 1970s, when concern about both emerging environmental crisis and environmental activism arose, and historians incorporated the concepts and models of ecology. The science of ecology, as the study of the relationships between biotic and abiotic elements within their environment, was considered the scientific basis for the rational and sustainable economic development of human society. The difficulties associated with the study of the interactions emerge from the complexity of natural and human systems, the intervention of a large number of human groups and institutions, and the intervention of perception in the processes of decision-making.

History narratives began to link scientific and technological progress, social and political changes, land occupation, and the extraction of resources to environmental transformations. Historians began to talk with scientists from other disciplines, in order to fully comprehend natural systems, and the disciplines started to cross-fertilize. By 1980, the discipline had a differentiated itself, through publications and historians with an elaborated research program.

New global environmental problems include: transboundary air pollution, destruction of the ozone layer, carbon emissions and global warming, and biodiversity decline; indicating the need for policies to be discussed, adopted, and implemented at the international scale. This phenomenon challenges the classical approach of history as a national narrative. However, problem-oriented regional and local studies still dominate the field of environmental history and few authors have adopted a global scope. The theoretical and methodological influence of Carl Sauer and cultural geography is perceptible in the focused and in-depth nature of the studies.

General studies of the conceptualization of nature are found in Clarence Glacken's *Traces on the Rhodian Shore* (1967), Donald Worster's *Nature's Economy: The Roots of Ecology* (1977), Keith Thomas's *Man and the Natural World: A History of the Modern Sensibility* (1983), and Carolyn Merchant's *The Death of Nature: Women, Ecology, and the Scientific Revolution* (1980). Regional concerns deal with particular historical processes and environmental traits. American and Australian environmental histories share a common interest in the phenomenon of population of their land, from 1620 and 1788, respectively. Australian and European environmental histories converge in the study of the processes of colonization, settlement, and impact on the new environment and indigenous people.

European environmental historians examine the old and highly-humanized landscape with reduced areas of natural quality, a long history of environmental interaction, and exploration of forms of adaptation. In contrast, North American historians largely wrote about the significance of wilderness, the relationship of native Indian populations with nature, and the struggle for survival in harsh environments. In Australian history, the role of fire and the concept of the outback are more salient. The Canadian school of the staple theory of growth analyzes the economic and environmental impact of the exploitation of national resources such as fur, forestry, whale, or cod, based on exports in world trade.

THE VARIOUS APPROACHES

Various approaches on how to focus the study of the discipline are found in contemporary environmental history that can be ascribable to the principal authors. Donald Worster proposes three levels, suggesting an analysis agenda for environmental history: the review of past environments and the role of key species; the analysis of modes of production resulting from the invention of technologies and type of organization; and the study of the perceptions, ideologies, and values that led to environmental decisions and guided the interpretation of change. William Cronon, adopting a postmodern point of view, considers the perspective of Worster a simplification, for he claims for a more complex understanding of the concept of nature and the modes of production.

Alfred Crosby elaborated the concept of ecological imperialism associated with the ecological catastrophe derived from the biological invasion caused by the European colonization of the world. Settlers conveyed their own genes, diseases, weeds, varmints, crops, and livestock during their 500 years of expansion. After the colonial encounter, America suffered a demographic collapse followed by a repopulation with European and African immigrants and their accompanying species, while Africa saw a dramatic depopulation and resettlement caused by the slavery system. Those areas also experienced a process of predatory appropriation of natural resources (minerals, forests, and land) by companies and settlers, greatly reducing wildlife and partially displacing local populations into reduced areas.

Carolyn Merchant embraces a pessimistic view of the relationship between scientific advance and the environment, and identifies the roots of present ecological problems in the early 16th century with the introduction of modern science and technology. According to Merchant, the change from an organic to a mechanical view of nature, as the result of the use of technology, led to a disruption in the relationship between nature and people and, ultimately, to its destruction. Merchant introduces the phrase ecological revolution when referring to the periods, during which societies change their relationship with nature, once essential discordances between the system of production and the environment materialize. Keith Thomas adopts a more optimistic view of the role of technology, because it implies the detachment of humans from a risky position of dominion over nature, as defined in religious texts. Thus, scientific discovery brought nature back to a living condition and saved it from the effects of an anthropocentric conception.

When confronting environmental issues, it is difficult to separate science from ideology and political compromise. The dual character of the scientist, as a producer of knowledge and individual, leads to a conflict in the personal domain. However, the question is if environmental history has any moral or political agenda as a discipline. The contact with other close social sciences, particularly with environmental ethics and political ecology, favors the osmosis of approaches. Some historians within the framework of New Left history, adopt a bottom-up perspective and, embracing a Marxist methodology, judge that nature is an exploited subject, like workers in the capitalist industrial system of production.

Some authors claim that the model of politically innocent science broke down (and the public confidence in science with it) in the 1960s when the role of the scientist shifted. The non-political scientist evolved into a scientist committed to causes in his or her community and a political activist. William Cronon fights the application of environmental history to the practical solution of social problems and claims it only can be useful to society by providing stories that help people to think about those problems.

THE ORIGIN OF THE DISCIPLINE

The first scientific meeting on the matter, the International Symposium on Man's Role in Changing the Face of the Earth, was held at Princeton University, New Jersey, in 1955, under the sponsorship of the Wenner-Gren Foundation for Anthropological Research. It was co-chaired by Carl O. Sauer, Marston Bates, and Lewis Mumford. Inspired by George Perkins Marsh's *Man and Nature*, it served to identify a community of scholars as involved in a distinctive field of study. The following year, the contributions were compiled and published as a two-volume work with the same title, edited by William L. Thomas.

The American Society for Environmental History (ASEH) was founded in 1977, and launched the journal *Environmental Review*. In 1990, it continued as *Environmental History Review* and, in 1996, was renamed *Environmental History*. The first meeting of the society took place at the University of California-Irvine in 1982. The first European Workshop on European Environmental History was held in 1988, in Bad Homburg, Germany, under the sponsorship of the Werner Reimers Foundation. It resulted in the publication of the book *The Silent Countdown: Essays in European Environmental History* (1990), edited by Peter Brimblecombe and Christian Pfister. From then on, environmental history matured as a discipline and was included in the curricula of various universities, although it has not yet completely reached a fully-recognized status.

Roderick Nash published *Wilderness and the American Mind* in 1967, a book with a great public impact that offers a literary-style examination of the evolution of the concept of wilderness in North America, from an aversion to a wild hostile nature, to an attraction for a wilderness in process of disappearing. He examines environmental thinking in the United States from early settlement to the beginning of the 19th century, resolving the differences between New World and Old World conceptions of nature, and the formation of an American conception of nature. Nash details this progression, adopting a regional perspective, in response to a historical context of national introspection. Nash consolidated the general use of the term "environmental history" after he developed a course with this title at the University of California, Santa Barbara.

The *Making of the English Landscape* was published by William George Hoskins in 1955, a precursor of the dozens of titles edited between 1955 and 1985, pioneering the study of landscape history in England and the world. Through the examination of the overlying time layers hidden in the English landscape, Hoskins gathered information on the cultural features of past societies and their ways of interacting with their environment, which could explain how people related to the landscapes according to possible use and physical limitations.

Clarence Glacken published, in 1967, *Traces on the Rhodian Shore: Nature and Culture in Western Thought, from Ancient Times to the End of the Eighteenth Century*. This comprehensive work studies the history of Western thought, until the 18th century, from the point of view of the mutual influence between nature and culture. Thus, Glacken identifies three main themes of reflection about history: the question of if Earth was created deliberately, the influence of the physical environment on the character of the peoples and human culture, and the extent that change is induced by human activity.

SOURCES OF INFORMATION

Not only written documents, but also maps, engravings, pieces of art, instruments, and artifacts have been widely used as sources of information in environmental history. Other less common records investigated are farmers' logs and travelers' diaries, meteorological and phenological records, terrestrial and aerial photographs, and proxy data in the natural sciences. Proxy data are supplied by a heterogeneous set of information sources, with varied spatial and time coverage, record continuity, and degree of uncertainty in regards to dating. Numerous environmental processes have not been registered, for they have been neglected, remained unnoticed, or had non-human agents or actors.

Natural surrogates include: glaciological (ice cores, glaciers), geological (sedimentary rocks, ocean and terrestrial sediments), and biological (coral reefs, pollen deposits, tree rings) records, containing information on past environmental conditions that replace the actual data on those processes. Oral history captures the information obtained from memories and perceptions, from people who were witnesses or actors of past events and processes, or simple recipients of information. The interviewer collects data not available from other sources or in cultures where written documentation is rare, but with an extremely rich oral tradition. Nevertheless, memory, as a source of information, is interpreted through past and present perceptions, attitudes, and values, holding intrinsic difficulties for its interpretation.

Landscape archaeologists survey and conduct excavations in past cultural landscapes, interpreting and recording anthropogenic evidences of occupation and modifications of the natural landscape as the result of human adaptation to the resources available in the natural environment. The approach in the field has changed by adjusting the scale of study. While initially, research in archaeology was conducted in individual sites, understood as separate documents, the scope moved to studying settlement systems and then to compiling information in the gaps, of interstices, between sites.

The reconstruction of past landscapes and land use practices over the long term and at a geographical mid-scale developed from the environmental archaeology approach in the 1950s. The evidence comes from the constituents of the built environment, roads, fossilized field systems such as agricultural plots and walls, and water infrastructures in the form of ditches for draining or irrigating.

The protection and proper management of archaeological sites sometimes becomes subject to ethical debate when sites are presently inhabited or are claimed by successors of the former population, so that use has to be negotiated with the descendant communities.

The humanities, social sciences, and natural sciences are all under the umbrella of environmental history. Landscape archaeology examines past cultural landscapes, such as Roman ruins in Algeria above, and human adaptation to natural resources.

The analysis of the ample range of complex and interrelated social, political, cultural or technological facets of the human system leads to interactions with other disciplines. Environmental history, while rooted in landscape history, developed as a multidisciplinary field of study where the humanities, social sciences, and natural sciences come together. Landscape remained as a central topic, but many other matters are studied. Economic history, environmental sociology, cultural ecology, political ecology, and historical geography provided the conceptual and methodological background, although the process of systematization and consolidation still continues in all these fields due to their recent origins.

According to the hybridization model elaborated by Mattei Dogan and Robert Pahre, scientific disciplines undergo a twofold process, fragmentation and recombination. Gradually, subjects increase their field of study and, eventually, become too broad for scholars to comprise, so that the discipline fragments into subfields and the practitioners move toward the margins of the field. Specialists from peripheral subfields interact, filling in the gaps between sciences and recombine the fragmented subdisciplines into a new hybrid. Innovation takes place with the cross-fertilization of concepts, theories, methods, or paradigms, and new themes of study arise. Ultimately, the new hybrid may become completely independent or retain a dual character.

THE HUMAN-ENVIRONMENT RELATIONSHIP

Two major paradigms have animated theories of the conceptualization of the relationships between humans and the natural environment: environmental determinism and possibilism, even though other debates in the social sciences should not be dismissed. Environmental determinism holds that the physical environment is a factor that shapes human occupation of the land and the use of resources, determining the course of history, the culture of an area, the settlement pattern, and human behavior. The people inhabiting a region are constantly adapting to the changing nature of their environment. The controversial aspect of this theory, which was used as a rationale for racism and imperialism, led some authors to accept the idea that the environment imposes constraints, but does not override human potential to adapt, approaching possibilism.

Thus, environmental historians, evading determinism, have neglected the study of nature's influence on populations. From the perspective of environmental possibilism, nature constraints allow for a range of possibilities or opportunities for development, so that a variety of human responses are practicable in a certain physical environment, as a function of its culture and history. The relationships between culture and the environment are flexible. The particular arrangement between a certain land and a culture was termed *genre de vie* (way of life) by the French geographer Paul Vidal de la Blache, the result of the people's response, configuring the personality of the region. His influence in the Annales School of history was decisive.

George Perkins Marsh, who published *Man and Nature or, Physical Geography as Modified by Human Action* in 1864, observed and analyzed the historical impact of civilization, particularly deforestation and watershed degradation, in various regions of the world, arguing for a moral compromise with the land to ensure human survival. Aldo Leopold, a conservationist who worked for the U.S. Forest Service, published his thoughts in the book *A Sand County Almanac* (1949). His major contributions were his understanding of environmental change as a historical process, and his concept of the land ethic. According to Leopold, human ethical values and responsibility could be extended to land, by enlarging the community to include environmental components. This attitude does not prevent nature exploitation, but affirms its right to be preserved.

Lynn Townsend White, a historian of the technological innovations in medieval society, thought that history could shed light on contemporary problems. In his paper in the journal *Science,* entitled "The Historical Roots of Our Ecologic Crisis" (1967), he examined the role of religion in the formation of a Western perception of nature and its control through technology. He traced back to the Judeo-Christian ethic, the trigger of the exploitative attitude, based on the dominion of the resources on Earth that God gave to humankind, which led to the contemporary environmental crisis. The work initiated an inflamed debate inside and outside the academic world, with arguments against non-Western or pre-Christian cultures that support human control of nature.

THE ANNALES SCHOOL

The most influential contribution to environmental history came from the field of history. The Annales school, which flourished at the University of Strasbourg, France, agglutinating a first generation of scholars around the journal *Annales d'histoire économique et sociale*, founded in 1929 by the medievalist historian Marc Bloch, and modern historian Lucien Febvre. This approach, a reaction to the dominant history of political events and the function of leaders, minimized the role of individuals and economic factors by interpreting the processes of innovation as a result of the intervention of social forces. Scholars were interested in identifying the latent and slow-changing social, economic, and political structures at the various scales of analysis, hence favoring the long-term processes over time. Following this interpretation, environmental history is then concerned by a long course of action.

Their proposal for a comprehensive study of society induced historians to collaborate with other social disciplines, such as economy, sociology (such as Marc Bloch); and anthropology and particularly geography (such as Lucien Febvre), and to adopt their methodologies, composing a global history. Questions concerning this approach focus on their disregard of the role of abrupt technological or social changes and the underestimation of the phases previously identified in economic history. Also, an examination of the application of this method to contemporary issues, with technology rapidly and deeply modifying the environment, is necessary as, according to Braudel, technology shapes civilization.

Marc Bloch challenges the idea of an escalating innovation and technological progression throughout history with his analysis of the history of the watermill in Europe, an instrument of feudal dominance and taxation. Lucien Febvre, who proposed to study human history within the framework of the natural environment, supported the contribution of geography to history. This influence is noticeable in his book *La Terre et L'Évolution Humaine* (1922).

Fernand Braudel, a disciple of Lucien Febvre, in his major work *The Mediterranean and the Mediterranean World in the Age of Philip II* (1949), adopted the approach of his mentor when he placed the space itself, the Mediterranean area, as the main actor. He contemplates the Mediterranean as an environmental unit, with a specific character, and studies how it shapes the social processes of Mediterranean history. However, opposing Febvre, he goes back to determinism when he recognizes the environment as an actor of long duration playing a decisive function in history.

Braudel identifies three layers when using separate resolutions and frameworks of analysis, which allows him to recognize hidden structures. The three layers are: events with a short duration, such as those reflected in the media, mid-term conjunctures of an economic nature, and *longue durée* (long-lasting) cycles of history that extend for centuries. The three classes of events are stable foundations of civilizations, driven, respectively, by the individuals, social phenomena, material flows, and the environment. As to the mid-scale processes, Braudel emphasizes the function of long-distance exchange, the result of productive imbalances, a phenomenon that stimulates advance and innovation. After its consolidation as a school of thought with Braudel, a third generation of scholars contributed to the fragmentation of the *Annales*, by putting a greater emphasis on anthropological methods.

Alfred Hettner (1859–1941), the German geographer, used a chronological approach, focusing on the understanding of regional identity. Studying the distributions of the physical and cultural geofactors through history, he considered geography could explain origin and process, and supported the adoption of a genetic perspective. Otto Schlüter looked at landscape as the essential object of study, as a space for the integration of factors where changes are identifiable, and particularly focused on the transition between natural and cultural landscape. A key concept in the study of landscape change is sequential occupation, proposed by the geographer Derwent Whittlesey in 1929. The term designates the process of consecutive and accumulative modification of the land by subsequent generations, so that each culture produces a distinct landscape at each time frame. Dewey was interested in the evolutionary and dynamic nature of the landscape, adopting, together with Sauer, Hettner's genetic approach.

Carl Ortwin Sauer, the cultural and historical geographer, emphasized the mutual influence between landscape and culture through history at the regional scale, in order to fully understand the interactions. He thought of landscape as the single object of study of geography. Sauer's early focus was on the reconstruction of past cultural landscapes, using the empirical recollection of narratives as a method and the elaboration of very detailed descriptions. In his work *The Morphology of Landscape* (1925), he identifies people and culture as agents, the natural area as the medium, and the humanized cultural landscape as the result, reshaped and renewed by incoming new cultures, agreeing with Whittlesey. Sauer distrusts technology for its detachment of land, and identified it as the causal factor of the destruction of values.

Henry Clifford Darby belongs to the school of British historical geography and local history. He studied and published the geography contained in the *Domesday Book*, a survey of 13,418 English settlements completed in August 1086. Darby adopted a close scholarly relationship with history for the study of the course of landscape construction by humans as agents, as shown in his book, *The Draining of the Fens* (1940). His earlier works are seen in the with landscape history, anti-modern, disclaiming technology (like Sauer), while in later works he advocates development over the preservation of hostile wilderness.

RELATED DISCIPLINES

Historical geography brings a long, scholarly tradition. Its theoretical background focuses on a description and explanation of spatial differentiation, and helps to reconstruct past environments and landscapes. Patterns are produced by different cultures along history as the result of their interaction with the Earth's surface. The study of landscape history approaches historical geography, but where the former analyzes single landscapes and applies a nostalgic narrative of the natural landscape lost, the latter makes generalizations and elaborates theories of construction.

The debate between determinism and possibilism also occurred in the field of anthropology. However, whereas Alfred Kroeber notably represented the latter paradigm, determinism saw two different perspectives. Environmental determinism understands culture as determined by nature, while cultural determinism, represented by Leslie Alvin White, maintains that culture determines environment. The cultural ecology perspective seeks to explain the interactions of human populations or societies with their environment at the local scale in terms of ecological knowledge gained, human strategies of ecological success, and cultural adaptation to the local environmental conditions, in particular techniques, economy, and social organization.

This subfield of anthropology materialized with the publication of Julian Steward's book *Theory of Culture Change* in 1955, which challenged the dominant determinist paradigm of culture determining nature, with an ecological or ecosystemic paradigm, where the physical environment influences culture and the formation of political, social, and economic structures. The fragmentation in the field of cultural ecology, due to the conceptual differences with respect to the mutual interaction between the environment and culture, has led to the birth of ecological anthropology. In this approach, interaction occurs with some of the components of the habitat, and the process of adaptation takes place at the scale of the technology used.

The concept of political ecology originated in a paper written by Eric Wolf, a disciple of Julian Steward, titled *Ownership and Political Ecology* (1972). The discipline is a synthesis of cultural ecology and political economy, and it studies the organization of the world political economy and its impact on the environment. Political ecology works at various spatial scales and takes into account the implications of political structures. It accounts for the effect of resource location on political, economic, and social structures, and the role of these in resource distribution, allocation, and extraction, and their environmental effects.

Decision-making involves interaction among groups based on categories of power, status, and hierarchy in processes of social dynamics; it also implicates the adoption of measures to mitigate environmental problems and the participation of stakeholders, including: state and international institutions, companies, transnational corporations, social organizations, and society at large. In this context, ideology is a factor that figures prominently in the interactions and the adoption of measures. In his book *Theory of Cultural Change* (1955), Steward introduces the concept of multilinear evolution. He proposes that certain basic types of cultures may develop synchronically and similarly, with some common cultural features, under comparable conditions, so that their variations are more adaptative strategies than stages in a single path or unilinear cultural evolution, as supported by Leslie White.

The study of the interactions of social organizations with the natural environment, taking into consideration behavior, as well as the resulting societal well-being and environmental quality, is the concern of environmental sociology. This subfield of sociology concerns the perceptual and behavioral factors, social structures, and processes that intervene in the degradation of the natural assets society depends on, and which threaten the sustainability of the human system. It explores social movements as a response to environmental change (modern environmentalism), and the inequities in social exposure to natural and technological hazards, and access to natural resources and environmental quality.

It introduces the concept of environmental justice. The discipline has moved from sociology of the environment, with the environment as an object of study but without changing the classical mainstream perspective of sociology, to an approach with society-environment relationships as the pivotal subject. Several pre-existing areas of interest converged into a unified discipline around the 1970s, in particular, the subfields of human ecology and rural sociology, which have long adopted a human-environment perspective, and then consolidated with the manifestation of global environmental change in the 1980s. The principal themes that human ecology brought to the new field, were the study of resource-dependent communities, natural resource sociology and resource availability, and social movements research.

Riley Dunlap and William Catton published a paper in 1978, reporting the limitations of mainstream sociology in addressing environmental problems. These include the adoption of the human exceptionalism paradigm (humankind as a differentiated species) and the socially dominant Western worldview, which fails to acknowledge the roots of human society in nature. Modern society is unsustainable and vulnerable for its excessive dependence and rapid depletion of nonrenewable natural resources. Dunlap and Canton also introduced the concept of ghost acreage, resembling ecological footprint and ecological overshoot, to identify the societal dependence on distant areas for procuring natural resources and the resulting large inputs of energy required for transportation, as well as exceeding carrying capacity of the ecosystems and stocks. They acknowledge the insufficiency of the present paradigm and the urgency for the elaboration of a new ecological paradigm (NEP), based on the necessary adjustments and adaptations to the increasingly disturbing and threatening global environmental change.

The new paradigm first should be adopted by the scientific community, and then extended to the whole society. Allan Schnaiberg proposed, in his book *The Environment: From Surplus to Scarcity* (1980), the notion of the treadmill of production. It denotes the self-reproducing nature of modern capitalism, promoting economic growth and private capital accumulation. Corporations are forced to expand their activity to survive in a very competitive market, and administrations favor growth to gain increasing tax revenues. The escalating process of accumulation leads to an intensification of the demand of inputs, in the form of natural resources, and the production of outputs, as pollution. Frederick Buttel indicates there are two key environmental phenomena that need attention. First, human consumption of goods and services, driving production, with little awareness of the environmental implications, a phenomenon that he designates with the term substructural environmental practice. The second phenomenon consists of the engagement in intentionally environmental practices, such as active environmentalism and environmental regulation, the result of the adoption of the new ecological paradigm.

Environmental Law Institute

THE ENVIRONMENTAL LAW Institute's mission statement is to advance environmental protection by improving enviromental law, policy, and management.

Even if aggressive mitigation measures are undertaken, the effects of climate change will be felt for decades. In response, countries and communities are developing and revising legal and institutional frameworks to improve adaptive capacity. Adaptation measures center on improving resilience, adaptive management, and early warning and emergency response. Laws and institutions can improve resilience to the potential effects of climate change by ameliorating other stressors. Laws governing planning and development, such as environmental impact assessment guidelines, can, and should, take climate change into consideration. Resilience alone is not sufficient to cope with the potential effects and uncertainties associated with climate change.

Adaptive management provides a framework for managing uncertainty. This iterative approach, which recognizes the uncertainties inherent in climate change and response measures, assesses needs and options, develops and implements response measures, monitors and assesses these measures, and modifies them, as appropriate. These different measures are illustrated by examples from managing water resources, the coastal zone, forests, and livelihoods, including agriculture.

PRECIPITATION PATTERNS

Changes in precipitation patterns foreshadow potentially substantial effects on ecosystems and human communities, including wetlands, lakes, rivers, agriculture, and domestic use. Measures to improve efficient water use, manage water demand, reuse water, and expand water resources can all improve resilience. Such measures include differential pricing structures, permitting, and requirements for water-conserving techniques. Adaptive water management, though still a developing field, is equally important. Experiences to date include the Murray-Darling Basin (Australia), and in the United States, experiences in hydropower licensing (Clark Fork Project), and management of the Platte River.

Early warning systems are essential to identifying potential climate-related threats, such as drought or hurricanes, and enabling timely and appropriate responses. Though developed countries have more sophisticated warning and response systems, developing countries have created a variety of cost-effective warning and response systems to cope with El Niño or to respond to hurricanes, typhoons, earthquakes, and other natural disasters.

COASTAL ZONE

The combined threat of sea-level rise, more severe hurricanes, and global migration toward the coasts has made it increasingly important for coastal zones to adapt to climate change. Coastal adaptation measures must cut across sectors and improve resilience of both existing and planned development. In addition to land-use planning, other laws and programs, such as those governing flood insurance, can have a profound effect on coastal development. National, state, and local laws and policies should be amended to steer development in more appropriate directions. Initiatives to retain and strengthen wetlands and barrier islands, which help buffer hurricanes and storm surges, can also improve the resilience of coastal areas.

A threshold question in coastal adaptation is whether to accept the effects of climate change (for example, by adopting a Living Coastline) or to rely increasingly on engineered solutions to resist such changes. Engineered solutions, such as the levies in New Orleans, often pose small risks of failure, but catastrophic results if they do fail, these are already leading to the armoring of coasts in many places, degrading rich tidal areas.

Finally, early warning and emergency response systems must be strengthened. As Hurricane Katrina demonstrated, both developed and developing countries are vulnerable to hurricanes, and the ineffectual emergency response revealed the challenges of implementing an effective response system. Fortunately, other experiences in emergency environmental response, such as the Joint United Nations Environment Programme (UNEP)/Office for the Coordination of Humanitarian Affairs (OCHA) Environmental Unit (though it does not address climate change) can provide guidance for the development of more effective emergency response systems.

FORESTS

Forests, and the millions of species that depend on them, are valuable economically and ecologically, providing an estimated $4.7 trillion in goods and services annually. Their ecosystem services include nutrient cycling, carbon sinks, climate regulation, and raw materials. Approximately 60 million people rely on forests for their livelihoods, with the production and manufacturing of industrial wood products estimated to contribute $400 billion to the global economy, approximately 2 percent of the global Gross Domestic Product.

Forests are especially vulnerable to climate change, given the difficulty in migrating to keep pace with temperature changes, and the varying climate tolerance levels of forest ecosystem species. Mountain forests are limited to migrating upslope to mountain peaks, while development may block migration of lowland forests. Climate change will also exacerbate existing stress from changing land use patterns that fragment habitats. Impacts such as unusually intense fires and devastating parasite infestations, historically stemmed by cold winter temperatures, are already occurring. Such impacts affect both the economic productivity and biodiversity of forests.

Increasingly, forests are managed adaptively, if not specifically in response to climate change. Adaptive measures have sought to reduce pressures on biodiversity from habitat conversion, over-harvesting, pollution, and alien species invasions. Specific projects include an adaptive management approach by the U.S. Forest Service to stem decline of the northern spotted owl. In addition, the 1994 U.S. Northwest Forest Plan established 10 Adaptive Management Areas, each with a focus, strategic plan, and activities consistent with their purpose. The Northwest Forest Plan demonstrates the importance of a clear organizational commitment, capacity, and leadership; effective public participation processes; clearly-defined elements of an adaptive management plan (including goals and objectives); and the use of creative and innovative approaches.

The mere presence of forests will help bolster environmental resilience to climate change by preserving biodiversity. Conservation of biodiversity and maintenance of ecosystem structure and function are important climate change adaptation strategies, because genetically-diverse populations and species-rich ecosystems are better able to adapt to climate change. Management structures can help build forest resilience by minimizing factors that degrade forests. For example, forests with natural species diversity can better adapt to other threats, such as population growth and depletion and degradation of forests, than can monoculture tree farms. Methods for maintaining species diversity without prohibiting tree harvesting include selective cutting and controlled burning.

LIVELIHOODS

The relationship between climate change and livelihoods is multi-dimensional; livelihoods are affected by climate change and used to mitigate its impacts. By restricting the availability of natural resources and ecosystem services (through drought, floods, and disease), climate change can make it more difficult for people to engage in the traditional livelihoods with which they have supported themselves and their families. At the same time, natural resource-dependent communities can reduce their vulnerability to climate change by diversifying their livelihoods and, consequently, the resources upon which they depend. To that end, laws, policies, and institutions can play a key role in facilitating the use of alternative resources and materials by communities seeking to adapt to the impacts of climate change. These tools can also be used to promote stakeholder participation in natural resource management decisions.

Climate change can hinder agricultural productivity and make certain crops less suitable for planting. Laws and institutions can be employed to improve water-management regimes, techniques, and practices; facilitate the continued development of drought-resistant crops and the use of genetically diverse crops and species; provide incentives for the planting of crops that are better adapted to changing climatic zones; and introduce new agricultural technologies. Climate change can affect fisheries, another key source of livelihoods, through changes in water temperatures and levels, as well as circulation and flows. Laws and institutions can facilitate adaptation by enforcing existing restrictions on pollution and habitat degradation, monitoring the impacts caused by climate change, creating protected areas for vulnerable species or habitats, and establishing commercial permitting and licensing systems for new species, when necessary and appropriate.

THE WAY FORWARD

Broad popular and political support is essential for successful adaptation, given that it will require measures that are challenging, costly, and innovative. Much of the burden and cost of changes ultimately will be borne by potentially affected communities. In order to be effective, then, adaptation must be done in a participatory and transparent manner.

Among the most significant challenges for adaptation is the uncertainty associated with specific effects of climate change in particular locales. Legislative bodies typically have found it difficult to draft laws that effectively deal with uncertainty and contingencies, but these will become increasingly important. One mechanism for coping with uncertainty is to set aside funds to pay for projects that may be needed, depending on changed circumstances. This is less likely to be viable in developing countries, unless such funds are made available through the World Bank or other multilateral institutions.

The transition to adaptive management likely will focus on four broad themes. First, policymakers, regulated entities, and the public must become more comfortable managing uncertainty. Carefully constructed and implemented adaptive management pilot projects can help increase confidence. Second, mechanisms for collecting and sharing information must be strengthened. Most countries have such mechanisms, but they often suffer from inadequate staff, funding, and technical resources. In addition, a clear legal framework for adaptive management can provide a mandate and serve to address barriers to sharing information. Third, processes must be developed to periodically assess the information that has been gathered. Finally, there must be an ability and willingness to periodically revise the laws, regulations, permits, and other measures, based on these assessments. Because provisions requiring periodic revision are lacking in most current environmental laws, policymakers should be educated about why and how to draft such provisions. Some

U.S. states have experience with these provisions and may be considered as models.

Environmental Protection Agency (EPA)

IN 1970, PRESIDENT Richard Nixon established the U.S. Environmental Protection Agency (EPA) as part of an executive reorganization plan. William Ruckelshaus served as the first administrator, which is the title of the head of the EPA. The mission of the EPA is to protect human health and the environment. Because global warming and climate change can have effects on both human health and the environment, they are encompassed as part of EPA's mission.

STRUCTURE AND MISSION

The vigor in which EPA pursues climate change research and policy recommendations is usually dependent upon how sympathetic the presidential administration is to such policies. In 2005, the EPA faced some criticism after a former oil lobbyist influenced reports about climate change. Since then, the agency has taken a closer look at the potential effects of global warming. More recently, the U.S. Supreme Court ordered EPA to become even further involved in global climate change remediation by regulating carbon dioxide (CO_2) and other greenhouse gases under the Clean Air Act. In *Massachusetts v. Environmental Protection Agency,* 12 states and U.S. cities brought suit against the EPA. The U.S. Supreme Court handed down the five to four decision in April 2007.

The EPA is organized into different program and regional offices across the United States, as well as several laboratories. The EPA is charged with several tasks. First, it develops and enforces regulations. Next, the EPA offers financial assistance in the form of research and community grants. Environmental and risk management research is also performed at some of the EPA's laboratories. The EPA also sponsors and facilitates partnerships with a variety of governmental and nongovernmental organizations and businesses. The different divisions engage in environmental education and outreach, as well. Finally, the EPA creates many of publications that are used by multiple stakeholders, businesses, and educational institutions.

The EPA's headquarters are located in Washington, D.C. There are 10 regional offices throughout the Unites States and 12 EPA laboratories. Native American tribes work with the EPA region that includes the state that their reservation borders. In some instances, tribes are delegated specific authority to implement EPA programs on their lands. In other instances, tribes work with the EPA to enforce regulations and alter guidelines. The EPA employs over 17,000 scientists, lawyers, policy analysts, and engineers. Many employees hold post-baccalaureate degrees. The EPA is not considered a cabinet-level agency, however, most presidents appoint the administrator to their cabinet. Usually, when choosing an EPA administrator, a public servant is sought, who is not necessarily a scientist.

REGULATION AND FINANCIAL ASSISTANCE

The EPA works to achieve positive results in several program areas. The first of these is to develop and enforce regulations that protect human health and the environment. Congress promulgates laws to limit environmental degradation and maintain human health. The EPA is charged with the task of creating regulations to fill in the specific requirements of the legislation. The EPA's employees conduct research and then set national standards and requirements. At times, the EPA delegates authority to states and tribes for monitoring and compliance. If necessary, the EPA can assist states and tribes in ensuring that specific environmental quality standards are met, or revoke enforcement authority all together.

Next, the EPA offers financial assistance to many stakeholders. Most money is provided directly to states as grants to assist them in administering delegated enforcement requirements and state environmental programs. The EPA also provides many research and fellowship grants for graduate and undergraduate students. These include funding for research, community involvement, small business initiatives, internships, and tribal collaboration programs. The EPA offers several well-known fellowships, such as the National Network for Environmental Management Studies Fellowships, Science to Achieve Results (STAR) fellowships, Public Health fellowships, and American Association for the Advancement of Science fellowships. Each of these opportunities allows graduate students to fund their education, as well as participate in training programs, and conduct innovative research, often incorporating some aspect related to climate change.

ENVIRONMENTAL RESEARCH

The EPA is considered a leader in confronting environmental problems and advancing risk assessment technologies and decision-making mechanisms. The EPA labs throughout the United States conduct basic scientific and groundbreaking research on current environmental issues. Together, with collaborations from business, academia, and industry, the EPA evaluates the environmental conditions of the United States and identifies, recognizes, and resolves present and future environmental problems.

The EPA has several offices and programs devoted to accomplishing the goals of environmental research. One is housed within the Office of Research and Development (ORD). This office focuses on producing basic peer-reviewed environmental research and engendering cost-effective new technologies. To further this goal, the office awards research grants and fellowships to universities. Another research program is designed to monitor and assess the nation's biological resources. The Environmental Monitoring and Assessment Program (EMAP) tracks the current status of U.S. ecological conditions, and predicts future trends and risks associated with natural resources.

The Lake Michigan Mass Balance Study is another EPA project. From 1994 to 1999 the Great Lakes National Programs Office undertook this research effort. The goal of this project was to better understand the types and amounts of toxic substances in Lake Michigan, as well as how to manage the associated risks. Another research program administered by the EPA is the Microbiology Home Page. This is a comprehensive information clearinghouse that provides detailed information about methods relating to a variety of microorganisms. The website is maintained by Human Exposure Division of the National Exposure Research Laboratory (NERL).

The EPA sponsors the National Center for Environmental Assessment (NCEA). This center is a general information resource about the overall process of human health and ecological risk assessments. Also, the center works to integrate dose-response, hazard, and exposure data into accepted risk characterization models. The National Center for Environmental Economics (NCEE) explores the different relationships among the economy, environment, human health, and pollution control mechanisms. The NCEE also communicates and resolves multidisciplinary issues relating to the environment and economics.

Another research program managed by EPA is the National Center for Environmental Research (NCER). This organization mostly supports extraneous research through grants and fellowships. It is part of the ORD and oversees the Science to Achieve Results (STAR) funding program for universities. Next, the National Environmental Scientific Computing Center (NESC2) administers EPA's first supercomputing center. This provides High Performance Computing and Communications (HPCC) that allow EPA to undertake global-scale modeling and research, better science to create improved regulations, and educational environmental and computer science programs. This program is part of the Environmental Modeling and Visualization Laboratory. The final research program administered by EPA is the Office of Science and Technology (OST), Office of Water. The OST is charged with developing standards under the Clean Water Act and Safe Drinking Water Act. This office also issues guidelines and advisories in conjunction with other water-related laws.

The U.S. Environmental Protection Agency also administers several research offices across the United States. These include the following: National Air and Radiation Environmental Laboratory (NAREL), Montgomery, Alabama; National Enforcement Investigations Center Laboratory, Denver, Colorado; National Exposure Research Laboratory (NERL), various locations; National Health and Environmental Effects Research Laboratory (NHEERL), various locations; National Risk Management Research Laboratory (NRMRL), various locations; National Vehicle and Fuel Emissions Laboratory (NVFEL), Ann Arbor, Michigan; and Radiation and Indoor Environments National Laboratory, Las Vegas, Nevada.

PARTNERSHIPS AND PROGRAMS

Another significant area of programming for the EPA is the sponsorship of voluntary partnerships and programs. The regional offices and headquarters of the EPA work with over 10,000 businesses, nonprofit organizations, local governments, and industries on voluntary programs. These groups engage in approximately 40 different programs promoting energy conservation and efficiency, as well as pollution prevention and education. Partners undertake projects in many areas including finding ways to conserve water, reducing greenhouse gases and toxic emissions, recycling solid wastes, mitigating indoor air pollution problems, and better understanding pesticide risks.

In addition to voluntary programs, the EPA promotes several other partnerships, such as stewardship programs, information exchange partnerships, and general partnerships. For instance, the environmental stewardship program provides resources for industry, governments, and other agencies to promote sustainable actions and environmental protection. The Information Exchange Partnership is an internet-based exchange of standards-focused secure data. This resource ensures integrated information, real-time access, and the ability to electronically collect and store accurate information. The Information Exchange Partnership also includes the Central Data Exchange. This allows the EPA and contacted program offices to receive environmental data submissions from state and local governments, tribes, industry, and other collaborative partners. The Central Data Exchange provides a means for fast and efficient communication between stakeholders and the EPA.

The EPA also participates in several other collaborative initiatives. For example, Binational.net is a program in which the EPA and Environment Canada work to preserve the Great Lakes. This program fulfills the requirements set forth in the Great Lakes Water Quality Agreement. The EPA and U.S. laboratories have also formed a voluntary partnership dedicated to improving the performance, environmental sustainability, and energy efficiency of nationwide laboratories. This is called Labs for the 21st Century. A final collaborative program of note is the Office of Pollution and Prevention and Toxics (OPPT) and Tribal Environmental Network. The EPA established this program to better facilitate communication with tribes and to assist Native American tribes with the protection of the environment.

Promoting environmental education is another area of EPA programming. It is the goal of this agency to promote environmental consciousness and respect by inspiring individual responsibility for caring for the environment. To accomplish this, the EPA provides a variety of resources to educators, students, and interested citizens. The Office of Environmental Education promotes grants, fellowships, educator training programs, and the President's Environmental Youth Awards.

The final program goal of the EPA is to publish and disseminate information. This is one way that EPA keeps the public abreast of current activities and the status of environmental regulations. The E-Government Act of 2002 requires that federal agencies keep an up-to-date inventory of information to be published on their websites, to establish and convey a publications schedule, and to allow public comment on those schedules. The EPA maintains this on their website and makes an effort to distribute publications as soon as printed.

Equatorial Countercurrent

EQUATORIAL COUNTERCURRENTS ARE major surface flows that carry water eastward in the Atlantic, Indian, and Pacific Oceans. They are located near the equator and are sandwiched between two westward-flowing currents, the North Equatorial Current and the South Equatorial Current. Equatorial countercurrents are unique, in that they flow in the opposite direction of the surface winds. The other major surface currents in the tropics flow in the same direction as the prevailing winds.

The equatorial countercurrents are driven by a distinct surface wind pattern in the tropics. Strong westward trade winds result in westward surface flow in most of the tropical Atlantic and Pacific Oceans. However, several hundred mi. (km.) north of the equator the winds are much weaker, in comparison. The stronger winds to the south pile up water where the winds are weak. As a result, the surface of the ocean can be up to 6 in. (15 cm.) higher and the thermocline (region of strongest decrease of temperature with increasing depth) as much as 328 ft. (100 m.) deeper than it is directly to the north. The excess water flows eastward under the influence of the Earth's rotation, giving rise to the equatorial countercurrents. In the Indian Ocean, the equatorial countercurrent is located several hundred mi. (km.) south of the equator, but is caused by a similar mechanism. In all three oceans, the equatorial countercurrent is concentrated in the upper 656 ft. (200 m.), above the thermocline.

The intensity of the equatorial countercurrent varies from season to season and from month to month. The strongest seasonal changes occur in the Atlantic Ocean. Eastward flow reaches a maximum in the summer and fall, with speeds of up to 12 in. (30 cm.) per second, and disappears in the spring. Seasonal changes are weaker in the Pacific Ocean. Here, the equatorial countercurrent exists year-round, and is strongest in the fall and winter, with speeds slightly greater than those in the Atlantic. In both the Pacific and Atlantic the equatorial countercurrent is located farthest north in the fall, centered near 8 degrees north. In the Indian Ocean, the countercurrent is present only during the winter.

Equatorial countercurrents, driven by tropical surface wind patterns, flow in the opposite direction of the surface winds.

There are large month-to-month changes in the strengths of the Pacific and Atlantic equatorial countercurrents. The changes are most pronounced during fall in the Pacific, and during summer in the Atlantic, and are associated with clockwise rotating eddies centered between the equatorial countercurrent and the South Equatorial Current to the south. The eddies move westward, driven by the contrast in temperature and flow between the equatorial countercurrent and the South Equatorial Current. Over an entire season, they act to decrease the strength and temperature of the equatorial countercurrent.

The equatorial countercurrent plays an important role in the circulation of mass, heat, and salt in the tropical oceans. It provides one of the pathways through which warm surface water returns eastward after being transported westward in the South Equatorial Current. In the Atlantic Ocean, the equatorial countercurrent also transports significant amounts of fresh water eastward from the mouth of the Amazon River. The Amazon water transported eastward decreases the surface salinity of the western tropical Atlantic Ocean. The strength of the Pacific equatorial countercurrent changes during alternating cycles of El Niño and La Niña. During La Niña, the equatorial countercurrent increases in strength, along with an intensification of the other major equatorial currents in the equatorial Pacific. The equatorial countercurrent becomes weaker during El Niño.

Equatorial Guinea

ONE OF THE smallest and least developed countries in Africa, Equatorial Guinea was formerly the colony of Spanish Guinea, in central Africa, with the mainland bordering with Gabon and the Cameroon, and the capital, Malabo, located on the island of Bioko (formerly Fernando Po) in the Bight of Biafra. It has a land area of 10,828 sq. mi. (28,051 sq. km.), with a population of 504,000 (2005 est.), and a population density of 47 people per sq. mi. (18 people per sq. km.). Located in the tropics, only 5 percent of the country's land is arable, with much of it used for subsistence farming, and growing cocoa and coffee; another 4 percent is used for meadows and pasture. In addition, 46 percent of the land is forested, some of it covered in dense tropical jungle, especially in the south. The country remains undeveloped, although oil deposits have recently been found offshore, promising prosperity for the ruling class in the country.

Approximately 91 percent of the Equatorial Guinea's electricity production comes from fossil fuels, with 9 percent from hydropower. In 1990, the country's per capita carbon dioxide emissions were 0.3 metric tons, rising to 0.35 metric tons in 2003. All the country's carbon dioxide emissions come from liquid fuel, since the country has a very poor public transportation network. Transportation from one part of the country to another is undertaken mainly by minibus or bush taxi along badly maintained roads, except on Bioko, where many of the roads are sealed. The discovery of oil is likely to lead to a higher demand for electricity and greater private ownership of automobiles.

The effects of climate change and global warming on Equatorial Guinea involve a greater risk of flooding, with much of the coast of the mainland low-lying. This would not only damage the coastal infrastructure, but could also lead to increased breeding grounds for mosquitoes, leading to increased prevalence of malaria, dengue fever, and other insect-borne diseases. The Equatorial Guinea government ratified the Vienna Convention in 1988, and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. It accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on August 16, 2000, which took effect on October 16, 2005.

Equatorial Undercurrent

THE EQUATORIAL UNDERCURRENT (EU) is a strong subsurface equatorial eastward jet, which is situated under the surface of the westward south equatorial current in the Atlantic, Indian, and Pacific oceans. The main EU core (in which velocity exceeds 20 in. [50 cm.] per second) occurs within an equatorial thermocline. EU wideness is about 428 mi. (400 km.) (plus or minus 2 degrees to the north and south from the Equator). Thickness of EU varies from 656–1,312 ft. (200–400 m.). Typical maximum velocity within the EU core is about 3.3–5 ft. (1–1.5 m.) per second.

TWO PRIMARY FACTORS

There are two principal reasons for EU, namely the southeast trade wind blowing over the equatorial zone, and the convergence of equatorial eastward nonlinear current. Long-term southeast trade wind forcing, as shown by George Philander, leads to pressure gradients directed from western boundaries of the oceans to the east. Convergence of eastward nonlinear current at the equator (due to changes in the sign of Coriolis force between the Northern and Southern Hemispheres) causes the generation of strong narrow undercurrents in the vicinity of the equator.

EU intensity is at a maximum in the Pacific Ocean (where it is called the Cromwell current). The maximum velocity of EU exceeds 59 in. (150 cm.) per second there. In the Atlantic Ocean (where it is sometimes called the Lomonosov current), its velocity is about half that of the Cromwell current. In the Indian Ocean, EU as a strong subsurface equatorial jet does not exist throughout the year. It occurs in boreal winter, when northeast monsoons are developing, and disappears in summer during southwest monsoon action.

EU is situated deeper in the western side of Atlantic and Pacific oceans because thermocline deepens just there (a long-term effect of southeast trade winds). The depth of EU core is up to 820 ft. (250 m.) in the western equatorial Pacific. To the east, EU becomes shallower and more intense. Maximum EU velocity occurs in the mid-equatorial oceans. Further to the east, EU is shallower, too. However, its intensity decreases. EU intensity decreases in the western and eastern sides of the equatorial basins is due to intensified horizontal mixing there, restricting its velocity. Often, there is the secondary (deep) core of EU that is mostly due to a barotropic eastward pressure gradient along the equator. However, the eastward velocity within this core does not usually exceed 8–12 in. (20–30 cm.) per sec.

The total transport of EU is about 50 Sverdrups in the central equatorial Pacific, while it is about 30 Sverdrups in the central equatorial Atlantic (one Sverdrup = 106 cu. m. per second). This transport is at a maximum in boreal spring (in the Pacific Ocean) and in fall (in the Atlantic). Such phase differences in seasonal cycles between two oceans is due to their different sizes. As was shown by Vitaly Bubnov in his comprehensive monograph, a seasonal EU cycle in the equatorial Atlantic is approximately in phase with the southeast trade wind forcing (in accuracy of a month), while in the equatorial Pacific they are approximately out of phase, as a result of different sizes and, hence, different equilibrium times.

Abrupt forcing of equatorial ocean (for instance, before El Niño, when trade winds weaken very quickly) generates different classes of equatorially trapped waves (such as, Kelvin, Rossby, inertia-gravitational, and mixed Rossby-gravitational or Yanai waves), most of them are modified by EU. Low-frequency (decade-to-decade) variability of southeast trade wind generates quasi-equilibrium EU variations. More/less intense southeast trade wind leads to more/less intense EU. As was shown by Albert Semtner and William Holland, EU becomes unstable if its velocity exceeds 39 in. (100 cm.) per second. As a result of instability, long planetary equatorial waves are generated. Their periodicity/wave length is about 30 days per 497 mi. (800 km.)

Eritrea

ERITREA IS LOCATED in the Horn of Africa between 12 degrees 22' and 18 degrees 02' north and between 36 degrees 26' and 43 degrees 13' east, bordering Sudan in the west, Ethiopia in the South, Djibouti in the Southeast and with the Read Sea in the East. Total land area is 77,236 sq. mi. (124,300 sq. km.) with a coastline of 1,180 mi. (1,900 km.), territorial waters are around 74,564 sq. mi. (120,000 sq. km.). Around 390 islands are located in the Eritrea Red Sea Zone, among them the prominent Dahelak Archipelago. The population is estimated to be around 3.5 million (2001 estimates), 20 people per sq. mi. (33 per sq. km.), with about 431,000 located in the capital, Asmara. Eritrea became independent as a nation after separation from Ethiopia in 1991, and similarly, Eritrea has suffered from erratic rains, droughts and famines.

Precipitation ranges from 7.8–43 in. (200–1,100 mm.). Due to high topographic variations it has diverse climatic zones with major rainfall in the Central Highlands and Western Lowlands during June and September. Summer rain is caused by southwesterly monsoon winds. Eastern lowland and the escarpments have rainfall between November and March, because of continental winds blowing over the Red Sea. The escarpment is the wettest area of the country due to orographic effects and bimodal rainfall regimes, in some places. The six agro-ecological zones are the moist highland, the arid highland, sub-humid, moist lowland, arid lowland, and the semi-desert, betweeen altitudes from 328–9,901 ft. (100–3,018 m.) above sea level.

The six major drainage basins are the Setit, the Mereb Gash, the Barka-Anseba, the Read Sea, the Danakil Depression, and the small catchments flowing to the Sudan. They are currently not used for irrigation and other infrastructure services. About 80 percent of the population is engaged in agriculture, mostly subsistence agriculture. Eritrea has a potential to expand fisheries and tourism in the coastal and marine areas as well as the industrial sector, but these efforts are just beginning. Currently, Eritrea as a Least Developed Country (LDC) is one of the world's poorest country with per capita income below $100 per year. Biomass accounts for about 75.5 percent and petroleum, the only fossil fuel, for 24.5 percent of the total energy consumption.

CO_2 emissions amounts 622,5 Gg, equivalent to 0.133298 per 1,000 people according to latest estimates, which is not much different from 1994 data. However, the major share of CO_2 emissions comes from the land-use change and forestry (LUCF) sector by burning fuel wood, deforestation and soil degradation with an additional net balance of emission of 1676 Gg in 1994. So the LUCF in Eritrea is a source rather than a sink for emissions. The second major source is from petroleum combustion in road transport and energy industries, accounting for about 283 and 241 Gg of CO_2. Nitrous oxides account for about 6 Gg, mainly from the energy secotor, methane 74 Gg mainly from agriculture.

Eritrea is most vulnerable to climate change. The UK8 model turned out to be the best predictor for climate change in Eritrea. With doubling greenshouse gases, temperature is expected to rise by 7.2 degrees F (4.1 degrees C) within the next century, affecting especially the Port City of Massawa, which is mainly located at sea level, leading to estimated economic losses of $14–$243 million. Harsh climatic conditions and periodic droughts already limit the scope of regeneration of biodiversity. Climate change would diversify and shift the bio-climatic zones. Surprisingly, agricultural yields are predicted to increase due to possible beneficial atmospheric effects of CO_2.

Climate change policies in Eritrea are intended to complement the country's objective for attainment of food security and poverty reduction. Planned adaptation programs are: reforestation/afforestation, mainly implemented by area closure systems; introduction of energy efficient technologies for power generation such as the Hirghigo Power Plant Project and into households; introduction of renewable energies; formulation of laws and standards; introduction of efficient public transport systems, particularly in urban centers; education and awareness measures. The country will require financial support and technology transfer from developed countries to be enabled for full implementation of the United Nations Framework Convention on Climate Change (UNFCCC) process. Eritrea ratified the Convention on April 24, 1995 and the Kyoto Protocol on July 28, 2005.

Estonia

THE NORTHERNMOST OF the three Baltic States, the definition usually excluding Finland, Estonia has a land area of 17,413 sq. mi. (45,226 sq. km.), with a population of 1,342,409 (2007 est.), and a population density of 75 people per sq. mi. (29 people per sq. km.). With 25 percent of the country arable land, 11 percent is used for meadows and pasture, 44 percent of the country remains forested.

With a high standard of living, and located in northern Europe, the energy usage in the country is high, with 7.9 billion kWh (2001) produced each year, and some 1.2 billion kWh exported. Only 0.1 percent of this comes from hydropower, with 99.7 percent from fossil fuels. This has resulted in Estonia having the 10th highest per capita carbon dioxide emissions of any country in the world: 16.1 metric tons in 1992, falling to 13.6 metric tons in 2003. Of the country's carbon dioxide emissions, 75 percent come from solid fuels, mainly coal, and also wood; 17 percent from liquid fuels, and 7 percent from gaseous fuels, with 1 percent from cement manufacturing. Because of the cold climate in the winter, 75 percent of carbon dioxide emissions come from public electricity and heat production, with 9 percent from transportation, and 7 percent from manufacturing and construction.

Global warming and climate change are causing higher average temperatures in Estonia. In addition, some of the snow has melted, creating more land for farming. However, this has led to a change in the crops that can be grown, and the warmer temperatures in the seas around Estonia have affected the local fishery industry. In 1989, the government of the Estonian Soviet Socialist Republic (a constituent part of the Soviet Union), ratified the Vienna Convention, and the Estonian government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and signed the Kyoto Protocol to the UN Framework Convention on Climate Change on December 3, 1998, ratifying it on October 14, 2002; it took effect on February 16, 2005. When ratifying the Kyoto Protocol, Estonia undertook to reduce per capita carbon dioxide emissions by 8 percent before 2012.

Ethics

THE CONSIDERABLE SOCIAL challenges posed by global warming and associated climate change, and the related scientific, policy, and public health issues are amenable to ethical analysis and inquiry. The role of ethical decision-making is to identify and analyze instances of ethical conflict or uncertainty, with the goal of making and implementing sound decisions, especially with attention to the rights, responsibilities, and interests of the parties involved. Several approaches for ethical analysis have been proposed for use in biomedicine and public health. Examples include principle-based approaches (such as beneficence, autonomy, and justice) and case-based methods based upon analogical reasoning (comparing like cases). Other theoretical approaches depend on rights or duties. In humanitarian approaches to ethics, people respond to human suffering by acting in a virtuous manner based on compassion or altruism. In fields such as biomedicine and public health, ethical frameworks tend to be anthropocentric: they focus on the welfare of humans and human populations and on interactions between human beings.

For environmental science, additional approaches to ethics have been proposed that consider the ethical relationship between human beings and the natural environment. Many current ecological problems are tied to human attitudes, values, ethics, and behaviors. Although environmental ethicists strive to avoid anthropocentric viewpoints (for example, by explicitly considering the impact of ethical decisions on animals, plants, and the ecosystem), they frequently draw upon traditional ethical theories and frameworks developed to decipher right or wrong human conduct. Environmental ethicists consider biological entities and the nonbiological world (for example, the atmosphere, land, and ocean) fundamentally interdependent and involving complex systems. Examples include coral reefs and related fisheries that are being destroyed by warmer waters and pollution. Thus, environmental ethics provides support for arguments that a sustainable environment is essential to human beings, including future generations. Some environmental ethicists have argued that the environment, with all its diversity and complexity, has intrinsic worth, even without its importance to humans.

Practical steps in ethical decision-making include: assessing the available factual information; obtaining additional factual information about issues at the center of the controversy (for example, comparing collective actions that could be taken to reduce emissions of greenhouse gases and forecasting the potential economic consequences); identifying the relevant ethical issues or questions; identifying the stakeholders and values at stake; identifying the available options, including possible alternative courses of action; and more clearly defining the language used by the disputing parties (for example, what is meant by "environmental sustainability"). The remaining steps are selecting the best alternative supported by the analysis and evaluating the actions taken and their eventual outcomes.

Principles of justice or equity have figured prominently in public debates about such issues. It has been observed that the people least likely to be responsible for greenhouse gases (for example, people in parts of Africa, Asia, and Oceania) are also those most likely to be adversely affected by global warming. Many of the world's poorest people are among the most vulnerable to storms, flooding, or rising sea levels. Poorer nations and communities may also be at increased risk for vector borne illness, hunger, or famine due to drought, heat, and extreme weather events, raising concerns about health or survival. Environmental ethicists have argued that those who could benefit most from mitigation and adaptation measures are often those who are least responsible for greenhouse gas emissions. Principles of procedural justice have informed discussions about the need to assure fair representation in decision-making related to global warming and climate change. Intergenerational equity underlies concerns about the need to look out for the interests of future generations. This includes taking steps to help ensure that the world inherited by future generations is not diminished by loss of animals, plants, ecosystems, or land that is suitable for homes or growing crops.

Ethical analyses also have contributed to policy decisions made about how best to respond to climate change in the face of scientific uncertainty. Although there remains some scientific uncertainty about the timing and magnitude of future effects of global warming and climate change, ethical analyses have contributed to policy decisions by governments, corporations, and other organizations about what steps should be taken to mitigate the adverse effects of climate change. Ethical principles and values such as beneficence, utility, prudence, and the precautionary principle underlie the need to take appropriate action, even in the presence of some scientific uncertainty.

Examples include limiting emissions of greenhouse gases, developing new technologies, strengthening public systems needed for emergency preparedness (for example, preparing for severe storms or flooding), protecting forests, improving irrigation systems, and developing sustainable agriculture to alleviate human suffering and ecological destruction. Finally, ethical principles also highlight the need for adaptation, a process by which individuals and communities institute policies, countermeasures, and appropriate actions to mitigate the adverse effects from climate change. Examples include improving and strengthening warning and forecasting systems, educating the public at large, and heightening community preparedness.

Ethiopia

ETHIOPIA IS LOCATED in eastern Africa, along the continent's Great Rift Valley. Some of the earliest humans emerged from this part of Africa millions of years ago. Ethiopia is expected to be one of the countries hardest hit by climate change, putting much of its 76.5 million residents at risk. In fact, some climate researchers now believe Ethiopia was one of the first victims of climate change, more than 20 years ago. Global dimming, a problem just now being studied by climatologists, is a reduction in the warmth of the Sun, as particulate matter in the atmosphere blocks the Sun's rays from reaching the Earth's surface. That solar heat is vital to the development of monsoons in that part of Africa. A dimming event in the 1980s was probably behind the catastrophic droughts of 1984–85, which led to a famine killing more than a million Ethiopians.

More frequent droughts in recent years have strained the Ethiopian economy, more than 80 percent of which is based on agriculture. In 2007, world health officials estimated that at least 1.5 million Ethiopians were at risk of starvation in the aftermath of a particularly dry year. Deforestation, soil erosion, overgrazing, and desertification have also put pressure on the ecosystem at large, with the loss of several native plant species, and some native bird species on the brink of failure. Climate change is hurting the lifestyle of 20 million nomads who live across the Horn of Africa. In recent years, intertribal fights over dwindling water resources and vanishing grasslands have been on the increase. In 2006, several tribal leaders gathered in Ethiopia for peace talks, but conflict is likely to continue, as resources grow scarcer.

Total carbon emissions in 1998 were 1,990,000 metric tons, a 33 percent decrease from 1990 levels, and well below the regional averages. An estimated 79 percent of emissions come from liquid fuels, and 21 percent from cement manufacture. The Ethiopian government is signatory to a number of international treaties, including biodiversity pacts, desertification reduction, and protection of endangered species and the ozone layer. It has also signed on to the Kyoto Protocol. The government has shown commitment to educating the public and supporting the development of sustainable practices and green technologies.

European Commission

THE EUROPEAN COMMISSION (EC) is a part of the European Union (EU) that functions to manage issues related to the environment, natural resources, sustainable development, and grants for research and development in matters of importance to the EU, such as the environment.

The EC holds numerous events throughout the year as well as throughout the EU in order to raise awareness of the environment and its protection, as well to honor people and organizations that are exemplary in their stewardship. One such occasion is European Mobility Week (EMW), an annual event taking place since 2002 in the European Union. During this week, the latest ideas and technologies for sustainable travel are showcased for the public and investors alike, taking place in each participating city.

Each local government participating in EMW is required to make one permanent change annually. Between EMW 2006 and EMW 2007, the average number of permanent changes per participant was actually 2.4. There is an annual contest comparing these permanent changes. In the year 2006, Copenhagen, Denmark won this contest by thinking of and testing fifteen new traffic changes, including novel parking strategies. In the year 2007, León, Spain won the contest by opening a new bus route as well as new city bicycle routes for noncar modes of transportation. EMW also includes a car-free day, which often has non-EU countries participating. In the year 2007, a Chinese city participated for the first time. Other returning countries included Brazil, Canada, and Thailand.

On June 15, 2006, the EU via the EC established EU Forest Action Plan. Trees and forests play a crucial role in global warming prevention, because they act as important carbon sinks, absorbing carbon dioxide from the atmosphere. The EU Forest Action Plan is targeted for the years 2007–11, and has four key foci: long-term improvement in economic competitiveness, namely using sustainable harvesting; environmental stewardship; quality of life enhancement; and improved coordination and communication. The EC stresses in this plan that protected forests are a necessity, and that to ensure their status, it is imperative to have international cooperation. Additionally, the plan states that forestland will contribute to the goals of the Lisbon Strategy, including the Gothenburg Objectives, for Economic, Social, and Environmental Renewal.

In addition to drafting its own plans and goals for carbon emissions reductions and limiting use of fossil fuels, the EC also respects international accords regarding the environment and its protection.

The EC is also investigating numerous alternative energy sources so as to reduce carbon emissions, such as Bio-energy, Concentrating Solar Power, Geothermal Energy, Ocean Energy, Photovoltaics, Small Hydro Energy, and Wind Energy. The EC recognizes that much advancement has been made already, but that further advancement will depend on public and international policies and their support for the abovementioned alternative means of energy. In 2005, a report from the European Commission (EC) entitled the Biomass Action Plan stated that at that time, the EU was obtaining four percent of its energy from biomass utilization, and that it had the potential to use up to eight percent by 2010, if policies were supportive.

In order to continue to uphold the Kyoto Protocol and future resolutions, the EC has established the European Strategic Energy Technology Plan (SET Plan). The goals are to incorporate renewable energy into twenty percent of the energy pool for the EU, to lower greenhouse gas emissions by twenty percent, and to reduce primary (fossil fuel) energy usage, also by twenty percent. These three goals are set for the year 2020. By the year 2050, the EC hopes to have the EU emissions reduced by 60 to 80 percent.

European Union

THE EUROPEAN UNION (EU) is a democratic organization of member European countries. The European Union was established neither to join all nations into one state nor to manage international cooperation; rather, it was established to act as a democratic forum in which policies could be made, affecting all member countries equally. The EU supports the diversity of its member nations, working together to foster shared values. Countries wishing to join the EU must apply and be approved.

The EU was originally formed after World War II in an effort to prevent further war among the European countries. Six initial countries formed the first version of the EU, and their interests were mostly in trade and economy. These six founding countries are Belgium, France, Germany, Italy, Luxembourg, and the Netherlands. Since then, Denmark, Ireland, and the United Kingdom joined in 1973, with Greece joining in 1981. Portugal and Spain joined in 1986; Austria, Finland, and Sweden joined in 1995; Cyprus, Czech Republic, Estonia, Hungary, Latvia, Lithuania, Malta, Poland, Slovakia, Slovenia joined in 2004; and Bulgaria and Romania joined the EU in 2007. As of 2007, the EU included 27 countries, home to nearly 500 million people. The euro, the shared currency of the EU, was introduced in 2002, and was used in 13 countries by 2007. As each member nation improves its economy, this number will rise.

Beginning in 2004, former rifts between Eastern and Western Europe began to heal when 10 nations, primarily from Eastern Europe, joined the formerly Western Europe-dominated EU. Since then, other developing European nations joined as well; as of January 2008, Croatia, the Former Yugoslav Republic of Macedonia, and Turkey were candidate EU countries.

The Schuman declaration is often cited as the blueprint for the EU. On May 9, 1950, French foreign minister Robert Schuman proposed an organization of European nations, to promote peace. In honor of his proposal, May 9, is Europe Day in today's EU. The Schuman declaration proposes that Europe come together over a series of unions, not all at once in one large plan.

One such union that Schuman proposed was the alliance of French and German coal and steel production, into an alliance in which other European nations could participate in. In fact, the Treaty of Paris, signed April 18, 1951 and enacted July 25, 1952, established the first European Steel and Coal Community and is considered the foundation of the modern European Union.

Although many subsequent treaties have been signed, which have amended the initial treaties of the EU, the Treaties of Rome are considered the first documents of the EU and the basis of its constitution. They are made up of the Treaty Establishing the European Economic Community and the Treaty Establishing the European Atomic Energy Community. Both were signed as the Treaties of Rome on March 25, 1957, and enacted on January 1, 1958.

In 2004, three years prior to the 50th anniversary of the European Union, a Constitution was written. The Official document is called the Treaty Establishing a Constitution for Europe and serves to unite and replace all pre-existing Treaties regarding the European Union.

The Treaty of Lisbon was signed on December 13, 2007, amending the original Constitution Treaty and, thereby, all prior EU Treaties. Also in 2007, the 50th anniversary of the signature of the Treaties of Rome was celebrated throughout Europe. A declaration at the Berlin celebration states "We are facing major challenges which do not stop at national borders. The European Union is our response to these challenges."

The EU acts much like a large nation in some respects, especially in its policies regarding economic improvement and environmental stewardship. Europe takes pride in its agriculture and agricultural products such as olive oils, meats, and cheeses. The EU recognizes that global warming and climate change would negatively impact this agriculture. Therefore, it has arranged conferences to discuss policies regarding agriculture, forests and deforestation, and sustainable economic growth that will protect the environment. For example, in March 2000, the EU held its Lisbon Summit, geared to stimulate the EU economy into becoming the leading global economy with sustainable economic growth. The resulting document was the Lisbon Strategy, including the Gothenburg Objectives, for Economic, Social, and Environmental Renewal. The strategy stresses environmental sustainability as a foundation for the economic growth and maintenance of Europe. The Lisbon Strategy is distinct from the Treaty of Lisbon, also sometimes called the Lisbon Treaty.

The large population of the European Union requires a large amount of energy, not much of which comes from the EU itself; changes are underway to improve the self-reliance of EU nations in terms of energy. For example, while approximately one-quarter of EU gas and oil is purchased from Russia, not a member nation, in 2005 a report from the European Commission (EC) entitled the Biomass Action Plan stated that at that time, the EU was obtaining 4 percent of its energy from biomass utilization, and that it had the potential to use up to 8 percent by the year 2010, if policies were supportive.

According to the Oak Ridge National Research Laboratory at Oak Ridge, Tennessee, in 1996, member countries of the European Union were among the top 20 carbon dioxide emitters in the world. These countries were Germany, the United Kingdom, France, Poland (which would join the EU in 2004), and Italy. The EU imports nearly one-half of its energy used.

This dependence on foreign oil puts the EU in a risky position, should another energy crisis occur. For this reason, as well as for environmental stewardship, the EU nations are actively investigating and incorporating alternate sources for energy. A goal value for energy from renewable sources is to generate 21 percent of EU electricity from renewable sources by 2010. As of early 2008, the only EU country that had a net export of energy was Denmark. Another energy goal of the EU is to open international, EU energy networks that would stabilize electricity prices across member nations and foster a more efficient use of power.

The EU has data on its website citing the amount of energy imported per member nation as well as the percentage of electricity generated that came from alternate, renewable sources for energy. These numbers, compiled by Eurostat, are for the year 2004.

Additionally, the website describes the 2003 Greenhouse Gas Emissions numbers, as well as target emissions for 2008–12. The target values are given as a percentage of their 1990 values. This percentage is because the Kyoto Protocol aims for each nation to reduce its greenhouse gas emissions to 8 percent lower than the 1990 emissions, by 2008–12. In order to make this goal feasible for the joint nations of the European Union, the EU has spread the numbers among each member nation, such that developing nations are allowed to increase their emissions in order to continue development while larger, more developed, and economically stable nations will reduce their emissions further.

The participating countries are those that were members of the EU prior to the year 2004; these countries are called the EU-15. The countries that joined in 2004 have individual reduction plans, and the countries of Cyprus, the United Kingdom, and Malta do not have target emissions values. The values for emissions in 2003 as well as the projected emissions for 2008–2012 (all as a percent of 1990 values) were compiled by the European Environment Agency, European Topic Center on Air and Climate Change.

Large numbers of cars and trucks and the ensuing traffic in the European Union add to global warming by emitting greenhouse gases. In order to curtail these emissions, the EU urges its citizens to use public transportation, and requests industries to use ships or trains to transport freight. In fact, trade between member EU nations totals approximately two-thirds of all EU trade. Additionally, one unified air-traffic control module for Europe is under consideration, to reduce air congestion.

Evaporation and Transpiration

EVAPORATION AND TRANSPIRATION are the two processes by which water is removed from the Earth's atmosphere. Because it can sometimes be difficult to ascertain which one is occurring, the term evapotranspiration is often used to describe the sum total of both processes. Evapotranspiration is an important part of the planet's hydrological cycle, and it is likely to change in a warming world.

Evaporation is the process of changing water from a liquid to a gaseous state. Water molecules are in motion, and if they generate enough speed and are going in the right direction, they essentially heat themselves to the equivalent of boiling, at which point, they have enough energy to escape the liquid state and pass into the atmosphere. Only a small percent of molecules will find themselves in these favorable conditions at any one point, so the overall rate of evaporation from any body of water is relatively low. Evaporation rates ebb and flow depending on local conditions. Bodies of water with a large surface area evaporate more than smaller bodies, as there are more water molecules near the surface. If the relative humidity is low, the evaporative rate is correspondingly higher. High temperatures also increase evaporation, as do high or sustained winds. In all, about 80 percent of evaporation comes from the Earth's oceans, with the remaining 20 percent coming from inland waterways and vegetation.

Transpiration is the evaporation of water from plants and trees. Approximately 90 percent of all water taken up by a plant is lost to transpiration. Generally, the ratio of transpiration is 200 to 1,000 kg. of water evaporates for every kg. of dry matter produced. One acre of corn will release 400,000 gallons of water into the atmosphere in a growing season, and a 49 ft. (15-m.) tall maple tree could lose 58 gallons (220 liters) of water per hour on an average summer's day.

Water evaporates through small openings in the leaf surface called stomata. These openings expand when light hits the surface of the plant, and close up at night. The stomata allow the leaf to expel oxygen and carbon dioxide. Transpiration helps a plant by pulling water up from the ground, and transporting minerals and fluids throughout the plant; the release of water also cools the plant.

Several forces act on a plant to increase transpiration. Unless the air around the plant is at 100 percent of relative humidity, the plant quickly begins to dry out and starts pulling moisture from the soil. Wind tends to enhance the effect by blowing humid air away from the plant. Sunlight warms up the leaves and opens the stomata; warm air temperatures create the same response. If the soil around the plant becomes too dry, the stomata close off to preserve as much moisture as possible, and the plant quickly begins to wilt.

The Earth's water budget is fixed and cyclical, and evapotranspiration is one of the processes by which water is exchanged between the surface and the atmosphere. The water vapor expelled by evaporation and transpiration forms clouds, which travel high into the atmosphere, cool, and produce rain, which then falls back to the surface, where the cycle begins anew. Some of the water that reaches the surface nourishes plant life, which transpires most of that water back into the atmosphere. Some of it sinks far enough into the soil to reach the water table, and recharges freshwater sources. The amount of water vapor in the atmosphere remains relatively constant at 12,900 cu. km., but each year, approximately 490,000 cu. km. of vapor cycles through the whole system.

Increased evapotranspiration is one of likely outcomes of global warming. Higher air temperature enhances both evaporation and transpiration. This will contribute to longer and more frequent periods of drought in the lower and middle latitudes in coming years.

For example, one computer model built in the 1990s estimated that by the end of the 21st century, summertime evapotranspiration in the American southwest could increase by 27 percent. The model found similar increases in 12 regions around the world. Between the growing human population in need of drinking water and the heightened probability of drought, the world's water deficit will probably increase in coming years.

Evaporation Feedbacks

THE INCREASE OF greenhouse gas concentrations in the Earth's atmosphere, above natural levels, is causing anthropogenic changes to Earth's climate. The temperature at the Earth's surface has shown a significant and rapid rise since the 1990s, compared to the past two millennia. It is challenge for scientists to attribute these known changes to specific mechanisms. Some of the complex feedback processes that add to these changes are not fully understood.

The energy balance, the distribution of energy in space (or Earth's atmosphere), and temporal energy variations characterize the Earth's climate system. The Earth's radiative energy balance is governed by the balance between solar radiation and absorption by the Earth and subsequent radiation from the Earth to outer space. The Earth absorbs solar shortwave radiation in the daytime, and emits thermal infrared or longwave radiation back to outer space to maintain the heat energy balance. However, this energy balance is more imbalanced recently, because of the many components of the Earth-atmosphere system, such as clouds or aerosols and other radiation scattering particles present in the atmosphere.

The National Aeronautics and Space Administration (NASA) CERES (Clouds and the Earth's Radiant Energy System) instrument on the Tropical Rainfall Measuring Mission (TRMM) and Terra satellite mission provide a new set of Earth radiation balance data. Along with these data and a 16-year record of the Earth Radiation Budget Satellite (ERBS), NASA has compiled the 22 years of accurate satellite observed broadband radiative fluxes, showing the huge energy imbalance or long-wave anomalies since 1995.

THE HYDROLOGIC CYCLE

The hydrologic cycle is part of this heat energy imbalance process. This feedback process complicates the global warming phenomena and involves water vapor, clouds, and aerosol particles. Evaporation is the basis of this important process. Water is evaporated by Sun, incorporated into clouds as water vapor, falls to the land and water bodies as rain, and enters water bodies to complete the cycle. Conversely, to make matters worse, water vapor acts as a prominent greenhouse gas as it is involved in an important climate feedback loop. Due to ascending evaporation from water bodies, the water vapor amount in the atmosphere increases.

The additional water vapor absorbs radiated thermal infrared energy that would otherwise escape from Earth's surface to outer space, and radiates the heat back to the Earth again. Thus, it makes the Earth's surface even warmer. This somber picture is further complicated by important interactions among water vapor, clouds, atmospheric motion, and radiation from both the Sun and the Earth.

Moreover, continuous increases of the Earth's surface temperature augments the sea or ocean surface temperature. Therefore, increased evaporation and higher annual rainfall amounts should occur. Computer simulation models found that a global warming of 7.2 degrees F (4 degrees C) is expected to increase global evaporation and precipitation by about 10 percent. Scientists found through models that the upper tropospheric water vapor amount will increase by 15 percent with each degree of atmospheric temperature rise, because of increased evaporation.

Another evaporation feedback mechanism involves the atmospheric wind-evaporation-convection feedback in the tropics. The feedback is shown to be very effective in channeling perturbations from one component of the climate system to other components, such as from evaporation to surface wind, and from atmospheric convective activity to evaporation. Through this feedback process, it is also observed that surface evaporation over tropical oceans is connected with cloud absorption of shortwave radiation. Diminished shortwave absorption by clouds causes excessive shortwave radiation at the Earth's surface, leading to excessive evaporation. As the loop continues, the Earth's surface gets warmer and warmer.

This same wind-evaporation-convection feedback in the water is also a concern. This is a huge contributor toward spatial variability of evaporation and precipitation on the Earth. Recent rises in the Earth's surface temperature may lead to a near-term collapse of the ocean's thermohaline circulation. Thermohaline circulation is a global ocean circulation pattern or convection mechanism. It distributes water and heats both vertically, through the water column, and horizontally across the globe. Due to this collapse of thermohaline circulation, warm surface waters move from the tropics to the North Atlantic and extra-warm water surfaces in the Pacific Ocean surface surrounding the equator.

Therefore, spatial variation in ocean temperature is observed. This spatial change in ocean surface temperature is changing usual wind direction, creating unusual evaporation rate, and subsequent spatial variability in rainfall. This pattern has been evident for the past two decades. Therefore, more precipitation is occurring in northern Europe, Canada, and northern Russia, but less to swathes of sub-Saharan Africa, southern India, and Southeast Asia. El Niño and La Niña are examples of the recently observed changed thermohaline circulation process. Scientists working specifically on polar warming amplification observation found that much stronger evaporation feedback leads to a final warming in low latitudes that is stronger in the atmosphere than at the surface.

Atmospheric water vapor or the evaporation feedback is supported by many studies and researchers concluded that this feedback process is positive, continually increasing the Earth's surface temperature. Scientists proved this observation with profound evidence using new satellite-generated water vapor data and concluded that the feedback is not overestimated in models. It is also observed that the global water vapor amount will increase by 7 percent with each degree of atmospheric temperature rise, thus complicating the global warming and climate change mechanism.

Evolution of the Atmosphere

EARTH'S ATMOSPHERE IS unique in the solar system: of all the heavenly bodies, Earth alone has an atmosphere capable of supporting life. An appreciation of this highly specialized nature of the contemporary atmosphere is vital to understanding its evolution. The atmosphere has not always been the way it is today, and the present atmosphere is almost certainly not directly related to Earth's primordial atmosphere. The contemporary atmosphere arose from thermal and geological processes occurring some time after Earth's formation, and its evolution to a life-supporting state is intimately linked to the evolution of life itself.

THE PRESENT ATMOSPHERE

The Earth's atmosphere is extraordinary; comparing the Earth to other planets in the Solar System illustrates just how extraordinary. The inner planets are often referred to as the terrestrial planets because they consist of rocky masses surrounded by gaseous atmospheres (with the exception of Mercury, whose atmosphere has long since been lost to space because of its proximity to the Sun). Venus and Mars both have substantial atmospheres and make excellent comparisons for the atmospheric evolution of Earth.

The atmospheres of Venus and Mars have evolved to consist primarily of carbon dioxide (CO_2), with some nitrogen and hardly any oxygen. Although Venus and Mars have important differences in their atmospheric chemistry, their atmospheres are essentially similar. Roughly speaking, both atmospheres consist of 95 percent CO_2 and 3 percent nitrogen. The amount of free oxygen on both planets is less than 1 percent. Earth's atmosphere may have evolved in a similar way: it was formed at roughly the same time from roughly the same material. Instead, Earth's atmosphere is markedly different. It contains hardly any CO_2 (although CO_2 plays a crucial role in regulating the planet's atmosphere and climate), consisting mainly of nitrogen, with a comparatively high oxygen content of around 21 percent. These differences result in an important chemical distinction between the atmospheres. The atmospheres of Venus and Mars are highly oxidized, containing a lot of chemically combined oxygen (mainly CO_2). In contrast, Earth's atmosphere is highly oxidizing, containing large amounts of free oxygen.

That one fifth of the Earth's atmosphere is comprised of oxygen is curious. Oxygen is a highly reactive gas, and the atmosphere and surface of the Earth contain many materials with which oxygen can react. Furthermore, the amount of time it would take for all the oxygen in the air to undergo these reactions is much shorter than the time the oxygen has been there. In short, there should not be anywhere near as much oxygen as there is in Earth's atmosphere; the atmosphere is a long way from chemical equilibrium.

From a chemical perspective, the Earth's atmosphere is like a bucket that, despite having a hole in the bottom, remains half full. It is impossible, unless water is flowing into the bucket at the same rate that it is leaking through the hole. In the same way, the composition of Earth's atmosphere is impossible, unless something is constantly adding oxygen to counteract the rate at which it is being lost through chemical reactions. The factor acting on the atmosphere to keep it in its state of chemical disequilibrium is life.

Biological activity on the planet uses energy from the Sun, during photosynthesis, to produce vast quantities of free oxygen. In the absence of life, there is no way for oxygen to have built up to the levels observed today. The evolution of the Earth's atmosphere has taken a very different path from that of Venus and Mars, and this path has led to an atmosphere that is outstanding among all the other known atmospheres. In this evolution, life has played a critical role.

FORMATION OF THE EARTH AND ATMOSPHERE

The evolution of the atmosphere begins 4–5 billion years ago with the formation of the Earth, but there is good evidence that the present atmosphere is not directly related to the Earth's original atmosphere by a continuous line of evolution.

As the Earth formed from the stellar nebula from which the Solar System was created, its rocky core acquired an atmosphere by gravitationally attracting nebula gases. This was the Earth's first, or primary, atmosphere. However, the hydrogen and helium thus trapped are likely to have escaped into space as the young Sun sprang to life, so these lightweight, primordial-nebula gases are not found in today's atmosphere. However, heavy, chemically-inert primordial gases such as neon and argon can be found. Being heavy, these gases would not have been lost to space, and their inertness would prevent them being removed from the atmosphere by chemical reactions. Therefore, their presence in the contemporary atmosphere would signal a direct line of descent from that primordial nebula to the present day atmosphere.

However, isotopic analysis shows that the neon and argon in today's atmosphere are predominantly the result of nuclear decay, rather than the remnants of that early atmosphere. It seems that at some stage soon after formation, the Earth lost its primordial atmosphere of nebula gases, and acquired a secondary atmosphere, from which the present atmosphere evolved.

The young Earth was a violent place, with radioactive decay, heavy meteor bombardment, and frictional and gravitational forces, all acting together to heat up the rocky mass of the planet. Much of the rock was molten. Under these conditions, gases were released from the planet's hot rocky core. These gases, predominantly nitrogen, CO_2, and water, had either been physically trapped within the solid Earth as it formed, or else were released by thermal decomposition of rocks and minerals. These are the gases that formed Earth's secondary atmosphere, the starting point for evolution towards the contemporary atmosphere.

In this earliest of epochs of geological history, the atmospheric CO_2 probably reacted again to form carbonate rocks, and the water eventually condensed to form the oceans. This left an atmosphere consisting predominantly of nitrogen. Trace amounts of free oxygen would be able to form in this atmosphere, as sunlight split (photolysed) molecules of water and CO_2 in the air. However, photolysis cannot result in particularly high concentrations of oxygen; a limit exists because the oxygen produced by photolysis absorbs light at the same frequency that CO_2 and water photolyse. As the concentration of oxygen builds up, it blocks the light needed to further increase its concentration. Without photosynthesis (that is, without a biological process for oxygen production), there is a natural limit on the amount of oxygen in the atmosphere. The exact concentration depends on CO_2 and water concentrations, and sunlight intensity, but no more than one-billionth of the present atmospheric level of oxygen existed before the emergence of life.

This limit to the pre-biological free oxygen concentration turns out to be critically important to the evolution of life, and, hence, to the evolution of the atmosphere. Had the atmosphere been appreciably oxidizing (containing significant levels of free oxygen), it would not have been possible for life's chemical precursors to accumulate on the planet's surface. The complex and fragile molecules of life, slowly forming and beginning to organize into proto-living systems in stagnant ponds and lakes, would have rapidly oxidized, and thus, destroyed, had the pre-biotic atmosphere been too oxidizing.

THE EMERGENCE OF LIFE AND OXYGEN

The emergence of life elegantly illustrates the intimacy of the connection between atmospheric evolution and biological evolution. The pre-biotic atmosphere, with its low concentration of free oxygen, not only provides favorable conditions for the development of biologically important molecules; the atmosphere also contains the chemicals from which life's precursor molecules themselves can be synthesized.

The famous Miller-Urey experiment in the 1950s demonstrated that a gas mixture containing methane, ammonia, hydrogen, and water subjected to simulated lightening discharges is capable of producing amino acids (essential biochemicals) within a very short time. Subsequent experiments have shown that gas mixtures more closely resembling the actual composition of the pre-biological atmosphere produce essential biomolecules under the influence of electrical discharges. Hence, laboratory experiments demonstrate that the atmospheric conditions on the early Earth were sufficient to give birth to the molecules of life.

It is unknown how life arose from this primordial mixture of chemicals, though plausible mechanisms can be postulated. There is certainly plenty of time in which rare events leading to unusually stable states could repeatedly occur; about a billion years separate Earth's formation and the dawn of life, sometime around four to five billion years ago.

The number of places on the planet's surface where life could form, however, must have been somewhat limited. The organic molecules needed for living systems are susceptible to destruction in the presence of free oxygen, and sunlight is a catalyst for this oxidation. Even though the concentration of oxygen in the early atmosphere was low, its presence would have confined the initial emergence of life to the water. Water acts as a filter, preventing the damaging ultraviolet wavelengths of light penetrating much below the surface. However, the oceans would have been unsuitable environments for early life because the turbulent vertical mixing of ocean waters would bring biomolecules and early organisms to the surface where sunlight could initiate oxidation. The first living things were, therefore, confined to the sub-surface waters of stagnant pools.

These early life forms were different from the majority of living things alive today; there was so little oxygen available that they evolved to survive without it. Relatives still survive on Earth today as the anaerobic bacteria that live in stagnant water. These early bacteria were photosynthetic, using visible wavelengths of light to make food and biomolecules from CO_2 and water. An important by-product of this activity of the first living things was oxygen.

Over the next billion years or so, these simple cells carried on a chain of life that steadily increased the oxygen concentration of the atmosphere, from its low point of less than one-billionth of today's value, to somewhere around one percent of the present concentration.

This increasing oxygen concentration was an important development, for with it the came an increase in the complexity of biochemistry available to living systems. Most importantly, the development of structural proteins that can be formed only in the presence of oxygen allowed the evolution of the cell nucleus.

With this change, biological complexity could increase rapidly by means of sexual reproduction; genetic material could be shared among members of a species. The concomitant increase in variability gave rise to simple animals and plants, as well as to more varied bacteria. Aerobic respiration became dominant, as it is today, and life was able to explore many more configurations and exist in many more niches.

All the while, photosynthesis was generating more and more free oxygen.

An important atmospheric change was occurring alongside all this biological activity; the action of sunlight on the increasing amount of oxygen in the air was generating ever-higher concentrations of ozone. As the ozone concentration increased, the intensity of damaging ultraviolet light at the surface of the waters was rapidly decreasing. Then, as now, the ozone layer served to protect life from harmful radiation from the Sun. The depth of water required to screen the Sun began to be reduced, and life could finally enter the open ocean.

This led to an explosion in the numbers of living creatures on the Earth, as life expanded into the newly available space. More life meant more photosynthesis and rapid increases in the atmospheric oxygen concentration. With increasing availability of free oxygen, even more complex biomolecules became possible, and multicellular life arose. Fossil evidence of jellyfish-like creatures from 670 million years ago gives valuable evidence of the oxygen concentration. These creatures had no lungs, and must have relied upon the ability of oxygen to diffuse across their skin. It is estimated that to support their existence, the atmospheric oxygen concentration must have been around seven percent of its present value at that time.

About 550 million years ago, fossils with strong and impervious exoskeletons suggest that the oxygen concentration had risen to 10 percent of present values (around two percent of total atmospheric composition), and the ozone concentration was approaching levels that would enable life to exist on the land, unmolested by ultraviolet radiation. Land-based life emerges in the fossil record at 420 million years ago, and by 380 million years ago the complexity of land-based life has multiplied remarkably leading to the appearance of the Carboniferous period's Great Forests (from which fossil fuels derive). The rapidly increasing oxygen and ozone levels allow ever more complex land-based life, and the forests soon find themselves home to amphibious animals, mammals, and eventually the flowering plants. With this blossoming of life, the atmosphere finally reaches present oxygen and ozone levels by 300 million years ago.

Without biological activity, the Earth's state of chemical disequilibrium, including oxygen levels, would be impossible.

RECENT CHANGES IN THE ATMOSPHERE

The evolution of the atmosphere has been intimately linked to the development of life, and there is a constant feedback between the atmosphere and the biosphere. Both CO_2 and water are greenhouse gases, and have played an important role in regulating the Earth's surface temperature during the atmosphere's evolution. Water vapor is by far the more abundant, with an average (though highly variable) concentration of one percent by volume. The equilibrium between liquid water and water vapor is crucial in controlling Earth's temperature. On Venus, the high temperature prevented liquid water from forming, which is thought to have led to that planet's runaway greenhouse effect.

Current ice-core data for atmospheric CO_2 concentration goes back 650,000 years. These data show that during this time the present ecosystem of land mammals and flowering plants have never experienced CO_2 concentrations above 300 ppmv (parts per million by volume) until very recent history. The concentration of CO_2 has risen rapidly in the last 300 years, since the beginning of the Industrial Revolution and the dramatic increase in fossil fuel use. Isotopic analysis shows that the rise in CO_2 concentration to its present value of more than 370 ppmv is largely due to human activities, chiefly fossil fuel burning.

The widely held scientific consensus is that this rise will lead to significant perturbations in the surface temperature and large scale global climate change, significantly altering the biosphere-atmosphere feedbacks. The unprecedented release of fossil carbon laid down in geological deposits during the life of the ancient Carboniferous Great Forests is perhaps the unfolding storyline in the atmosphere's continuing evolution.

FEEM (Italy)

THE FONDAZIONE ENI Enrico Mattei (FEEM) is a nonprofit, nonpartisan institute in Italy. The chief focus of FEEM is research in sustainable development. In July 1989, the president of Italy recognized FEEM as a research institution; FEEM has been operating since 1990 as a self-described "global network of environmental economists." There are four principle criteria that guide the research endeavors of FEEM: analysis of relevant fields of research, a focus on legitimate "real-world" issues in sustainability, utilization of multi-disciplinary and collaborative research schemes, and development and support of international networks for research and sharing of knowledge and information. FEEM has seven programs of research: Climate Change Modeling and Policy, Corporate Social Responsibility and Sustainable Management, International Energy Markets, Knowledge Technology and Human Capital, Natural Resources Management, Privatization Regulation Corporate Governance, and Sustainability Indicators and Environmental Evaluation.

FEEM scientists from Italy and abroad carry out research. Italian and international researchers can work at FEEM through fellowship options. One such international fellowship is the Marie Curie Individual Fellowship, for scientists with research experience outside of Italy. Italian scientists can apply directly for a FEEM fellowship. Scientists not fitting qualifications for these two fellowships can still work at FEEM. Culture Factories, run by the foundation, are locations for courses free to its registered users. Users are typically university students. The courses cover topics such as computer programming, graphic design, website design, preparation for the European Computer License exam, and languages.

FEEM has offices in several Italian cities, and its main headquarters are in Milan, with other locations in Genoa, Rome, Turin, and Venice. FEEM's Milan office coordinates and manages most of the research, as well as houses the administration. Additionally, the majority of FEEM research is conducted in Milan. The Genoa office opened in April 1998, as did the Culture Factory. Major activities of the Genoa office include training and research in the programs of Corporate Social Responsibility and Sustainable Management, and Natural Resource Management. The Rome office opened in 2000, and, houses a Culture Factory. FEEM opened its Turin office in January of 1998, which housed the first FEEM Culture Factory. This office carries out research in the program of Knowledge Technology and Human Capital. Finally, the Venice office has been in operation since 1996.

Here, research is conducted for the programs in Climate Change Modeling and Policy, Natural Resources Management, and Sustainability Indicators and Environmental Evaluation. This office opened its Culture Factory in 1999.

FEEM can also act as a consultant to public and private sectors with questions of economics and environmental impact. FEEM collaborates with institutions such as the Abdus Salam International Centre for Theoretical Physics, the European Union, the United Nations including the United Nations Commission of Sustainable Development, the World Bank, and other European, U.S., and global universities and institutions. The foundation is managed by a board of directors, which is overseen by a chairperson, an Audit Committee, a Scientific Advisory Board, executive director, research director, and coordinators for administration, applied research, the Culture Factory Project, international projects and relations, and publications. In 2006, FEEM published a series of books called the Fondazione Eni Enrico Mattei Series on Economics, the Environment, and Sustainable Development.

Fiji

A NUMBER OF islands in the Pacific, Fiji has a land area of 7,056 sq. mi. (18,274 sq. km.), with a population of 853,445 (2006 est., and a population density of 119 people per sq. mi. (46 people per sq. km.). Some 10 percent of the country's land is arable, with another 10 percent used for pasture, mainly of cattle and goats. About 65 percent of the land is forested, with a significant timber industry, leading to rapid deforestation. Fiji has a relatively low per capita rate of carbon dioxide emissions, at 1.1 metric tons per person in 1990, and remaining relatively stable, rising slowly to 1.3 metric tons in 2003. Although there is extensive use of electricity throughout the country, 82 percent come from hydropower and only 18 percent from fossil fuels. This has the result that most carbon dioxide emissions do not come from electricity generation (solid fuels account for only 7 percent of these emissions), 87 percent of emissions come from liquid fuels, mainly from automobiles and household generators, with 6 percent from the manufacture of cement.

Fiji faces major problems from global warming and climate change, with the rising sea level threatening the flooding of many parts of the country. Some reports from around the islands show that the average shoreline has been receding at 6 in. (0.15 m.) per year since 1920. The most dramatic effects of global warming have been seen on the island of Gau, in the Lomaiviti Group, to the east of the main island Viti Levu, which has lost 656 ft. (200 m.) of coast, with threats to Beachcomber Island and Treasure Island in the Mamanuca Group to the west of Viti Levu; with Lelevia and Caqelai also likely to be affected in the next 25 years. Other places likely to be affected are Tokou village on Ovalau Island, and even some villages on low-lying land on Viti Levu, such as Culanuku and Toguvu.

Another problem has been the rise in the amount of coral reef bleaching, especially during the summer months, mainly caused by the rise in water temperature, which is expected to cause a decline in marine life living on coral reefs. There has also been a noticeable rise in tropical cyclones, from three during the 1940s, to 15 in the 1990s. The Fijian government ratified the Vienna Convention in 1989, and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, ratifying that in 1993. They signed the Kyoto Protocol to the UN Framework Convention on Climate Change on September 17, 1998, ratifying it the same day; it took effect on February 16, 2005.

SEE ALSO: Hurricanes and Typhoons; Oceanic Changes; Sea Level, Rising.

The shoreline in Fiji may be receding at a rate of six inches per year since 1920. The rising sea level is also a threat.

Finland

HISTORICALLY, FINLAND WAS a poor country, but in the post-World War II era, it transformed itself. Finland in the 21st century has a highly developed industrial economy and a standard of living that places it among the 10 richest nations in the European Union. More sparsely populated than most European nations, modern Finland must still confront the environmental problems that trouble all industrialized countries. Severe winters and long distances separating parts of the population increase the need for fuel. These needs added to the heavy demands of energy-intensive industries make Finland's per capita energy consumption among the world's highest.

Since the 1970s, the Finnish government has been engaged in conservation, using state-owned enterprises and price controls to encourage responsible consumption. These measures, coupled with exploiting the abundant peat lands as a fuel source, and imposing high standards for energy efficiency in home construction reduced energy use for heating by more than 30 percent within 10 years. However, Finland's need for energy continued to expand, as did the problems from dependence on fossil fuels. As a signatory to the Kyoto Protocol, the nation is committed to the reduction of greenhouse gases. As a member of the Arctic Council, Finland recognizes the greater urgency experienced by nations whose Arctic areas are face warming at twice the rate of the rest of the Earth.

Global warming in the 20th century increased temperatures in Finland by approximately 1.3 degrees F (0.7 degrees C). With further increases, Finland could experience a dramatic increase in annual precipitation. The climate changes could decrease energy demands, as warmer winters would require less fuel, and the increased rainfall could lead to increased productivity in agriculture and timber. On the other hand, changes will result in heavier flooding, which, in turn, will speed coastal erosion and pose additional threats to biodiversity. In 2007, species of butterflies and fish typically seen in warmer climes had already made their way to Finland, and environmentalists expressed concern about the effects of melting permafrost on reindeer, a crucial ingredient in the economy and the culture of the Sámi people of northern Finland.

From 2000 through 2005, the World Economic forum ranked Finland in the top position in the

Environmental Sustainability Index, and the 2006 Yale University study accorded Finland the third spot in its Environmental Performance Index. Finland has benefited from is heavily forested land (72 percent of the country) in decreasing its CO_2 levels. The country also ranks high in its use of renewable energy. Because many Finns use wood from their own forests as a secondary source of heat, and because the pulp and paper business burns its byproducts, about 20 percent of Finland's energy consumption is wood-based. Finland also uses nuclear power to cut its dependence on imported energy. The $5 billion, 1600-watt Olkiluoto 3, scheduled to begin operation in 2011, is expected to provide 15 percent of Finland's electricity. In 2006, Finland reported that greenhouse gas emissions for 2005 were below the levels targeted by the Kyoto Protocol.

Floods

A FLOOD IS the intrusion of water into normally dry land. While floods are a natural part of the ecological cycle and have some benefits for the health of the biosphere as a whole, flooding has always been one of the most devastating types of natural disasters for humans, responsible for thousands of deaths and billions of dollars in property damage each year. Climate change is expected to increase the risk of flooding for people around the world, both by raising global sea levels and increasing severe inland flooding events.

FLASH FLOODING

Flash flooding is most commonly caused by heavy rainfall over a short period of time, from a tropical system or an unusually heavy thunderstorm event. Less common causes include dam and levee breeches or the release of ice jams. Flash floods come on quickly and with little warning, developing in less than six hours from the initial rain or water event. They can move with great speed and strength, uprooting trees, picking up large boulders, destroying bridges, roads, and homes in a matter of moments. Flash flooding is responsible for at least 80 percent of all weather-related deaths in the United States each year, mostly due to people becoming trapped in automobiles. As little as 2 ft. (0.6 m.) of water can lift and move a full-sized commercial vehicle.

Although flash flooding is commonly associated with canyons or narrow valleys, where geography dictates the flow of excess water, or arid regions where the ground is not able to rapidly absorb large amounts of rainfall; urban areas are often affected by the phenomena. Buildings and impervious surfaces such as roadways and parking lots collect tremendous amounts of rainfall and divert it into storm drains, which can quickly be overwhelmed, sending the overflow into communities that are often unprepared for the threat.

Globally, flash floods are responsible for an average of 5,000 deaths and millions of dollars of property damage each year. Many regions do not have the forecasting or notification technology to alert vulnerable populations to oncoming flood events. Since 2006, the World Meteorological Organization (WMO) has been working to implement a system known as the Flash Flood Guidance Center with Global Coverage, which would give developing countries greater ability to mitigate loss of life in flash-flooding events.

INLAND AND RIVERINE FLOODING

Flooding within a watershed, or riverine flooding, is another common form of inland flooding. Like flash flooding, riverine flooding is generally caused by rainfall or runoff that is too heavy to be absorbed into the watershed, sending the water over the bounds of the river or stream's banks and inundating nearby flood plains. Unlike flash floods, they build slowly, over a period of many hours or days, and last for a longer period of time, often more than a week, and sometimes over a month. Flooding along the Mississippi River Valley in 1993 lasted for 45 days, with some areas still partially flooded for 183 days; a flood event in Bangladesh in 1998 lasted for 68 days before finally receding.

Riverine flooding tends not to be as deadly as flash flooding, but causes great damage to property and agricultural lands, as was seen in the Mississippi Valley floods of 1993. High water displaced 70,000 people in nine states, damaged 50,000 homes, destroyed 12,000 acres of farmland, and caused an estimated $15 billion in losses.

COASTAL FLOODING AND STORM SURGE

By 2006, an estimated 44 percent of the world's 6.5 billion inhabitants lived within 93.2 mi. (150 km.) of a seacoast. Eight of the world's 10 largest cities are coastal, including: New York, Tokyo, Shanghai, Kolkota, Sao Paulo, and Mexico City. This puts tens of millions of people at risk from coastal flooding and storm surge, with more people gravitating toward the oceans each year. As the Boxing Day Tsunami of 2004 illustrated, the impact of coastal flooding can be devastating: over 220,000 people around the Indian Ocean were killed in a single day.

A tsunami is a series of waves created by the displacement of water and is generally the result of geological events such as an undersea earthquake, a volcanic eruption, or a massive landslide. However, meteorological events are a much more common threat to coastal communities.

Coastal flooding occurs when the sea level rises above the normal tides, usually in response to an offshore storm or low-pressure system, but occasionally from significant runoff from nearby land. In its mildest forms, coastal flooding causes beach erosion, while moderate to major flooding can wash out roads and structures close to the shoreline. In coastal cities like New York, heavy coastal flooding can cause havoc by inundating the subway system and underground utilities, freezing transportation, and disrupting the power grid.

Storm surge is a phenomena tied to low-pressure systems such as tropical cyclones or hurricanes. The force of the winds inside a hurricane pushes the water up in front of it. This piling effect combines with normal tides, sometime rasing the mean water level by more than 15 ft. (4.5 m.). Wind and wave action turn this high water into a destructive force once they make landfall: 90 percent of all human deaths in hurricanes are cause by storm surge.

IMPORTANCE IN ECOSYSTEM

Flooding has long been recognized as vital part of the ecosystem. Floodwaters often carry sediment and nutrients along their path, nourishing the land wherever they are deposited. This builds valuable habitats for a variety of wildlife and vegetation, and rich alluvial soil for agricultural use. The earliest human civilizations arose on the flood plains of the Tirgis and Euphrates Rivers of Mesopotamia. For centuries, the regular flooding of the Nile River between July and September of each year deposited soils in Egypt's narrow Nile River Delta, allowing the cultivation of crops that made the growth of Egyptian civilization possible.

Worldwide, riverine flood plains cover more than 772,204 sq. mi. (2 million sq. km.) of land and coastal flood plains cover much more land. Most are considered environmentally threatened; in the United States and Europe, almost 90 percent of riverine flood plains are under cultivation, making them, in the words of one researcher, "functionally extinct." One of the main reasons for the threat is the prevalence of flood controls such as dams, levees, impoundments, and flood gates, which protect human life and property, but often destroy natural flood cycles.

HUMAN IMPACT

The desire to prevent flooding is understandable, as floods are among the deadliest of natural disasters for humans. Between 1900 and 2004, an estimated 6.8 million people were killed by flood events. About 98 percent of these deaths occurred in Asia.

Floods affect human health and safety in several different ways. A rapid rise of water, from events such as flash flooding or a tsunami, can cause immediate death from drowning or injury. As floodwaters recede, injuries are joined by a greater risk of disease from contamination of drinking water tainted by raw sewage or pollutants. Cholera and other diarrheal diseases are common in the days and weeks after floods. Standing floodwaters can become breeding grounds for vector-borne diseases like malaria; displaced rodent and reptile populations can also cause illness and injury. Critical infrastructure such as hospitals, municipal water, sanitation, and food distribution systems are often destroyed in major flood events, leaving the displaced population at even greater risk.

CLIMATE CHANGE AND SEA LEVEL RISE

Predictions regarding sea-level rise are one of the most controversial aspects in climate science, with estimates ranging from a few inches to several meters. Dramatic images of the Statute of Liberty barely peeking above the waterline aside, there is little doubt that there will be a rise in the overall sea level over the coming century.

Water will expand as ocean temperatures rise, and the melting of the polar ice caps will contribute to the overall volume of water. But the rise is not uniform across all oceans, and the mechanisms that contribute to the rise are not yet clearly understood, casting doubt on all projections.

Sea levels have climbed 400 ft. (130 m.) in the past 18,000 years. For 3,000 years, the rate of that rise was .004–.008 in. (0.1–0.2 mm.) per year. Beginning in 1900, it climbed to .04–.08 in. (1–2 mm.) per year, and in 1993 accelerated to approximately .12 in. (3 mm.) per year (although it is not yet clear if this is a cyclical variance or part of an overall trend). Were these rates to hold steady, this would correspond to a rise of 11–13 in. (280–340 mm.) by 2100. However, some climate models, particularly those who look at the partial or complete melting of the Greenland Ice Sheet, indicate a more dramatic rise of about 3 ft. (1 m.), a rise that would, among other things, swamp most of the cities along the United States' densely populated eastern seaboard.

Rising water levels put the 634 million people who live within 30 ft. (9 m.) of sea level at risk for higher storm surges, coastal erosion, loss of agricultural and aquacultural land, loss of tourism, and a decline in soil and groundwater quality. Several small islands in the Pacific and Indian oceans, most notably the island nation of Tuvalu and the Maldives, are already seeing anomalous flooding and higher tides. Residents of these islands may be the first in a long line of "climate refugees" to come.

Natual flooding is an important to the ecosystem, but is threatened by dams, levees, impoundments, and flood gates.

CLIMATE CHANGE AND FLOODING

Inland flooding will also be impacted by climate change. Rainfall patterns are expected to change over the next century, with climate models predicting more heavy-rain events, separated by prolonged periods of dry weather. Much of this will be due to the heating of the atmosphere: warmer air holds more water, raising the potential for a quick release of a large volume of water.

Air pollution will also play a role, as more particulates in the atmosphere gives this increased amount of water vapor more condensation nuclei, or seeds, around which they can coalesce. This will increase the incidence of flash flooding and landslides in many areas. So-called "100-year flood plains," literally parts of a flood plain that are only expected to flood once in a century, could expect to see flooding three to six times in a century.

Developing countries will see increased risk of loss of life in severe flood events. In summer 2007, the most intense floods seen in generations hit more than 20 African nations. Over 1.5 million people were displaced and at least 300 killed. Coming at the height of the growing season, the flooding destroyed domestic and export crops, and will exacerbate the region's already severe food insecurity crisis. Meanwhile, more developed nations are planning extensive and costly new flood control systems and sea defenses to help mitigate future flooding.

Florida

THE FOURTH MOST heavily populated state, Florida is also the top travel destination in the world. In 2006, nearly one million visitors, domestic and international, poured $83 million into the state's economy, according to Visit Florida Research. Nearly $4 billion went back into state coffers as taxes. Agriculture ranks second only to tourism in Florida's economy. The state produces 75 percent of the oranges grown in the United States, and 40 percent of the world's orange juice. Both as the state with the nation's second longest coastline, more than 8,400 mi. (13,516 km.), and as the largest farm-income state in the southeastern United States, Florida is particularly vulnerable to the impact of global warming. Like most coastal states, Florida has already felt the effects of global warming, and experts warn of more severe consequences as climate changes accelerate. Florida has responded with a multitude of strategies designed to address all facets of the problem.

A 2001 study conducted by scientists at Florida's universities noted signs of coastal erosion, dying coral reefs, saltwater intrusion into inland freshwater aquifers, and increased air and sea temperatures, all generally-accepted signs of global warming. Predictions were dire. If sea levels rise the estimated 8–30 in. (20–76 cm.) over the next 100 years, seawater could advance inland as much as 400 ft. (122 m.). Not only would such an advance devastate the beaches that help to draw millions of tourists to the state, but homes and infrastructure would also be at risk, a critical concern in a state where 77 percent of the population lives in coastal cities. Salinity could become another major concern as freshwater supplies become contaminated, and potability of water supplies for the state's cities and orchards are threatened. Saltwater could also encroach on coastal wetlands, posing a particular threat to the Everglades and the more than 60 threatened or endangered species that inhabit the area, including the wood stork, the American crocodile, the West Indian manatee, and the Florida panther (with an estimated wild population of only 30 to 50 animals).

Although Floridians and their visitors depend heavily upon air conditioners and enjoy more than a million residential swimming pools that require pool pumps, Florida ranks 46th among the 50 states in total energy consumption per capita. Greenhouse gas emissions reveal a less positive picture. In 2001, 3.92 metric tons of greenhouse gases per one million Florida residents were released into the atmosphere, making the state the 13th highest emitter. Carbon dioxide accounted for around 92 percent of Florida's emissions in 2003. Between 1990 and 2003, the state's CO_2 emissions from fossil fuel combustion increased by 30 percent. The utility sector accounts for 50 percent of the emissions, and transportation for another 41 percent.

Florida has a long history of conservation. The state is the site of the nation's first wildlife refuge (Pelican Island) and the first eastern National Forest (Ocala National Forest). Concerted efforts to protect the ecosystem of the Everglades have been ongoing for nearly half a century. Since 1999, Florida's governors have pursued the most ambitious land acquisition program in the nation, acquiring nearly 2.5 million acres at the cost of more than $5 billion. The Florida Department of Environmental Protection, the state agency assigned the responsibility of managing Florida's natural resources and enforcing environmental laws since its creation in the mid-1970s, is engaged, with the South Florida Water Management District, in implementing the 30-year, $10.5 billion state-federal partnership to restore America's Everglades, the largest environmental restoration project in the history of the world.

Despite this impressive record in land management, however, Florida had been tentative in addressing global warming. Former Governor Jeb Bush signed the Florida Renewable Energy Technologies and Energy Efficiency Act in June 2006, and created the Energy Commission, a group charged with advising the state legislature on energy policies. The state followed this step by inventorying greenhouse gases, experimenting with net metering (a program to measure a customer's total electric consumption against that customer's total on-site electric production), encouraging electric power customers to use renewable sources, and adopting more environmentally-friendly building codes.

The most far-ranging action came in July 2007, when Governor Charlie Crist signed three executive orders in a single day that mandated changes in Florida's actions relating to climate change. The first order set reduction targets for greenhouse gas emission by state agencies of 10 percent below current levels by 2012, 25 percent below by 2017, and 40 percent below by 2025. It also adopted the Leadership in Energy and Environmental Design (LEED) Green Building Rating System for all state and state-funded buildings and required state vehicles to use ethanol and biofuels when these fuels were available. The second order set statewide greenhouse gas emissions targets of reaching 2000 emission levels by 2017, 1990 levels by 2025, and 80 percent below 1990 levels by 2050. Tied to these targets is the adoption of the California tailpipe emissions standards.

Additional changes included in the order are revisions in the Florida Energy Code for Building Construction to make new construction more energy efficient, a requirement that utilities produce a minimum of 20 percent of their electricity from renewable sources, and the authorization of statewide net metering. The final order created the Governor's Action Team on Energy and Climate Change, a 21-member panel of representatives from government, business, academia, and environmental groups, and charged them with recommending ways to achieve the ambitious new targets. The first phase of the group's responsibilities was to be completed before December 1, 2007. Governor Crist also signed agreements with Germany and the United Kingdom for mutual discussion of ways to reduce greenhouse gas emissions and to extend the ideas of the Kyoto Protocol.

Auburn University

Florida International University

THE UNIVERSITY IS one of the 11 public universities that make up the Florida State University System and is located in the city of Miami. The bill providing for the establishment of Florida International University (FIU) was signed into law in 1965. In 1969, the country's youngest university president at that time, Charles E Perry, took charge at 31 years of age. The university accepted its first 5,667 students in September 1972. About 38,000 students are currently enrolled in over 280 majors. FIU has 10 academic colleges including South Florida's first public College of Medicine. The School of Hospitality is ranked among the best in the country, catering to Florida's top industry, tourism. The university is home to the National Hurricane Center. FIU is at the forefront of research on hurricane damage mitigation and the management of South Florida's unique wetlands.

The city of Miami, also known as the gateway to South America, is home to a large population of Spanish-speaking immigrants and has seen tremendous growth in housing to accommodate this influx of people. High rates of population growth and housing development in hurricane vulnerable states, such as Florida, mean increasing risk to human life and property. One of the first major storms to be recorded and measured in Florida was the Great Miami Hurricane, which swept over the center of the city in September 1926, as a Category 4 storm on the Saffir-Simpson scale, damaging every building in the downtown area and causing many deaths. On August 24, 1992, hurricane Andrew powered across the southern tip of mainland Florida as a Category 4 storm with even stronger winds gusts, and left behind over $20 billion in wind and water damage. On August 25, 2005, hurricane Katrina passed over Miami as a Category 1 storm before it gathered strength and brought devastation to New Orleans.

As part of an effort to protect the millions of dollars invested in research programs at universities, the federal government set up the Disaster Resistant University (DRU) program. In 2007, FIU became the first public university in Florida to become DRU-certified. Under this program, the Federal Emergency Management Agency has responsibility for reviewing and approving the DRU certification. When a major storm requires the evacuation of people from locations vulnerable to wind damage, storm-surge, or flooding, the university is one of the designated hurricane shelters for residents of Miami-Dade County. Also, when a Category 3 or higher hurricane threatens the Florida Keys, FIU is the officially designated shelter for people seeking sanctuary from the approaching storm.

The steady increase in societal and economic risks associated with storm events comes at a time when researchers in the United States have linked the increasing number of north Atlantic hurricanes to climate change. In 2007, the State of Florida took a step in advancing its climate research capabilities and ability to significantly reduce hurricane damage by awarding $18 million for hurricane research, including $15 million for the construction of the International Hurricane Research Center (IHRC) located at FIU. The IHRC houses a machine called the Wall of Wind powered by race car engines and capable of simulating Category 4 hurricane winds and rain, to create and test hurricane-resistant construction techniques and materials in order to improve the safety of residences and businesses.

The Florida Hurricane Alliance (FHA), coordinated by the IHRC, is a collaboration of engineers, meteorologists, biologists, epidemiologists, and others from universities across Florida. The FHA focuses on hurricane-related loss reduction by conducting research, such as studies on the effects of storm-surge along Florida's long and highly-developed coastline. IHR scientists at FIU's Laboratory for Coastal Research measure changes in shoreline and beaches in response to short-term events such as hurricanes and also over longer periods of time. At other FIU laboratories, satellite images are combined with computer animation to create simulations and interactive visuals for training and outreach. Research is also being done to develop energy-efficient equipment and solar energy powered buildings. With the price of weather and storm-related events on the increase, researchers are modeling insurance costs under different scenarios of damage, finding ways to providing incentives for people of protect their homes, and developing new wind-resistant structures for homes and businesses.

The National Hurricane Center (NHC), located on the campus of this university, is one of nine units that make up the National Centers for Environmental Prediction. The NHC is the main institution capable of analyzing and coordinating complex hazardous weather information and producing tropical cyclone forecasts for 24 countries in the Americas and the Caribbean. NHC collaborates with FIU and many other universities in activities such as the Joint Hurricane Test Bed, a multi-faceted effort to improve and expedite tropical cyclone forecasts. The mission of the NHC is to provide the best forecasts possible that will save human lives and property. In the event of a major storm, NHC's weather forecast bulletins help administrators and politicians reach important decisions that affect millions of people around the country.

The university is only 25 mi. (40 km.) from the Everglades National Park, a United Nations Educational, Scientific and Cultural Organization (UNESCO) World Heritage Site, International Biosphere Reserve, and a Wetland of International Importance. FIU is also a short drive from the open waters of the Florida Bay, the Biscayne National Park, and White Water Bay. The university is suitably positioned for conservation and management studies in marine and freshwater habitats. FIU's new program in Marine Biology seeks to take advantage of this unique environment by offering courses to university and advanced high-school students. Also at FIU, the Southeast Environmental Research Center (SERC) was established in 1993, to conduct ecological studies within South Florida's wetland environments threatened by urbanization, water diversion, and agricultural practices. Funded by the National Park Service, U.S. Environmental Protection Agency, South Florida Water Management District, National Science Foundation, among others, SERC's scientists work throughout the region using state-of-the-art laboratories and equipment to monitor the state of marine and freshwater ecosystems.

Rahul J. Shrivastava
Florida International University

Florida State University

LOCATED IN TALLAHASSEE, in the southern part of the state, Florida State University (FSU) has been involved in global warming and climate change research since the early 1960s. In conjunction with the geological sciences division of FSU, the Office of Polar Programs of the National Science Foundation established the Antarctic Marine Geology Research Facility (AMGRF) to serve as a curatorial and research center. The AMGRF was originally planned as a resource for analyzing deposits from the Antarctic continental shelf that had been collected by U.S. Coast Guard icebreakers as part of early deep freeze expeditions under the auspices of the U.S. Navy Hydrographic Office.

Today, the AMGRF is home to one of the largest collections of marine sediment cores in the entire world, and is the only American repository for Antarctic marine sediments, containing more than 12.4 mi. (20,000 m.) of deep-sea core sediment and more than 5,000 kg. of dredge, trawl, and grab samples. Additionally, AMGRF provides access to approximately 1.7 mi. (3,000 m.) of rotary-cored geological material obtained by Antarctic drilling programs. Ongoing projects include the Cape Roberts Project, a cooperative study of paleoenvironmental changes in the Antarctic involving the United States, Australia, Germany, Italy, the Netherlands, New Zealand, and the United Kingdom; Shaldril, a consortium of American scientists engaged in ship-based diamond coring along the continental margin of Antarctica; and Antarctic Geological Drilling (ANDRILL), a multi-national drilling project composed of scientists from the United States, Germany, Italy, New Zealand, and the United Kingdom that seeks to obtain stratigraphic records of historical paleoenvironmental changes in Antarctica.

In spring 2007, scientists at AMGRF hosted a multinational workshop to tell key researchers about mounting evidence on the connection between changes to Antarctic ice and global warming. Attendees at the conference included scientists involved in ANDRILL who were responsible for removing the core, and scientists, students, drillers, and educatiors from the United States, Germany, Italy, and New Zealand. During the event, scientists were able to study a new core that had been obtained by drilling 4,214 ft. (1,284 m.) below the sea floor located beneath the Antarctica's Ross Ice Shelf, which is the largest floating ice body anywhere in the world. The new core contained sediments dating as far back as 10 million years, offering evidence that the shelf had been engaged in an advancing and retreating cycle for the past 5 million years in response to climate changes. The Ross Ice Shelf is believed to have broken off from the larger West Antarctic Ice Sheet, which is predicted will collapse totally as a result of global warming. If such an event occurs, sea levels could rise as much as 20 ft. (6 m.), creating a worldwide catastrophe.

FSU is home to the Center for Ocean-Atmospheric Prediction Studies (COAPS), which conducts research into agricultural forecasting, air-sea interaction, ocean and coupled air-sea modeling, climate change and prediction, climate variability, and statistical studies. COAPS is also involved in predicting the social and economic consequences that arise from variations in ocean-atmospheric conditions. Funding for the COAPS program comes from a number of national government agencies, and working grants, annually total approximately $3 million. COAPS researchers are engaged in cooperative efforts with the National Oceanic and Atmospheric Administration (NOAA) Applied Research Center, the Research Vessel Data Center, the SAMOS Initiative, the Florida Climate Center, the Southeast Climate Consortium, and the HYCOM Consortium.

A number of studies that are underway at FSU have great potential for identifying the effects and consequences of global warming and climate change. Since 2006, researchers at Florida State University have been involved with the NOAA cooperative, created to study the dynamics of ecosystems within the Gulf of Mexico. Through the auspices of the newly-established Northern Gulf Institute, FSU scientists are working with those from Mississippi State University, the University of Southern Mississippi, Louisiana State University, and the Alabama Dauphin Island Sea Lab to conduct research on coastal hazards, climate change, water quality, ecosystem management, coastal wetlands, and pollution.

Also in 2006, the National Oceanic and Atmospheric Administration awarded a five-year, $6.2 million grant to FSU scientists at COAPS to develop a hurricane-prediction model that has the potential to mitigate the effects of major storms on lives and property. This prediction tool may be critical in light of the mounting evidence that climate change has caused Atlantic tropical cyclones to gain in power in recent years.

Along with scientists from the University of Minnesota, Syracuse University, the University of Maine, and the U.S. Geologic Survey, FSU scientists are engaged in a National Science Foundation study of the carbon balance in the peat lands of Lake Agazzi, Minnesota to determine the effects of climate change precipitated by global warming. Because these peat lands, which are large wastelands composed of undecomposed organic matter, have remained largely untouched, the study is expected to render valuable information on the ways in which global warming impacts the environment.

Studies of the greenhouse gases that are being emitted from melting permafrost in North Siberia have led a FSU scientist working with researchers from several other universities to determine that climate change is occurring more rapidly than previously predicted. In the study, published in the September 7, 2006, issue of *Nature*, they assert that this methane, which is 20 times more potent than carbon dioxide, is releasing carbon that has been buried for 4,000 years into the atmosphere as a result of global warming. This methane is further accelerating the pace of global warming.

Food Miles

RECENT YEARS HAVE seen increasing concern about the long-term sustainability of food systems and their unintended side effects that can be imposed on the global environment and human wellness. Food miles are an appraisal of the distance a food or beverage travels from field to plate. While the cost of making things has never been cheaper, the cost of moving them around has never been as high, and it is getting higher. This is partly a consequence of outsourcing practices involving industries and retailers.

The logic is that the fewer miles foods are transported, the less fuel is used, thereby reducing the carbon footprint on the environment and improving sustainability. Some major retailers, such as Asda (Wal-Mart) in the United Kingdom, have introduced measures aimed at cutting CO_2 emissions, such as a change to bio-diesel and moving more freight by train. Direct deliveries of locally grown goods have increased as people have become more interested in provenance issues. In the United States, supermarket chains like Whole Foods and Wal-Mart announced they are reducing the transport distances of the foods they purchase. For example, in 2006, Wal-Mart announced that it would source its seafood only from fisheries certified as sustainable and well managed by the international Marine Stewardship Council.

The trade-off between minimized financial investment with high levels of automation on one hand, and intensively-used, low-cost transport on the other, needs strategic re-thinking. The attention retailers are paying to food miles demonstrates this, as they look to differentiate themselves from the competition, and, in the end, to protect the environment. Carbon footprint labels will bring the concept of food miles to bottled beverages in a way that is currently only the case with fruits and vegetables. The externalities arising from production systems indicate some important policy priorities for developed nations, particularly in North America and Europe. Some governments are taking action to reduce the environmental and social costs of food transport, particularly in the United Kingdom and New Zealand. At a broader level, the European Union has been considering the reduction of greenhouse gas emissions by 20 percent by 2020.

It is very difficult to determine the distance food travels, and by what means. Therefore, buying locally with clear provenance can make the food industry more sustainable. Purchasing seasonally helps neutralize the need for artificial heating in greenhouses. The drive to reduce food miles and reduce CO_2 could have social impacts on growers in developing countries, as global value chains are redirected. A specific tax on food miles for manufacturers and retailers reported in the companie's annual reports could also help to achieve sustainability.

Fresh and processed foods can travel large distances around the world. However, sometimes it is not easy to identify the place of origin. Also, sourcing products locally is a great initiative, but many of the products may not be available locally. Transport is only one issue of the overall environmental impact of food and beverages production and consumption. The delivery cost captured by food miles does not take into account the energy use or CO_2 emissions in the production stage. It also assumes the same level of energy efficiency, no matter where it originates. For example, New Zealand is the world's biggest exporter of dairy products. Calculating food miles does not capture other carbon costs such as the use of heated indoor milking sheds common among northern hemisphere dairy farms.

Export-oriented countries, such as New Zealand, have been taking measures to counter the food miles argument, particularly in the United Kingdom. For example, this is the case of fresh fruits and vegetables, dairy products, and wine. The distance products travel are not necessarily directly related to their carbon footprints. If the concern about food miles is global warming, then the focus should be on gas emissions and energy efficiency, not on distance.

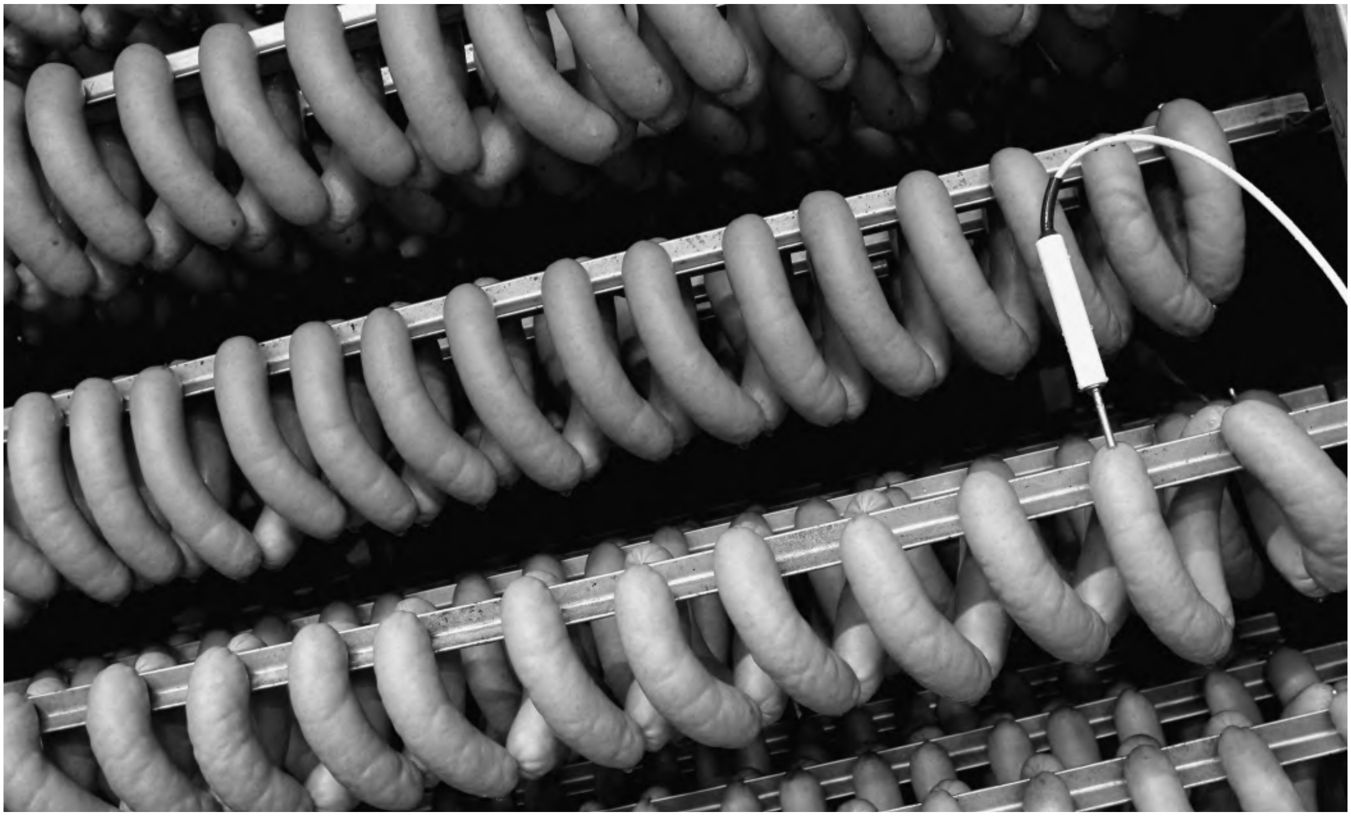
Food Production

FOOD PRODUCTION IS the growing of plant crops and animals for human consumption. It is one of the most vital activities engaged in, with food and water central to the continuation of human life. Climate change threatens to change age-old patterns of agriculture at a moment in history when there are more people alive on the planet than ever before, and may lead to a long period of global food insecurity.

Food takes many different forms, but a general description is: anything that can be metabolized by a living organism to create energy or build tissue. For humans, this means matter comprised of some combination of carbohydrates, proteins, lipids (fats), or water. Food is often grouped into the broad categories: grains, fruits, vegetables, meats, fish, legumes, and includes a separate category for the byproducts of meat and poultry production, such as milk, eggs, cheese, and yogurt.



Sausages in production: According to the United Nations, 259 million metric tons of meat were produced in 2004. Food production is the world's most common profession, with 36 percent of all workers engaged in agriculture in 2006.

Humans have been practicing agriculture since the dawn of civilization. It was the move from nomadic hunter-gatherer societies to permanent farming communities in the fertile flood plains of Mesopotamia 10,000 to 12,000 years ago that marked the beginning of historical records.

As these early agrarian societies began cultivating grain crops and domesticating animals, the outlines of society began to form. With a steady supply of food, population increased. People began to specialize in crafts to support the population around them. Social hierarchies, government, trade, written language, and slavery were just some of the structures built on the foundation of agriculture.

Today, humans cultivate about 2,000 plant species for food, with a definite preference for grains and cereals. According to the United Nations Food and Agriculture Organization (FAO), global production of cereal crops in 2004 was around 2.3 billion metric tons, compared with 886 million metric tons of vegetables, 259 million metric tons of meat, and 130 million metric tons of fish. Food production is the world's most common profession, with 36 percent of all workers engaged in agriculture in 2006. This is actually a drop from 42 percent in 1996, and reflects the shift of more and more workers to urban centers. Agricultural workers range from subsistence farmers, to owners and employees of huge industrial operations, while millions more support themselves through fishing, ranching, hunting, and foraging.

Agriculture is one of three anthropogenic causes of global warming identified by the Intergovernmental Panel on Climate Change (IPCC), after fossil fuel use and land use. The clearing of new agricultural lands creates pollution through the burning of biomass, releasing greenhouse gasses and particulate matter into the atmosphere; the loss of trees reduces the planet's natural carbon sink, the natural process whereby trees remove carbon from the air. Most modern fertilizers are petroleum-based, releasing tons of nitrous oxide and other gasses every year. Livestock are responsible for 40 percent of annual methane emissions.

Since the development of agricultural chemistry in the 19th century, there has been a steady stream of innovation, including specialized machinery, fertilizers, pesticides, fungicides, and soil amendments, advances in animal husbandry, plant breeding, hybridization, and gene manipulation. Yet, for all these technological advances, food production still relies principally on sunlight, precipitation, temperature, and soil quality. It requires predictability and stability. Farmers need to know when the growing season will begin and end, and approximately how much rain will fall between those two dates. Anomalies in the weather can have a catastrophic effect on crop yields.

CLIMATE CHANGE AND FOOD PRODUCTION

Of all the potential impacts of climate change, it is the threat to the food supply that is perhaps the most frightening. With more than six billion mouths to feed and only so much arable land on which food can be grown, the margin for crop failure is shrinking. Food abundance, the norm for the past several decades, is beginning to give way to scarcity. For example, global droughts during the 2007 growing season led to shortfalls of millions of metric tons of grains, forcing exporting powers like Australia to have to consider importing to meet internal demands. Protests have been launched against the increased price of tortillas in Mexico and pasta in Italy. The United Nation's World Food Programme (WFP) has seen operating costs jump 50 percent since 2002, and expects another 35 percent rise by 2010.

One benefit of climate change is the expansion of vineyards in the United Kingdom: the last time wine was produced on a such a wide scale in England was during the Medieval Climate Optimum of 800–1300 C.E., before the Little Ice Age of the 16th to the mid-19th centuries. Warmer temperatures are expected to expand growing seasons in regions close to the poles, opening up new land to agricultural development, particularly in the northern latitudes. Climate zones may move north by anywhere between 100–350 mi. (161–563 km.), and up 500–1,800 ft. (152–585 m.) in elevation. Some current climate zones will disappear completely, while new microclimates will be created.

Another potential benefit of global warming will be the fertilization effect of carbon dioxide (CO_2). Carbon dioxide is a plant nutrient that, under optimal conditions, can stimulate and enhance photosynthesis. It can also improve a plant's ability to use water by inhibiting transpiration, the evaporation of water out of organic material. Higher CO_2 concentrations could also mitigate the damaging effects of other environmental pollutants, such as SO_2, the main pollutant in acid rain. Over 90 percent of the world's crops could theoretically benefit from CO_2 fertilization, although some staple crops like maize, sorghum, millet, and sugar cane would not. A 1990 study estimated that it could increase crop productivity 10 to 20 percent over the next century.

Crop growth is implicitly tied to air temperature. Higher temperatures speed a plant's development, which for farmers means a shorter period between the planting and harvesting of crops. In some areas, planting will be able to begin earlier in the calendar year, and temperatures may allow multiple planting cycles in a season. But outside the northern latitudes, the impact of higher temperatures becomes a negative. Prolonged periods of 90 to 100 degree F weather causes severe damage to most crops. Heat-stressed livestock do not thrive, with high temperatures reducing, for example, milk production.

The same fertilizing effects of CO_2 seen in plants also work on weeds, which may become more invasive in a warming world. This will require heavier application of weed-controlling agents, most of which emit greenhouse gases as they break down, to protect threatened crops. Insects and pests are likely to take advantage of warmer winters and move into new regions; a longer period of summertime warmth will also allow some destructive insects, like grasshoppers, to go through several reproductive cycles in a single year, maximizing the potential damage. Bacteria and fungi will take advantage of new wind patterns and warmer, wetter conditions to bloom.

Higher temperatures also have an effect on soil quality. Warmer soil breaks down organic matter more quickly, stripping it of nutrients and requiring the use of more fertilizers to enhance soil fertility. These, like pesticides and herbicides, emit pollutants. Dried-out soil is also more prone to erosion. Precipitation patterns are expected to change dramatically over the next century. Climate scientists expect that there will be more prolonged dry spells, punctuated by brief, heavy downpours. This will have a negative impact on crop yield, because most staple crops are sensitive to drought stress. Heavy rain falling on very dry soil exacerbates soil erosion. Increased risk of flooding raises the likelihood of crop damage or outright destruction. Aside from the increased risk of drought, farmers will also have to face an overall reduction in available water for irrigation, stemming both from changes in the global hydrologic cycle and an increasing urban population.

There are a number of ways farmers could adapt to climate change, ranging from very simple techniques such as changing their sowing dates to take advantage of an earlier spring, to the more complex options including developing methane-recovery systems that sequester livestock manure into digesters and turn them into biogas. While the use of genetically modified (GM) crops remains controversial in many parts of the world, gene manipulation could create crops that are more resistant to many of the situations that might present themselves in a warming world.

Foraminifera

FORAMINIFERA ARE MARINE eukaryotic unicellular organisms that construct a shell or test. They use chemicals from their surroundings to construct calcareous or siliceous crystals, or particulate grains to form an agglutinated test. They are heterotrophic protoctists with granular reticulopods (pseudopodial networks) exhibiting two-way streaming. Foraminifers are Linnean classified by their chemistry, mineralogy, structure of the test walls, cytology, and DNA of protoplasm.

Foraminifers can be either benthic or planktonic. Benthic foraminifers, in the shape of simple agglutinated tubes, lived in the Cambrian (500 million years ago). Planktonic foraminifers appear in the fossil record during the Jurassic (206 million years ago). Both variants provide excellent fossil records and are the most diverse group of shelled marine microorganisms on Earth. Most live in specific environments and cannot survive drastic environment changes. Most foraminifers evolve relatively quickly and only range in the geological record for a short time (approximately 10^5 years), making them useful for developing theories on evolution, origination, extinction, and biogeographic distribution of past and present environments projected into the future.

The ecological controls on foraminifers depend on if they are bathyal-abyssal open ocean, or shallow water foraminifers. Benthic foraminifers are affected by the input of organic matter and other food sources from the surface layer 328 ft. (100 m.), amount of available oxygen, sediment influx, and seafloor currents, salinity, and temperature. Benthic foraminifers are used to evaluate surface productivity in the ocean. Controls on planktonic foraminifers include salinity, temperature, upwelling, and the productivity of the surface layer. Planktonic foraminifers are used to reconstruct ocean currents, circulation, paleotemperatures, and large-scale shifts in Earth's surface thermal regime.

Stable oxygen and carbon isotopes, as well as trace elements taken up in tests of foraminifers, are used reconstruct gross past climate trends and temperature cycles. Foraminifers are sampled from marine sediment cores from around the globe. They are correlated with the magnetic stratigraphy and biostratigraphy of other microfossil groups among the Atlantic, Pacific, Indian, and Arctic oceans.

Oxygen and carbon in biogenic carbonates are determined by the mass ratios of CO_2. ^{16}O and ^{18}O for foraminifers are used for fractionation comparison. $\delta^{18}O$ in seawater is linked to the hydrologic cycle (evaporation, atmospheric vapor transport, freshwater return to the oceans by precipitation, runoff or melting of icebergs, and long-term storage in aquifers and ice sheets). Lighter isotopes evaporate first and precipitate last. Therefore, the farther the precipitation occurs from source waters, the more depleted in ^{18}O the vapor becomes. Temperature and salinity can be deduced from ^{18}O values. There are many factors that affect the fractionation of oxygen in foraminifer tests, including ontogenics, symbiotic photosynthesis, respiration, gametogenic calcite, and carbonate ion concentrations. All of these factors need to be taken into account when interpreting $\delta^{18}O$ in planktonic foraminifers and sometimes in benthic foraminifers.

Carbon isotopes are derived from organic matter and sediment carbonate reservoirs. Surface waters are enriched in ^{13}C due to the fractionation that occurs in photosynthesis. In deep water, $\delta^{13}C$ is controlled by the amount of organic decay, time of exposure at the sea floor, and rate of decay of organic matter. Change in depth of calcification of foraminifers is also recorded.

Trace elements are also used to reconstruct past oceanic conditions, providing independent validation of other proxies such as stable isotope values and ratios. The calcite test of a foraminifer is composed of 99 percent $CaCO_3$, with the remainder comprised of trace elements. The composition of a test reflects seawater composition and the biological and physical conditions of the environment. Paleotemperature proxies (Mg), seawater nutrients, carbon and carbonate levels (Cd, Ba), physical properties such as temperature and pressure (Mg, Sr, F, B), history of ocean chemistry (Li, U, V, Sr, Nd), and secondary post-depositional processes such as $CaCO_3$ and SiO_2 diagenesis (Mn) are combined for the development of paleoceanographic reconstructions.

Forced Climate Variability

STUDIES ON GLOBAL warming and climate change generally distinguish between internally generated and externally-forced climate variability. Internally generated variability is the result of processes within a system, while externally-forced variability is caused by some factors outside the system. A classic example of externally-forced climate variability is represented by the changes caused by variations in the amount and distribution of solar energy incidents on the Earth because of the differences in the solar luminosity or in the Earth's orbital parameters. The distinction between the two types of variability is not always so clear-cut, because it depends on how the boundaries of the system under examination are defined. For example, when studying or modeling the atmosphere in isolation from the rest of the climate system, changes in sea surface temperatures would be termed external forcing. Yet, in a coupled ocean/atmosphere model, variability induced in the atmosphere by variations in sea surface temperatures would be internally generated variability. There is still considerable debate concerning the extent of internal climate variability.

Internal climate variability not forced by external agents occurs on all time-scales, from weeks, to centuries and millennia. Slow climate components, such as oceans, have particularly important roles on decadal and century timescales because they complement high-frequency weather variability and work together with faster components. Thus, climate is capable of producing long timescale internal variations of considerable magnitude without any external influences. Externally-forced climate variations may be caused in changes by natural forcing factors, such as solar radiation or volcanic aerosols, or changes in anthropogenic forcing factors, such as increasing concentrations of greenhouse gases or sulfate aerosols. Therefore, the response to anthropogenic changes in climate forcing is set against the background of natural internal and externally-forced climate variability that can take place on similar temporal and spatial scales.

The action of natural climate variability means that the detection and attribution of anthropogenic climate change should demonstrate that an observed change is significantly different statistically than can be explained by natural internal variability. However, although a particular change in climate is detected, this does not necessarily mean that its causes are understood. In order to define more precisely the adaptation and mitigation strategies needed to deal with the potential impacts of expected climate change, a deeper understanding of the intrinsic and externally-forced variability of the climate system is needed to detect, attribute, and predict global and regional climate change provoked by natural and anthropogenic causes.

Examples of externally-forced climate variability include variations in solar output and volcanic eruptions that cause a general cooling of climate by injecting aerosols into the stratosphere. Human activities can also produce changes in the composition of the atmosphere. The extent of this externally-forced variability depends on the extent of the forcing and the sensitivity of the climate system to the forcing. When the forcing is gradual, as in the case of the increase in the Sun's emissions over the Earth's life span, all the different components of the system retain their equilibrium. In contrast, forcing that produces immediate changes or consists of a short-lived impulse, such as volcanic eruptions, provoke a transient reaction with multiple timescales.

The intensity of solar radiation varies over a large range of timescales and the extent of these variations depends on wavelengths. Sunspots are cool patches that break up the convective movement of cells in the photosphere. They take place in conjunction with strong magnetic fields and their lifetimes range from a day to a few months. In contrast, faculae are hot spots in the pattern of convective cells that often accompany sunspots and strong magnetic fields. Their lifetimes are comparable to those of the sunspots. Flares are intense emissions of ultraviolet and x-ray radiations and high-energy particles that the sun's outer atmosphere emanates within its active regions. Their main features are strong magnetic fields, violent motions and a lifespan of an hour. During the active phase of the 11-year solar cycle, there are numerous sunspots, faculae, and flares, appearing first at higher latitudes, and later at lower ones as well. During the quiet phase of the solar cycle very few of these disturbances occur.

The impacts on climate due to volcanic eruptions are mainly represented by the effects of sulfate aerosols formed from SO_2 emissions. Yet, traces of these aerosols remain in the troposphere for only a few weeks. Thus, only major eruptions, such as the 1991 Mt. Pinatubo eruption in the Philippines, penetrate the lower stratosphere and have a significant impact on global climate. Aerosol clouds generated by major volcanic eruptions can reduce the flux density of direct solar radiation incident on the Earth's surface. This reduction in total incident solar radiation produces lower global-mean surface air temperature following major volcanic eruptions than in the long-term average. The duration of the cooling of the Earth following major volcanic eruptions appears to be longer than the one to two-year duration of aerosols in the stratosphere. This is due to the interaction of the ocean mixed layer and its large heat capacity. An additional period of a year or two is necessary for the layer to regain the heat lost due to the air-sea temperature imbalance while the aerosols were in the atmosphere. The global-mean surface air temperature returns to its pre-eruptions level only when the equilibrium of the ocean is restored. In addition to these forcings, there are others that are associated with human-induced activities such as the burning of fossil fuels that result in a buildup of carbon dioxide in the atmosphere and the consequent greenhouse warming.

Forests

THE EARTH'S SURFACE is covered by diverse vegetation, from tropical and polar deserts, to alpine and arctic tundra, to coastal temperate and tropical rainforests. Forests cover a large fraction of the Earth's terrestrial biosphere (approximately 4 billion hectares) and differ from other vegetation types in several important ways. Forests tend to occur where soils and climate are more favorable to plant growth. As a result, forests tend to store larger quantities of carbon then other terrestrial ecosystem types. Forests are taller than non-forest vegetation types (such as grasslands), and as a result, forests more profoundly affect microclimate at the ground level through canopy shading and reduced effects of wind.

Forests tend to use more water than nonforest vegetation, which together with higher rain interception rates, results in less water entering soils and leaving forests through ground and surface channels. Forests have very different effects on soils compared to other vegetation types. Forests tend to return larger inputs of litter to the soil surface, resulting in the accumulation of a sometimes-thick organic layer, including large woody debris. There is more soil-mixing in forests when large trees fall over and root systems tip up. Disturbances such as fire or hurricanes are more intense, as larger amounts of biomass are consumed or displaced.

Forests occur across a remarkable diversity of soil types, climates, elevations, and aspects. They range from monotypic stands of pine, to highly-diverse tropical rainforests with many hundreds of tree species per hectare. Together, compositional, environmental, and physical/chemical diversity results in very wide ranges in forest productivity, with differences in species composition and productivity altering the chemical and physical properties of soils. Overall, rates of net primary production for forests can range from 200 g. or less per sq. m. per year in cold climates on infertile sites, to several kg. per sq. m. per year in warm, wet climates on fertile sites. Of particular interest to ecologists is how forest composition affects the factors that regulate forest productivity, including nutrient availability, water-holding capacity, and carbon content. For all these reasons, forests receive substantial attention from global change scientists.

FOREST CARBON STORAGE

Forests exert a disproportionately large influence on the global carbon cycle. The Earth's forests store over 1,200 Pg of carbon (1 Pg [petagram] equals 1 x 1,015 g.), which is approximately half of all organic carbon in the terrestrial biosphere. More than 80 percent of this forest carbon resides in boreal and tropical forests, with the remainder in temperate forests. Terrestrial vegetation, especially in forests, interacts strongly with the atmosphere, with impacts on carbon dioxide concentrations and fluxes. Every year, the terrestrial biosphere removes approximately 120 Pg of carbon from the atmosphere through photosynthesis, while releasing an almost identical amount of carbon back to the atmosphere as carbon dioxide through plant and soil respiration. By comparison, humans release approximately 6 Pg of carbon to the atmosphere as carbon dioxide through fossil fuel combustion. Forests also modify weather patterns and local- to regional-hydrologic cycles, and higher rates of plant productivity in forests translate to larger export of products, including biomass feedstock for paper, dimension lumber, and biofuels.

Globally, two to five times more carbon is stored in forest soils than aboveground forest biomass. Despite the large above and belowground differences in carbon storage, only 60 Pg carbon out of the 120 Pg carbon fixed annually by terrestrial vegetation through photosynthesis is allocated belowground for the construction and maintenance of root systems and mycorrhizae, the belowground symbiotic fungal partners of plants that allow plants to increase their exploration of soil for nutrients. Notably, this belowground carbon flux is the Earth's third largest biologically mediated carbon flux after oceanic photosynthesis and terrestrial photosynthesis.

From an evolutionary perspective, this flow of carbon represents the currency with which chloroplasts in leaves (photosynthetic endosymbionts) acquire nutrients, water, and structural support from mycorrhizae. Most of the carbon allocated belowground is rapidly released back to the atmosphere, with up to 80 percent released within one year of entering soil. When only net primary production is considered (that is, gross photosynthesis less plant respiration) the relative proportion of net primary production in forests that is allocated to belowground may be 20–50 percent of what is allocated to aboveground net primary production, in contrast to grassland or tundra ecosystems where the opposite pattern is found. The carbon that remains belowground takes the form of newly-formed soil organic matter or coarse roots, the two main long-lived stocks of organic carbon in soil. The roots of large trees may be extensive, for resource acquisition and to support large aboveground biomass.

Climate change, along with elevated carbon dioxide, increased nutrient deposition rates, invasive species, and land use change are likely having large, often site-specific (and sometimes opposing) effects on forest carbon budgets. Together, these changes on a global scale have the potential to drastically alter how forests interact with the atmosphere. There is great uncertainty regarding how the balance of photosynthesis and respiration will change in response to these global change variables, because many effects are opposing. Because so much organic carbon is stored belowground, accurate estimates of how belowground carbon allocation and belowground process rates in forests will respond to climate change are needed to understand how climate change will alter root growth, carbon inputs belowground, and soil organic matter formation. These, in turn, will influence biotic and abiotic properties of soil such as bulk density, cation exchange capacity, and water-holding capacity, which in turn affect plant growth.

CLIMATIC EFFECTS ON FORESTS

Increasing temperature, nutrient deposition rates, and atmospheric carbon dioxide may stimulate forest production, but these effects may saturate, or be canceled by, increased water limitations to forest productivity due to warmer or drier conditions or by increases in atmospheric plant toxins such as ozone. Warmer temperatures may drive higher respiratory process rates, which may increase carbon losses from forests. However, substrate limitations to microbial decomposition rates in soils or to biochemical processes in plants (acclimation) may limit losses of ecosystem carbon to the atmosphere. Uncertainty increases as ecosystems adapt or become modified by these global change variables.

For example, plant stress may increase with climate change, resulting in greater susceptibility to pests and pathogens. A change in nutrient availability or a warmer climate may, therefore, alter species composition by favoring the recruitment and survival of more tolerant plant species over species previously occupying sites under a cooler climate or nutrient-poor conditions. Climate change may also alter disturbance regimes. For example, in a warmer and drier world, it is anticipated that certain plant species will experience more frequent periods of drought stress and susceptibility to pest and pathogen attacks, resulting in higher mortality and fuel loads. Higher fuel loads and a changing climate will interact to increase intensity and frequency of major fire disturbances.

In already warm and dry ecosystems, warming and drying, therefore, may cause a large transfer of carbon from soils and vegetation to the atmosphere, and these changes would result in a positive feedback on global warming by accelerating the increase in atmospheric carbon dioxide concentrations. Conversely, in currently cool and wet climates, forest productivity may increase as growing season length and nutrient availability increase with warming, potentially resulting in an increase in carbon storage. This would have the opposite negative feedback effect on future warming through a net reduction in the rate at which atmospheric carbon dioxide concentrations are increasing.

Superimposed on the uncertainty of how global change variables will impact forests and forest carbon budgets is the uncertainty concerning ever-evolving patterns of human land use, especially the conversion of forest to nonforest, decisions over abandonment that result in the opposite process, as well as the magnitude and direction of changes in the amounts and distribution of total annual precipitation. The global sum of these changes is receiving tremendous scientific attention, but uncertainty of predicted outcomes from these effects and their interactions remains high.

Foundation for International Environmental Law and Development

THE FOUNDATION FOR International Environmental Law and Development (FIELD) was established in London in 1989 by a small group of international lawyers interested in the protection of the environment and the promotion of sustainable development. The organization provides advice and assistance to governments, inter-governmental and non-governmental groups worldwide. FIELD works for the development of international legislation that defends the environment and encourages fair and sustainable development. FIELD has a charitable, nonprofit status and attempts to develop skills and abilities in the citizens of developing and transition countries. In 2005, it became a subsidiary of the International Institute for Environment and Development (IIED). FIELD remains an independent charitable organization but shares offices, core services, and a Board of Trustees with IIED. Thanks to their alliance, the two organizations can combine their strengths: FIELD's expertise in law and advocacy and IIED's experience in social, political, and economic sciences.

The foundation is interested in researching proposals for possible legislation, disseminating good practices though education and teaching, and lobbying for passing legislation for environmental protection and sustainable development. In particular, FIELD has three core programs covering biodiversity and marine resources; climate change and energy; and trade, investment, and sustainable development. The Biodiversity Program was established in 1997, and its projects are aimed to the conservation of biological diversity, the sustainable use of its components, and the equitable sharing of benefits arising from the utilization of genetic resources. In addition to these three issues, the work of the program also focuses on liability and reparation for damage caused to biodiversity. The Trade, Investment and Sustainable Development (TISD) Program focuses on how the international regulations and institutions that manage the processes of globalization impact on developing countries and sustainable development. TISD also addresses how such regulations and institutions relate to international protocols intended to protect the environment. FIELD aims to foster the political and economical empowerment of marginalized countries and communities so that they can make informed choices about trade rules and their effect on the natural environment. FIELD lawyers have monitored and influenced the law and policy of the World Trade Organization, the European Union and other regional trading blocks, the Organisation for Economic Co-operation and Development (OECD), and various environmental treaty bodies.

The foundation considers climate change as one of the most serious ecological threats facing the planet. Climate change and global warming have put the environmental, social, and economic security of many countries is at risk. FIELD has been directly involved in the development of international legislation about climate change, and continues to play an important role in its implementation. The foundation points out that climate change and global warming are already affecting the Earth's physical and biological balance. FIELD's program aims to address the threats that climate change and global warming create for developing and poorer countries. It works to strengthen international and regional legal frameworks and their application to ensure that these weaker communities are not left without help to bear the economic, health, environmental, social, and political burden of climate change effects. The main focus of FIELD's climate change work has been on providing legal assistance for the 43 members of the Alliance of Small Island States (AOSIS) in negotiating and implementing the United Nations Framework Convention on Climate Change (UNFCCC) and its Kyoto Protocol. Since 1998, FIELD has also actively promoted the implementation of the UNFCCC and the Kyoto Protocol in the European Union (EU), in particular through the elaboration of the EU emission allowance trading scheme.

Fourier, Joseph (1768–1830)

JOSPEH FOURIER WAS a French mathematician, also acknowledged as an Egyptologist and administrator, who greatly influenced mathematical physics through his *Théorie analytique de la chaleur* (1822; *The Analytical Theory of Heat*). He analyzed the conduction of heat in solid bodies in terms of infinite mathematical series now called the Fourier series. His work went well beyond the area of heat conduction, stimulating research in mathematical physics. Since Fourier, the discipline has been identified with the solution of boundary-value problems, focusing on many natural occurrences such as sunspots, tides, and the weather. Fourier has also contributed to the theory of functions of a real variable, one of the main branches of modern mathematics. The mathematician was one of the earliest proponents of the theory of global warming, although his many other achievements have overshadowed such contribution. In an article first published in 1824, Fourier pioneered the study of global warming, arguing that the atmosphere absorbs some of the Sun's warmth and sends it back to the Earth.

Fourier was born on March 21, 1768 in Auxerre, Bourgogne, France, the ninth of 12 children from his father's second marriage. His childhood was marked by the premature death of both his parents. His mother died when he was 9 years old and his father, a tailor, died the following year. Fourier started his education at Pallais's school, run by the music master from the cathedral. Because of the great potential that he had shown, he proceeded, in 1780 ,to the *Ecole Royale Militaire* of Auxerre where first he excelled in literature, but very soon understood that his favorite field was mathematics.

In 1787, Fourier entered the Benedictine abbey of St Benoit-sur-Loire to become a priest. His interest in mathematics continued, however, and Fourier was not completely sure that training for the priesthood was the right decision. In his correspondence with C. L. Bonard, the professor of mathematics at Auxerre, he admitted that he really wanted to make a major impact in mathematics. In the end, Fourier did not take his religious vows and left St Benoit in 1789. The following year, he found employment as a teacher at the Benedictine college, Ecole Royale Militaire of Auxerre, where he had studied. With the outbreak of the French Revolution, political commitment also entered Fourier's life, and, in 1793, the mathematician became involved in politics and joined the local Revolutionary Committee. Fourier was "enamored," as he wrote, of the ideal of equality that pervaded the Revolution at the beginning, although he was appalled by the excesses that soon characterized the Terror.

After being briefly imprisoned due to internal feuds within the Revolutionary Front, later in 1794, Fourier was accepted to study at the Ecole Normale in Paris. This institution had been established for training teachers, and was intended to serve as a model for other teacher-training schools. Fourier began teaching at the Collège de France and, thanks to his contacts with Lagrange, Laplace and Monge, who had been his teachers at the Normale, began further mathematical research. He was appointed to a position at the Ecole Centrale des Travaux Publiques. After a second arrest, in 1975, Fourier went to teach at the Ecole Polytechnique. In 1797, he succeeded Lagrange as chair of analysis and mechanics.

In 1798, Fourier joined Napoleon's army in its invasion of Egypt as scientific adviser. Fourier acted as an administrator as French style political institutions and administration were installed. In particular, he helped create educational facilities in Egypt and carried out archaeological explorations. While in Cairo, Fourier was among the founders of the Cairo Institute and was one of the 12 members of its mathematics division. He was also elected secretary to the Institute, a position he held during the French occupation of Egypt. After his return to France, Fourier was entrusted with the publication of the enormous mass of Egyptian materials collected during the expedition. This became the *Description de l'Égypte,* to which he also wrote a lengthy historical preface on the ancient civilization of Egypt. From 1802 to 1814, he was appointed administrator the Isère *département*. Because of his competent work as an administrator, in 1809, Napoleon made him a baron. Following Napoleon's downfall in 1815, Fourier was appointed director of the Statistical Bureau of the Seine. In 1817, he was elected to the Académie des Sciences, becoming its perpetual secretary in 1822. Because of his work in Egyptology he was elected, in 1826, to the Académie Française and the Académie de Médecine. He died on May 16, 1830, in Paris.

During the 1920s, Fourier began to analyze the question of how the Earth stays warm enough to maintain its diverse range of flora and fauna. He wondered why the heat generated by the Sun's rays does not get lost after striking and bouncing off the great oceans and landmasses of the planet. Fourier formulated a first hypothesis of global warming. According to Fourier's metaphor, the atmosphere is compared to an invisible domed container made of glass that absorbs some of the Sun's warmth and reradiates it onto the Earth's surface. Such a gigantic bell jar is formed out of clouds and invisible gases. Water vapor and other gases simulate a vault that conserves heat. Fourier described this hypothesis in the article "General Remarks on the Temperature of the Terrestrial Globe and Planetary Spaces," which was published in the *Annales de chimie et de physique* in 1824. The article was not well-received during Fourier's lifetime, but is now considered a first formulation of global warming.

Framework Convention on Climate Change

THE UNITED NATIONS Framework Convention on Climate Change (UNFCCC or FCCC) is an international environmental treaty produced at the United Nations Conference on Environment and Development (UNCED), informally known as the Earth Summit, in Rio de Janeiro in 1992. The treaty set the goal of reducing emissions of greenhouse gas in order to combat global warming.

The original framework of the treaty did not set mandatory limits on greenhouse gas emissions for individual nations and contained no enforcement provisions; it is therefore considered legally nonbinding. Rather, the UNFCCC stated that mandatory emission limits would be established by further "protocols" that would serve as updates of the convention. The principal update is the Kyoto Protocol which, since its enforcement in 1997, has become more frequently referred to than the framework convention itself. While the FCCC was ratified by the U.S. Senate and signed by President George W. Bush in October 1992, neither the Bill Clinton administration nor the Bush administration sent the protocol to Congress for ratification. The Bush administration explicitly rejected the protocol in 2001. The Kyoto Protocol legally binds signatories to reduce greenhouse gas emissions of an average of 6–8 percent below 1990 levels between the years 2008–12, defined as the first emissions budget period. Under the Protocol, the United States would be required to reduce its total emissions an average of 7 percent below 1990 levels.

The FCCC was adopted at the United Nations Headquarters, New York on May 9, 1992. It was open for signature at the Rio de Janeiro from June 4–12, 1992, and thereafter at the United Nations Headquarters, New York, from June 20, 1992 to June 19, 1993. By that date, the Convention had received 166 signatures. The Convention took effect on March 21, 1994. Those States that have not signed the Convention may accede to it at any time. Its stated objective is "to achieve stabilization of greenhouse gas concentrations in the atmosphere at a low enough level to prevent dangerous anthropogenic interference with the climate system." Signatories of the UNFCCC must submit a national greenhouse inventory, an accounting of greenhouse gas (GHG) emissions and removals. The Convention on Climate Change sets an overall framework for intergovernmental efforts to tackle the challenge posed by climate change. It recognizes that the climate system is a global and shared resource and that emissions of carbon dioxide and other greenhouse gases can have a deep impact on its stability. The FCCC enjoys near universal membership, with 191 countries having ratified. Through the FCCC, governments are committed to gather and share information on greenhouse gas emissions, national policies, and best practices; devise national strategies for addressing greenhouse gas emissions and adapting to expected impacts; provide financial and technological support to developing countries so that they can face the challenges of climate change; and cooperate in preparing for adaptation to the impacts of climate change.

The UNFCCC treaty set the goal to reduce emissions of greenhouse gas, but set no mandatory limits on emissions.

The FCCC divides its member countries into three main groups according to differing commitments. Annex I Parties include the industrialized countries that were members of the Organisation for Economic Co-operation and Development (OECD) in 1992. In addition, countries with economies in transition (the EIT Parties), including the Russian Federation, the Baltic States, and several Central and Eastern European States, are included in this group. Annex II Parties consist of the OECD members of Annex I, but not the EIT Parties. The FCCC requires them to provide financial resources to developing countries to organize emissions reduction activities and to adapt to adverse effects of climate change. In addition, Annex II Parties have to promote the transfer of environmentally-friendly technologies to EIT Parties and developing countries. Funding provided by Annex II Parties is directed mostly through the FCCC's financial mechanism.

Finally, non-Annex I Parties are, for the most part, developing countries. Certain groups of developing countries are recognized by the FCCC as especially vulnerable to the adverse impacts of climate change, including countries with low-lying coastal areas and those affected by processes of desertification and drought. Other countries in this group have economies that rely heavily on income from fossil fuel production and commerce. These are thus recognized as particularly vulnerable to the potential economic impacts of climate change response measures. Through investment, insurance, and technology transfer, the FCCC stresses the importance of activities that will answer the special needs and concerns of these vulnerable parties. The 48 Parties, classified as least-developed countries (LDCs) by the United Nations, are given special attention under the FCCC on account of their limited capacity to respond to climate change and adapt to its adverse effects. Parties are urged to take full account of the special situation of this group of countries when considering funding and technology-transfer activities.

Several categories of observer organizations also attend sessions of the Conference of Parties and its subsidiary bodies. These include representatives of United Nations secretariat units and bodies, such as United Nations Development Program (UNDP), United Nations Environment Program (UNEP) and United Nations Conference on Trade and Development (UNCTAD), as well as its specialized agencies and related organizations, such as the Global Environmental Facility and the Intergovernmental Panel on Climate Change (IPCC). Observer organizations also include intergovernmental organizations (IGOs), such as the OECD and its International Energy Agency (IEA), along with non-governmental organizations (NGOs). Since the 11th Conference of Parties, over 750 NGOs and 56 IGOs are admitted as observers. The NGOs represent a broad spectrum of interests, and embrace representatives from business and industry, environmental groups, indigenous populations, local governments and municipal authorities, research and academic institutes, parliaments, labor unions, religious groups, women, and youth.

GREENHOUSE GAS INVENTORIES

In accordance with Articles 4 and 12 of the FCCC, and the subsequent decisions of the Conference of the Parties, Parties to the FCCC submit national greenhouse gas inventories to the Climate Change secretariat. Following Article 12 of the Convention, the Conference of the Parties has elaborated several different types of reports and related guidelines consistent with the common, but differentiated responsibilities of the Parties, relating to their Annex status. These inventory data are provided in the national communications under the Convention by Annex I and non-Annex I Parties, and in addition Annex I Parties submit national greenhouse gas inventories annually. The greenhouse gas data tables contain estimates for: Carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), Perfluorocarbons (PFCs), Hydrofluorocarbons (HFCs) and Sulphur hexafluoride (SF_6). Parallel to the stress on greenhouse gas emission limitation, the FCCC also stresses the importance of adaptation to climate change. Article 4.8 of the FCCC encourages Parties to consider actions, including those related to funding, insurance, and the transfer of technology, to meet the specific needs and concerns of developing countries, particularly small island countries and countries whose economies are highly dependent on fossil fuels.

In one of its subsequent decisions, the Conference of Parties requested the Convention secretariat "to work on the synthesis and dissemination of information on environmentally sound technologies and know-how conducive to mitigating, and adapting to, climate change; for example by accelerating the development of methodologies for adaptation technologies, in particular decision tools to evaluate alternative adaptation strategies." This request aimed to assist Parties in applying the best available methods to assess the impact of, their vulnerability to climate change, and their adaptation options. The secretariat has responded positively with a number of activities. It produced a report in 1999 entitled "Compendium of Decision Tools to Evaluate Strategies for Adaptation to Climate Change" and has organized workshops and meetings of experts. In 2003, the secretariat issued a new version of the Compendium to reflect new developments. A final draft of the updated compendium, titled "Compendium of Methods and Tools to Evaluate and Adapt to Climate Change" was put on-line.

To facilitate adaptation to climate change, the FCCC and subsequent decisions of the Conference of Parties have established the National Adaptation Programs of Action (NAPAs) to provide LDCs with plans to respond to their pressing needs with regard to adaptation to climate change. The rationale for NAPAs rests on the limited ability of LDCs to adapt to the adverse effects of climate change. In order to address the urgent adaptation needs of LDCs, NAPAs stress the importance of enhancing adaptive capacity to climate variability. NAPAs start with existing concrete coping strategies in LDCs countries at the grassroots level, and develops them to identify priority activities, rather than focusing on scenario-based modeling to assess future vulnerability and long-term policy at the state level. NAPAs give prominence to community-level input as an important source of information, recognizing that grassroots communities are the main stakeholders in the process of climate change adaptation.

CONFERENCE OF PARTIES

The Conference of Parties (COP) meets annually to assess progress in dealing with climate change. The COP also carried out the task of negotiating the Kyoto Protocol in the mid-1990s to establish legally binding obligations for developed countries to reduce their greenhouse gas emissions. The COP is the highest decision-making authority of the FCCC. It is an association of all the countries that are Parties to it. The COP is responsible for managing international efforts to address climate change. It monitors the implementation of the FCCC and checks the commitments of Parties in light of the FCCC's objective, new scientific findings and experience gained in implementing climate-change policies. A key mission for the COP is to review the national communications and emission inventories submitted by Parties. Based on this information, the COP evaluates the effects of the measures taken by Parties and the progress made in achieving the ultimate objective of the FCCC. The COP meets every year, unless the Parties decide otherwise. Just as the COP Presidency rotates among the five recognized United Nations regions (Africa, Asia, Latin America and the Caribbean, Central and Eastern Europe, and Western Europe and Others), there is a tendency for the location of the COP to also shift among these groups.

SUBSIDIARY BODIES

The FCCC established two permanent subsidiary bodies: the Subsidiary Body for Scientific and Technological Advice (SBSTA) and the Subsidiary Body for Implementation (SBI). These bodies give advice to the COP and each has a specific task. They are both open to participation by any Party. Governments often select their representatives among experts in the fields of the respective bodies.

As its name suggests, the SBSTA's mission is to supply the COP with advice on scientific, technological, and methodological issues. SBSTA works in two key areas for the success of the convention: the development and transfer of environmentally-friendly technologies, and the improvement of the guidelines for preparing national communications and emission inventories.

The SBSTA also carries out methodological work in specific areas, such as the Land Use, Land Use Change and Forestry sector (LULUCF), adaptation ,and vulnerability. In addition, the SBSTA acts as the link between the scientific information provided by expert sources such as the IPCC on the one hand, and the policy-oriented needs of the COP on the other. It works closely with the IPCC, sometimes requesting specific information or reports, and also cooperates with other relevant international organizations that share the achievement of sustainable development as their main mission.

The SBI gives advice to the COP on all matters concerning the implementation of the FCCC, including budgetary and administrative issues. A particularly important task for the implementation of the FCCC is to assess the Convention's overall effectiveness through an examination of the information provided by the Parties in their national communications and emission inventories. The SBI reviews the financial assistance given to non-Annex I Parties to help them implement their Convention commitments, and provides advice to the COP on guidance to the financial mechanism operated by the Global Environmental Facility (GEF).

The SBSTA and SBI also work together on cross-cutting issues that touch on both their areas of expertise. These include capacity building, the vulnerability of developing countries to climate change and response measures, and the Kyoto Protocol mechanisms. The SBSTA and the SBI have traditionally met in parallel, at least twice a year. The meetings of the two subsidiary bodies are either held at the same location as the conference of Parties or, when they are held at different times, at the Convention's secretariat.

The UNFCCC operations are supported by its secretariat in Bonn, Germany. The secretariat has been housed in the historic Haus Carstanjen, where the Marshall Plan was signed, since August 1996. It was previously located in Geneva, Switzerland. The main tasks of the secretariat are to provide practical arrangements for sessions of the Convention and Protocol bodies; to check the implementation of the commitments under the Convention and the Protocol through collection, analysis and review of information and data provided by Parties; to aid Parties in implementing their commitments; to provide support to the compliance regime of the Kyoto Protocol; and to coordinate with the secretariats of other relevant international bodies, the GEF and its implementing agencies (UNDP, UNEP and the World Bank), the IPCC, and other relevant conventions.

Specific tasks include the preparation of official documents for the COP and subsidiary bodies, the coordination of In-Depth Reviews of Annex I Party national communications, and the compilation of greenhouse gas inventory data.

Since the adoption of the Kyoto Protocol, the work of the secretariat has grown considerably. The secretariat employs about 200 people. Its head, the Executive Secretary, is appointed by the Secretary-General of the United Nations in consultation with the COP, and has the title of Assistant-Secretary-General. The Executive Secretary is responsible to the Secretary-General through the Under-Secretary-General heading the Department of Management on administrative and financial matters, and through the Under-Secretary-General heading the Department for Economic and Social Affairs on other matters.

Every two years, the Executive Secretary proposes a budget, setting out the main goals to be pursued by the secretariat in the coming biennium and the funding needed to carry out this work. This proposal is considered in the Subsidiary Body for Implementation (SBI), which then recommends a program budget for approval by the COP. For the biennium 2006–07, the program budget adopted by COP 11 stands at about $27 million for 2006 and $26 million for 2007. The Program Budget is funded by contributions from Parties, their shares being based on the UN scale of assessment.

CONTROVERSIAL WATERS

The work of the FCCC has not always been smooth, and the COP have often been characterized by controversies between different countries that have paralyzed the body. Developing countries lament that they do not receive enough assistance from developed countries. At the 12th Conference of Parties in Nairobi, Kenya, in 2006, delegates from developing countries explicitly complained about "climate tourists," Western delegates who had attended the conference to "see Africa, take snaps of the poor, dying African children and women."

France

THE LARGEST AMONG the nations of Western Europe, France boasts a long history of world leadership in the arts, sciences, and industrialization. As the first decade of the 21st century nears its end, France remains an influential nation with a Gross Domestic Product of $2,124 billion, and the sixth largest economy in the world. The nation's moderate climate and its ample agricultural land have made it the European Union's largest agricultural producer, ranking second only to the United States in the world market. Its varied coastlines, mountain ranges, vineyards, and cities rich in culture and tradition make France one of the most popular tourist sites in the world. Like other wealthy Western nations, France has been confronted with the problems attending urbanization, industrialization, and the loss of open space. In 1971, France created the Ministry of the Environment to develop solutions to these problems on a national level; later, the country became a signatory to the Kyoto Protocol and to two-dozen other international efforts to address the problems on regional and world levels.

Global warming is of particular concern to France because temperatures have increased since 1950 in France at nearly twice the average rate. The French remember summer 2003 and the more than 15,000 deaths in their country, and environmentalists have warned that future summers could be much hotter. The nation's extensive coastline also renders it particularly vulnerable to the changes in sea streams that accompany global warming. More than a fifth of the French coast already shows signs of erosion. The Intergovernmental Panel for Climate Change (IPCC) set up by the World Meteorological Organization and the United Nations Environmental Program (UNEP) to assess factors connected to climate change, estimates that sea levels by 2100 could rise at a rate three times that of the 20th century. The government has built artificial reefs in an effort to contain erosion, but experts hold little hope that such measures can stem the damage over the long term.

Increases in water temperature and deforestation are among the consequences of climate changes already in progress. These changes have led to the extinction of some species of fish and the spread of the Asian Hornet. The latter, which may have arrived in France from the Far East via a shipment of Chinese pottery in 2004, pose a major threat to France's beekeepers. Experts report that it takes only a few of the hornets to destroy a nest of 30,000 bees.

Of even greater concern are the effects upon France's renowned wine industry, which contributes $13 billion to the nation's economy and is intricately linked to French culture. The immediate effects of higher temperatures were beneficial, as warming produced wines with higher sugar and alcohol levels and lower acidity. However, droughts have plagued Provence and other areas of southern France, and even the northernmost areas of Alsace and Champagne have experienced harvest seasons that have moved from the traditional October harvests to as early as August. Bernard Seguin, a French climatologist, compared a one degree increase in temperature in a vineyard to moving the vineyard 124 mi. (200 km.) south. Scientists point out that the highly detailed records maintained on wine grapes over generations along with the grapes' unusual sensitivity to climate changes make them a valuable tool for studying effects of the changes on the rest of the ecosystem.

While scientists debate the theories, France has taken practical action, including making environmental protection a part of its Constitution and formulating a Climate Plan, begun in 2004, and updated annually, that targets every area of French life that can help reach the national goal of saving 54 million tons of CO_2 by 2010. Increasing public awareness of the problems and the individual role in the solution has been an important component of the plan. An 80 percent public awareness of global warming in France suggests that the goal of informing the public has been achieved. France also made an early commitment to protecting open spaces. Nearly 30 percent of France's land area today consists of forests and woodlands. Reforestation has become a common strategy to decrease CO_2 emissions, but the French government has been subsidizing reforestation since 1947, and it earmarked tens of millions of euros to aid communities and individuals in renewing privately-owned forests 2000–10.

Perhaps the most dramatic and consequential measure France has taken to deal with the problems of global warming is to rely on nuclear power as its chief source of electricity. Energy production by wind power and biofuel have increased in France, but it is the 80 percent of its energy needs being met by nuclear power that gives France the cleanest air among industrialized nations. The energy produced by the nuclear plants is also inexpensive, making it an ideal export to other European Union (EU) nations such as Germany, Italy, and England. The 58 nuclear power plants in a nation roughly the size of Texas also account for France's 40 percent reduction in CO_2 emissions and 70 percent reduction of nitrogen oxide and sulfur dioxide emissions. France's emissions of greenhouse gases are the lowest among the EU powers, and they are still declining.

Among the major Western European nations, France is closest to fulfilling is Kyoto Protocol responsibilities. President Nicolas Sarkozy, who was elected in May 2007, promised tax reforms that include a new tax on CO_2 emissions and a tax on goods imported from countries that have not signed the Kyoto Protocol. France seems positioned not only to hit its own targets in the world response to global warming, but also to influence nations that have elected not to comply.

Friends of the Earth

FRIENDS OF THE Earth (FoE) is a nongovernmental organization that focuses on the relationships between human rights, social justice, and environmental issues. The vision for FoE is "of a peaceful and sustainable world based on societies living in harmony with nature." FoE implements this vision by campaigning, undertaking education and awareness-raising programs, and by building networks and collaborations from grassroots to global levels. Founded in 1961, FoE's inaugural members included France, Sweden, England, and the United States. By 1981, a small International Secretariat had been established, and by 1983, FoE had 25 members, with an Executive Committee that worked on the issues in between meetings. All new FoE groups must adhere to strict criteria, ensuring consistency across the world in FoE actions and campaigning. Today, there are over 68 Friends of the Earth member groups, both national and local, that work toward implementing the FoE vision. FoE operates as a federation of autonomous environmental organizations from all over the world, and has a membership of 1.5 million in 70 countries.

FoE has a history of initiating many campaigns across many issues. For example, during the 1970s, FoE negotiated and worked on a campaign that supported protection of various whale species, without destroying economic livelihoods. In the 1980s, FoE undertook a number of tropical rainforest campaigns that helped to highlight the changing circumstances of the world's indigenous peoples living in these areas. In Europe, FoE focused on issues such as the effect of acid rain, air pollution, packaging, and biotechnology. In these contexts, FoE has often acted as the third party in court cases, raising awareness of and trying to change outcomes of some developments. For example, in the case *Friends of the Earth Inc., et al. v Laidlaw Environmental Services (TOC), Inc. 2000,* heard in the U.S. Supreme Court, FoE filed a citizen suit against Laidlaw. FoE alleged that Laidlaw was noncompliant with a National Pollutant Discharge Elimination System (NPDES) permit granted to Laidlaw and sought declaratory and injunctive relief and an award of civil penalties.

While FoE campaigns on many issues, it is currently prioritizing climate change, which it believes is the biggest environmental threat to the planet. Initiatives have included: demanding strong national emissions reductions target; bringing lawsuits against major polluters, such as oil corporations; challenging a number of big oil projects around the world projected to accelerate climate change; and joining forces with climate-affected communities to facilitate a global movement that will redress social and economic equity issues between and within countries.

For example, in 2003, FoE launched a Climate Justice program. This program involves supporting people, and initiating legal challenges to governments, related to climate change. Challenges to date have been: against the Bush administration's export credit bodies for not doing climate change accounting when providing monies for fossil fuel projects, and, in 2004, against the German government for its lack of transparency in fossil fuel projects. FoE is also working with indigenous peoples, such as the Inuit, who are developing a petition to the Inter-American Commission on Human Rights against the United States, for violations of human rights due to climate change, especially in the areas of property, culture, and subsistence.

Finally, in 2006, FoE members from 51 groups gathered at the International Conference on Climate Change in Abuja, September 28–29, 2006, culminating in the Abuja Declaration. This document recognizes that in the context of climate change, there is a need to work toward alternative energy sources, and to pursue a different vision of an energy future. This vision incorporates the principles of abandoning the belief in export-led growth in favor of servicing local (basic) needs; restructuring the price and production of energy; developing a new approach to restructuring ownership of the energy regimes; and abandoning what FoE terms the "mistaken dichotomy" between development and environment.

The declaration calls on governments of all nations to take action on developing an alternative future. This includes calls for a global moratorium on new oil and gas exploration and development until full eco-restoration and reparations are implemented in communities already impacted by extractive industries, and for governments to develop cleaner energy sources.

Gabon

LOCATED IN CENTRAL Africa, the Republic of Gabon was formerly a French colony and has land borders with Cameroon, Equatorial Guinea, and the Republic of the Congo. Gabon has a land area of 103,347 sq. mi. (267,668 sq. km.), with a population of 1,384,000 (2005 est.), and a population density of 13.5 people per sq. mi. (5.2 people per sq. km.).

Some 80 percent of the country is covered in forests, with a small lumber industry operating to harvest mahogany, ebony, and walnut. Only 1 percent of the land is arable, with 18 percent used for meadows and pasture. In spite of significant oil production, 70.6 percent of the electric power in Gabon comes from hydropower, with the remainder from fossil fuels. This use of fossil fuels, largely liquid fuels or gaseous fuels, contributes to the country's carbon dioxide emissions. In 1990, Gabon generated 6.3 metric tons of carbon dioxide per capita, but it fell considerably, to only 2.9 metric tons per person in 1991, afterwards rising slightly. Emissions fell again dramatically in 1998 to 1.3 metric tons, and by 2003 were only 0.91 metric tons. Much of the remaining emissions come from use of automobiles, leading to a small level of carbon monoxide emissions. Some emissions also come from cement manufacturing, which in 1998 accounted for 9 percent of the country's total carbon emissions.

This reduction in carbon dioxide emissions remains one of the most dramatic in the world, and came through investing heavily in hydropower. The government had also built the Transgabonais railway during the oil boom, with the first trains taking passengers in 1986. There is also a good bus service covering most of the country. The French Atomic Energy Commission discovered, in 1977, a prehistoric natural "nuclear reactor," which was located in an open-pit uranium mine at Oklo in the upper Ogooué River Valley in Gabon.

The Gabonaise government of Omar Bongo took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and two years later ratified in the Vienna Convention. Gabon was the 166th country to sign the Kyoto Protocol to the UN Framework Convention on Climate Change, which took place on December 12, 2006. The government has begun a program of establishing 13 national parks, with the plan that ecotourism could replace logging entirely as a source of income for the country.

Gaia Hypothesis

IN THE EARLY 1960s, scientist James Lovelock was invited by the National Aeronautics and Space Administration (NASA) to participate in a scientific research project aimed at trying to find evidence of life on Mars. His job was to design instruments capable of detecting the presence of life that could be sent on a spacecraft to Mars. This led him to think about what constitutes life, and how it can be detected. This culminated, in 1979, in the publication of his book *Gaia: A New Look at Life on Earth*. His hypothesis was that the Earth itself was a live organism. The term Gaia was borrowed from Greek mythology, where Gaia is the goddess of the Earth. Lovelock's thesis is that the Earth is self-regulating and that the physical and chemical condition of the Earth, as well as the oceans and atmosphere, are kept fit because the Earth, or Gaia, is actively regulated by life itself. The Gaia hypothesis is based on the belief that Gaia evolves according to Darwinian laws of self-selection. The Gaia hypothesis does not see the Earth as a sentient organism; rather, that Earth and all the systems on it are finely balanced and interrelated to create the conditions conducive to life on the planet.

According to the Gaia hypothesis, even if all human life on Earth is extinguished, the planet will self-regulate to maintain its own life, and possibly other forms of life within it. For example, Lovelock highlights the resilience of some species of blue-green algae, which are highly resistant to short-wave, ultraviolet radiation. Life overall is robust, even if humans are not. Lovelock identifies three crucial characteristics of Gaia. The first is the tendency to keep constant conditions for terrestrial life forms. This tendency predates the arrival of humans, and he argues that as long as the planet's natural homeostasis (equilibrium) is maintained, the planet will continue to survive as a whole. He argues that the history of the Earth's climate proves his theory that Gaia is a living organism, stating, "if the Earth were simply a solid inanimate object, its surface temperature would follow the variation in solar output."

Second, Gaia has vital organs at the core, as well as ones on the periphery. Lovelock argues that it is human interference with the vital organs that will determine whether or not the planet will survive. He believes that Earth can survive without 30 percent of its surface. However, he argues it is possible that the world's carbon sinks and microscopic creatures may be vital organs, due to the key role they play in maintaining the balance of the Earth's systems. Maintaining the balance within the oxygen-carbon cycle is vital to life. Other core regions within Gaia include the region between the latitudes 45 degrees north and 45 degrees south, which include the world's tropical forests and scrub lands. Any disruption of these areas may sustain perturbations so drastic that the planet will not survive.

Lovelock argues that the third characteristic of Gaia is the way in which the planet obeys the laws of cybernetics. Gaia's response to major changes to equilibrium will obey the laws of cybernetics, where the time constant and loop gain are important factors. Lovelock points to the fact that despite the Earth revolving around the sun, its mean temperature has never varied by more than a few degrees from its current levels. Thus, it has never been too hot or cold for some form of life to survive on the planet, despite changes to the early atmosphere and variations in the sun's output of energy. This is because the Earth has been able, through the law of cybernetics (as with all living creatures) to self-regulate, which includes instigating the processes of self-correction in the event of any imbalance. However, increasingly, the planet is facing pressure that may disrupt its ability to self-regulate and recover from factors that cause imbalance to the systems within it. Lovelock argues that the disadvantage of such systems is that while they may experience major change, the period within which they manifest that change is so long that there will be

According to the Gaia Hypothesis, the Earth has always been able to self-correct any imbalance.

lag time between the effect and action to mitigate it. In his second book, *The Death of Gaia*, Lovelock is very pessimistic about the outcome of this lag, arguing that in relation to climate change, a failure to take action before the full effects of the problem are seen will have disastrous consequences for life on Earth.

The Gaia hypothesis has attracted much interest. In relation to climate change, it provides an innovative scientific analysis of the planet's feedback, loop, and cybernetic systems to highlight that unless that balance is maintained, human impacts on that system will cause catastrophic effects, such as runaway climate change, and, as Lovelock concludes, of such magnitude that life will no longer exist.

Gambia

THIS WEST AFRICAN country, astride the Gambia River, is entirely surrounded, on land, by Senegal, and has a land area of 4,007 sq. mi. (10,380 sq. km.), with a population of 1,517,000 (2006 est.), and a population density of 397.6 people per sq. mi. (153.5 people per sq. km.). Some 18 percent of the land is arable, with a further 9 percent used for meadows and pasture, mainly for cattle. In addition, 28 percent of the country is forested.

The electricity production in Gambia is entirely from fossil fuels. Its main power station had the only significant failure from the Year-2000 (Y2K) computer software problem, which has since been resolved. The country has had a steady carbon dioxide emission rate per capita, at 0.2 metric tons per person 1990–2003. All the carbon emissions in the country come from liquid fuels. Because of its geography, there is little need for extensive car ownership, especially with the Gambia Public Transport Corporation providing a well-regulated bush taxi service for Banjul, the capital, and other parts of the country.

Much of the country is low-lying, and Gambia is at risk of flooding with the rising water levels from global warming and climate change, and coastal erosion. This can already be seen at the beaches around Cape St. Mary and at Kololi, where sections of what had been coastline have disappeared since the early 1990s. Dutch technology is now used to try to stem this. The Gambian government of Sir Dawda Jawara ratified the Vienna Convention in 1990, and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. The government of Yahya Jammeh accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on June 1, 2001, with it coming into force on February 16, 2005.

Geography

GEOGRAPHY IS AN academic discipline that traces its roots to classical Greece. The Greek scholar Eratosthenes (275–195 B.C.E.) is usually identified as the father of geography. He coined the term geography, which is derived by combining the Greek noun for Earth (*geo*) with the Greek verb "to write" (*graphein*). Literally translated, geography means to write or describe the Earth. Based on his travels up the Nile River and his knowledge of geometry, he was able to accurately calculate the circumference of the Earth.

Since the time of the ancient Greeks, geography has evolved into a varied discipline with many research subjects and methodologies. Some scholars have attempted to impose a narrow definition on the sprawling reach of geography. However, other geographers suggest that four research traditions have evolved within the discipline, all of which examine the regional dimensions of human and/or physical processes on the surface of the Earth. These themes include: physical geography or environmental science, the primary emphasis on natural processes such as hydrology, geomorphology, meteorology, and biogeography; spatial science, using deductive mathematical models, geographic information system (GIS) and global positioning system (GPS) technologies, remote sensing, and statistical analyses to study terrestrial processes; nature-society relations, focusing on the interface between human activities and environmental changes; and regional geography, examining people, places, and regions using an array of methodologies.

There is overlap between these traditions. The organization of geographical research into these four broad themes has been affirmed by Association of American Geographers (AAG), the preeminent American organization of academic geographers, who have organized the subsections of their flagship journal, the *Annals of the AAG*, to roughly correspond to these divisions. The Royal Geographical Society (RGS), the British counterpart to the AAG, and other organizations of academic geographers largely agree with this sweeping definition of Geography. Given the broad reach and crosscutting nature of the discipline, it is appropriate to view global warming through the prism of geography.

PHYSICAL GEOGRAPHY

Physical geographers have studied the causes and consequences of global warming from different perspectives, including biogeography, the cryosphere, geomorphology, and hydrology. For example, biogeographers have studied how rising temperatures or changing precipitation regimes will affect entire plant ecosystems or biomes such as boreal forests. They have also examined how specific plant species will cope under different climate conditions. In many instances, the research predicts that warm-weather plant species will successfully migrate toward higher latitudes. On the other hand, some cool-weather plant species found at high altitudes may die out if they are not able to ascend beyond a certain elevation to avoid the heat.

Geomorphologists suggest that global climate change could have drastic impacts on river flows, coastlines, and soils. These studies of fluvial and coastal geomorphology suggest that increased precipitation will increase flooding and soil erosion. This will, in turn, affect agriculture and other human activities.

Geographers who study the cryosphere (frozen regions of the Earth) predict large changes as a result of melting permafrost and melting glaciers. Forests and other plant ecosystems that were once protected from insects and other pathogens by freezing temperatures could be at risk as temperatures rise. If there is large-scale die-off from newly-invasive pests, dying trees can become a fire hazard.

Climatologists have focused on the potential of more frequent and more intense hurricanes and other weather events. Other topics within this subgenre of geography include the likelihood of droughts in China, and the predictions of local and regional-scale temperature variations across the globe. Of course, climatologists have been at the forefront of research documenting the existence of global warming. Climatologists have used maps to study geographic variations in oceanic temperatures and to predict future changes to ocean currents such as the Gulf Stream.

SPATIAL SCIENCE: METHODS, MODELS AND GIS

Geographers have always relied on maps to display their research findings. Research on global warming is no different. In fact, computer cartography, GIS, and remote sensing are widely used by climatologists, trained in many disciplines, as a way to catalogue the evidence for climate change in the past and to organize evidence for climate change now and into the future. Geographers can construct mathematical models that incorporate many independent variables related to temperature, precipitation, topography, atmospheric gases, population growth, industrial development, and rates of deforestation, to predict how the manifestations of climate change will vary by geographic scale and region.

Some of the data needed to build these models, such as historic temperature records, can be gleaned from secondary sources. However, much of the data needed, such as land cover or atmospheric gas composition, needs to be gathered using satellite images and other remote-sensing techniques. Satellite imagery is particularly useful for detecting changes in vegetation. Vegetation stressed due to drought, disease, or human activity can be detected using infrared filters on satellite images.

Maps, the stock-in-trade of geographers, are used by every major research and policy agency on the planet, including the U.S. Environmental Protection Agency (EPA), the U.S. Department of Agriculture (USDA), the United Nations Food and Agriculture Organization (FAO), the European Space Agency (ESA), and the National Aeronautical and Space Agency (NASA) to display information related to global warming. NASA websites offer online cartographical movie clips that show future scenarios for regional impacts of climate change.

NATURE AND SOCIETY

Geographers in this subgroup are interested in the human dimensions of global change. They are interested in the human causes and consequences of global warming. Consider the issue of water resources. The uneven distribution of water resources has caused many political confrontations in the past. Water scarcity and related water diversion projects in California, the former Soviet Union, and along the Nile River have all created regional and/or international political strife. Global warming is likely to exacerbate these issues as precipitation decreases further in some places and intensifies in others. Water resource geographers attempt to understand how human behaviors affect water supplies and how policies can be crafted to increase the supply of potable water to those who need it most.

An understanding of the geography of energy production and consumption is central to understanding the causes and consequences of global warming. Energy geography will also be essential to the development of strategies to combat global warming. Energy geographers work with climatologists to identify places with good wind energy potential. Some communities actively recruit wind power development. Others are not so sanguine. Hence, energy geographers work with land-use planners to find sites for wind turbines that are energy efficient and acceptable to communities in the area.

Geographers interested in natural resource management, tourism, and recreation also have an interest in global warming. Ski resorts increasingly rely on artificial snow to extend their seasons because of declining winter precipitation. Hence, some ski resorts may be forced out of business if alternative water supplies cannot be found. Large inland bodies of water are also affected by climate change. In 2007, the water levels in Lake Superior reached record lows. Declining water levels hinder navigation and beach access for recreation and commerce. This could have dire economic consequences for many communities that depend on tourism dollars.

Coastal and marine geographers study how temperature changes could increase sea levels, the intensity of hurricanes, and the extent of beachfront erosion. Many beach communities along the Atlantic Coast spend millions of dollars replenishing beaches that have been destroyed by severe wave action. If sea levels rise and storms become more intense, these communities will have to spend even more money maintaining their coastlines.

Damage and flooding to coastlines as a result of climate change will, of course, do more than just affect tourism. There are many large cities and population centers that exist, near or even below, sea level. Examples of at-risk regions certainly include Bangladesh, islands of the Indian Ocean, such as the Maldives, but also the Netherlands, the Florida Keys, and large cities of North America and Western Europe including New Orleans, New York City, Venice, and Copenhagen.

REGIONAL GEOGRAPHY: PEOPLE, PLACE, AND REGION

Scholars from the human geography tradition examine the political, economic, demographic, and cultural implications of climate change. For centuries, explorers have attempted to find a Northwest Passage that would shorten the sailing distance between Europe and Asia. Explorers such as Henry Hudson believed that a route existed through the Arctic Ocean along Canada's northern coast. He failed to find it, as did dozens of other explorers of note. In fact, severe weather and thick pack ice proved to be an impenetrable barrier to commercial shipping through the 20th century.

However, there is evidence to suggest that rising temperatures will melt the pack ice in the Arctic Ocean, allowing the Northwest Passage to become a viable commercial navigation route. However, there are serious geopolitical issues to resolve as Canada has declared that the passage exists entirely within Canadian waters. Other countries, such as the United States and European countries, claim that the route is an international channel independent of Canadian sovereignty. While nation-states quarrel over who has sovereignty over northern seaways, the plight of Inuit cultures goes largely unnoticed. However, many of the traditional hunting rituals and life-ways depend on frozen sea ice. However, rising sea levels and a longer ice-free summer season are causing coastal erosion that is forcing indigenous communities to relocate and adapt.

Global warming will also have economic impacts that vary regionally. Panama is currently investing hundreds of millions of dollars expanding its famous canal. However, if the Northwest Passage does become commercially viable, this might undermine the ability of Panama to recoup its investments in an enlarged canal. Other cities that depend on oceanic trade, such as Singapore and Hong Kong, may suffer economically as trade is diverted away from Southeast Asia northward through the Arctic Ocean.

Global warming may have profound impacts on where people live. Rising sea levels may force millions of people to relocate to higher ground. Changing patterns of precipitation may affect the livability of inland cities such as Phoenix, Arizona; Denver, Colorado; or Las Vegas, Nevada. These are rapidly growing cities located in arid and semi-arid environments. Phoenix and Las Vegas depend on water that is diverted many hundreds of miles. If water sources decline, this will limit the economic and demographic growth of these cities.

An important aspect of understanding geographic variation is how seemingly meaningless regional differences can become a basis for deep social inequality. Hence, a geographic perspective can help to understand, and possibly remediate, the social and regional injustices that could occur from global climate change. Hurricane Katrina and the fate of the residents of New Orleans have already given us a foretaste of how regional differences get translated into social inequalities. In the case of New Orleans, the people most severely affected were poor and from minority neighborhoods. Public health will also be affected by climate change, because a changing climate will likely cause diseases to shift into new regions. It will be the wealthy people and countries that will be most able to adapt. Global climate change will likely worsen existing inequalities. This dynamic may be repeated at different scales in different regions unless a geographic perspective is used to implement policies that promote a more egalitarian policy response to climate change.

Geophysical Fluid Dynamics Laboratory

THE GEOPHYSICAL FLUID Dynamics Laboratory (GFDL) is a laboratory in the National Oceanic and Atmospheric Administration (NOAA)/Office of Oceanic and Atmospheric Research (OAR). The GFDL aims to produce reliable knowledge and assessments of natural climate variability and anthropogenic changes. It also seeks to develop the required Earth System Models. The Laboratory is housed at the Forrestall Campus of Princeton University. The GFDL has pioneered the study of global warming as it developed the first climate models to study the phenomenon. It has also contributed the first comprehensive ocean prediction codes, and the first dynamical models with significant skill in hurricane track and intensity predictions. Most of the research within the laboratory centers around the development of Earth System Models for assessment of natural and human-induced climate change

The GFDL is involved in research to expand the scientific understanding of the physical processes that govern the atmosphere and the oceans as complex fluid systems. These systems can then be modeled mathematically and can be studied by computer simulation methods. The GDLF includes 300 researchers from all over the world. It is divided into branches. The Atmospheric Physics and Chemistry unit focuses on processes that impact the vertical structure of the atmosphere, such as convection and radiation. The group is particularly interested in the role of aerosols in climate change. The Biospheric Processes unit studies interactions between the physical climate and biogeochemical systems, and is the center for the development of GFDL's Earth System Model. The Climate Diagnostics unit compares observational datasets with models, and uses models to isolate key processes that regulate inter-annual variability in the ocean and atmosphere. The Climate Dynamics and Prediction unit is the largest group in the lab and is in charge of developing numerical models for climate predictions and projections. These predictions can range from seasonal-to-centennial timescales. Major projects include the development of El Niño predictions for seasonal forecasting, and the production of Intergovernmental Panel on Climate Change- (IPCC) class climate models. The Oceans and Climate section deals with the role of oceans in the large-scale climate system and with the development of numerical codes to simulate the ocean. Finally, the Weather and Atmospheric Dynamics unit works on the dynamics of the atmosphere, with particular attention to the interactions between waves and turbulence and the large-scale flow. The group is in charge to devise the GFDL's hurricane model.

The GFDL was first established in 1955, as the General Circulation Research Sector of the U.S. Weather Bureau and American meteorologist Joseph Smagorinsky was its first director. The General Circulation Research Sector was initially based in Washington, D.C., and began to study ways to represent the circulation of the atmosphere with computer models. Due to postwar tensions, the American Government was eager to fund projects in geophysics and computers, so Smagorinsky was able to develop his Research Sector and attract important meteorologists to work there, including climate modeler Syukuro Manabe and ocean modeler Kirk Bryan. In 1959, the group slightly modified its name becoming the General Circulation Research Laboratory. It took its current name in 1963 and, five years later, moved to Princeton University. The Geophysical Fluid Dynamics Laboratory was one of the first institutions to devote its attention to the phenomenon of global warming in the late 1960s. It produced one of the first estimates of the impact of CO_2 emissions on climate.

The GFDL has continued to research the phenomenon of global warming. It has warned that the strongest hurricanes in the present climate will be replaced by even more intense ones over the next century as the Earth's climate is warmed by increasing levels of greenhouse gases in the atmosphere. The computer simulations conducted at the GFDL have shown that the warming due to increasing greenhouse gases concentration will not be uniform throughout the globe. It will be faster over land masses than over oceans. In addition, computer simulations point out that the most intense warming will take place in winter months in the areas of North America and north-central Asia. Summer warming will be accompanied by drier land in many regions. Computer models designed by the Laboratory also agree that air temperatures of the Artic surface are extremely sensitive to climate change, doubling twice as fast as the global average. Over its 50-year history, the Geophysical Fluid Dynamics Laboratory has played a leading role in the development of computer models to predict the behavior of the atmosphere and the oceans, as well as their roles in climate change.

Georgia (Nation)

A SMALL COUNTRY with a population of under six million, the nation of Georgia is located at the juncture of Europe and Asia. In 1991, Georgia gained its independence from Russia. Despite inadequate sewage management that has left the Black Sea heavily polluted, experts view Georgia's environmental problems as less serious than those of more industrialized former-Soviet countries. National security and economic problems have demanded more immediate attention. Nevertheless, Georgia is party to a dozen international agreements on the environment, including the Kyoto Protocol and the Ozone Layer Protection, a United Nations agreement involving Countries with Economies in Transition (CEITs).

Ironically, the collapse of the Soviet Union led to a substantial decline in Georgia's greenhouse gas emissions. The year before Georgia declared its independence, its CO_2 emissions totaled 37 millions tons. Seven years later, in 1997, emissions had declined by nearly 10 million tons. The figure has begun to increase again in the 21st century. While industrial production is still below those of the Soviet-led era, traffic-related pollution is a substantial problem. Not only has the number of vehicles increased, but many vehicles are also old and poorly maintained. The quality of fuel they burn is often inferior, leading to concerns about lead pollution, as well as CO_2 emissions.

Another concern relevant to global warming is deforestation. Illegal logging has remained a persistent problem in a country where energy became scarce and expensive in the 1990s, and the poverty rate soared. Trees were felled for fuel in greenbelts, in parks, and even in city streets. Little effort at reforestation ensued. However, Georgia has rich potential for developing clean and renewable energy sources. It is the most mountainous country in Europe, and the Black Sea forms its western boundary, making both wind and hydropower feasible. Legislative action in the late 1990s made it clear that Georgia understood the need to develop its renewable resources, but development has been slow, due to economic conditions. Exploiting coal reserves was a cheaper solution to immediate needs, even if doing so increased emissions. The 2006 Yale University study ranked Georgia 75th among 133 nations in its overall environmental health, a ranking largely due to its failures in sustainable resources.

The peaceful Rose Revolution saw a pro-Western government assume power in Georgia. Committed to democratic reforms, the government has also opened the country's economy and intensified efforts to join the North Atlantic Treaty Organization (NATO) and to meet the criteria of the action plan inaugurated under the European Union's (EU) European Neighborhood Policy. One step in that plan calls for Georgia to implement its policies concerning sustainable resources. Georgia's expectation of joining NATO in the near future, and its long-range goal of EU membership, may increase concern about greenhouse gas emissions and other environmental issues.

Georgia (U.S. State)

GEORGIA IS THE largest state east of the Mississippi River. Because the economy is heavily dependent on manufacturing and agriculture, the state is involved in activities that are known to negatively affect global warming and climate change. With a population increase of 29 percent 1990–2001, Georgia's carbon dioxide emissions rose by 16 percent. As a result, Georgia ranks 11th in the nation in CO_2 emissions. Overall, global warming pollution in Georgia increased 26 percent 1990–2004. Georgia ranks second in the nation in pollution produced from electric power plants because of eight coal-fired plants built before the concept of global warming was understood. Because Georgians recognize the threat that global warming and climate change pose to health, the environment, and financial prosperity, the government has joined with nongovernmental organizations and the business community to establish programs that focus on energy, agriculture, forestry, transportation, and waste management. The state is under intensive pressure to force power companies to replace the polluting facilities and develop alternative energy sources.

The Georgia Environmental Facilities Authority (GAFA) and the Georgia Department of Natural Resources share major responsibility for managing Georgia's responses to global warming and climate change. Other entities involved include the Department of Agriculture, the Forestry Commission, and the Soil and Water Conservation Commission. GAFA works with county and city governments, other state agencies, and private organizations to promote responsible environmental practices. The Environmental Protection Division (EPD) of the Department of Natural Resources administers 26 state environmental laws and works with the U.S. Environmental Protection Agency (EPA) to implement four federal laws. EPD has the authority to impose fines and shut down facilities that are not in compliance. Various divisions within EPD have direct responsibility for meeting established standards. For example, the Fuel Storage Division monitors the maintenance of fuel tanks. In 1991, Georgia created the 15-member Governor's Environmental Advisory Council to evaluate the effectiveness of the state's environmental programs and make suggestions for improvement.

Atlanta is the state capital and the center of population and industry. Composed of 13 counties, metropolitan Atlanta ranks ninth in population among American metropolitan areas. The vast majority of the people who work in Atlanta commute from other areas, presenting major pollution problems. The Hartsville-Jackson International Airport is the busiest passenger airport in the world, increasing levels of toxic emissions in the Atlanta area. Special attention is paid to eastern Georgia, which borders the Atlantic Ocean. Global warming poses a major threat to this area because of rising sea levels, potential coastal erosion, and loss of wetlands. If coastal marshes are destroyed by salt-water intrusion, the fishing industry would suffer, and the habitat for ocean life and wintering waterfowl would be greatly compromised. Controlling global warming and climate change is also essential to protecting the ecosystems of the 328 species of birds, 92 species of mammals, 83 species of reptiles, 250 species of fish, and the 77 species of amphibians that are found in Georgia. The state's forests are at particular risk from rising temperatures, which increase the threat of massive fires such as those that spread from South Georgia to Florida in 2007. Smoke from those fires blanketed much of the state, creating health and environmental problems.

In order to deal with the ongoing problem of reducing global warming and climate change, Georgians have instituted a number of programs. The Georgia Weatherization Program, for instance, provides assistance to low-income people, with preference given to the elderly, the disabled, and families with children, to make their homes more energy efficient. The program has served nearly 8 million homes since it was created in 1976, reducing CO_2 emissions approximately one metric ton per home served.

In response to high pollution levels of ozone and particulate matter in Georgia, the state has passed strict vehicle emissions standards for residents of the metropolitan Atlanta area. To encourage carpooling, vehicles carrying multiple passengers are allowed to drive in High Vehicle Occupancy lanes on downtown sections of Interstates 85, 75, and 20. Plans to extend areas covered by the Metropolitan Atlanta Rapid Transit Authorit (MARTA), Atlanta's mass transportation system, are generally viewed as one of the most effective ways of reducing metropolitan pollution. Metropolitan Atlanta leads the nation in the number of vehicle miles traveled daily, with a yearly average of more than 40 billion miles each year. Particularly during hot, humid summers, air quality has, at times, been so poor that the state has been in danger of losing federal construction funds. The smog that blankets the city during periods of heavy pollution is a major health and environmental concern.

Since 1996, the Clean Air Campaign, a nonprofit organization comprised of more than 70 groups, has been involved in raising public awareness and in exerting pressure on state and local legislators to improve air quality in the Atlanta area. Program officials work closely with the Department of Natural Resources and the Department of Transportation. Activities are largely funded through Congestion Mitigation and Air Quality grants and matching state and corporate funds. Efforts to reduce pollution in the metro area include working with the public and businesses to promote the free Ride-Matching program and encouraging telecommuting, walking, biking, and riding MARTA. The success of the Clean Air Campaign is documented by significant reductions in nitrogen oxide and CO_2 emission levels, traffic congestion, and fuel consumption.

The State of Georgia offers tax relief to companies that institute emission-reducing programs such as the Advanced Travel Center Electrification (ATE) program, which was established to provide long-haul truckers with an alternative to the practice of idling trucks while drivers rest, releasing tons of CO_2 and pounds of NO_x and CO_2 into the air each year and wasting valuable fuel. ATE offers an external system, which can be mounted on the truck to provide heat, air, power, internet access, television, and phone services while the truck is turned off. Revenues from the program are shared between ATE designer, IdleAire Technologies Corporation, and parking space property owners. The Congestion Mitigation and Air Quality Program offers some funding for the ATE system, and the state matches 20 percent of project costs.

Farming is the largest industry in Georgia. By cutting down on the use of fuel-consuming equipment, Georgia's No-Tillage Assistance Program (NTAP) works with the agricultural sector to reduce global warming. NTAP offers funding for leasing no-till equipment such as energy-efficient terrace plows, drills with small seed attachments and acreage meters, tractors and trailers that work with these plows and drills, row crop planters, hydro-seeders, and sprig spreaders. The Resource Conservation and Development Council maintains the equipment at branches throughout the state. GEFA and RC&D bear most of the cost, but farmers pay a small rental fee. More affluent farmers have purchased their own equipment. Official estimates suggest that Georgia has saved almost 3 million gallons of fuel since the program started in 1987, reducing CO_2, NO_x, and CO emissions by tens of thousands of tons.

Geospatial Technology

GEOSPATIAL TECHNOLOGY INCLUDES three different technologies that are all related to mapping features on the surface of the Earth for environmental management. They are geographical information systems (GIS), global-positioning systems (GPS), and remote sensing (RS). This is also synonymous with spatial information technology. Together, the three components of geospatial technology can track, map, analyze, and disseminate environmental management information. RS technology helps survey the entire Earth with unprecedented regularity, thus any environmental change can be noticed. Global atmospheric conditions are monitored on an hourly basis by weather satellites. RS imagery provides information on drought, vegetation, flood damage, forest fires, deforestation, and other natural disasters. GIS provides the tools to accurately map this information in both global and local perspectives. GPS technology accurately tracks the position of environmental fallout.

Geospatial information technology can play a vital role in global warming research by helping to make a connection between climate change and individual people. It is best achieved by mapping the impact of climate change at the local level through the use of satellite imagery. Thus, the public will be aware of the actual impact of global warming. Through the use of Web GIS, a virtual globe can be created and presented with environmental change information such as atmospheric, societal, and ecological changes occurring around the world. Virtual globes are a new medium for conveying information; one example available to the public is through Google Earth and Map.

Geospatial technology provides resource managers, as well as general public, with the insight and ability to react to climate change. One can monitor, map, and share the effects of: El Niño Ocean warming and La Nina ocean cooling; tropical forest depletion; the melt-down of sea glaciers in Antarctica or at the poles; vegetation monitoring through detailed knowledge of soils, erosions rates, nutrient cycles, and local agricultural practices; and water resources management through weather monitoring. With GIS, the global temperature pattern is mapped and shared among users. Researchers are using geospatial technology to quantify the carbon amount in biomass and using that information in carbon sequestration. Researchers at The Massachusetts Institute of Technology (MIT) with ESRI software have developed a Carbon Management Geographic Information System for the United States in order to capture, integrate, manipulate, and interpret data relevant to CO_2 capture and sequestration. Precipitation

One way geospatial technology can help make individuals more aware of the impact of climate change is via satellite imagery.

and rainfall pattern changes are consequences of global warming. These patterns are mapped and analyzed locally and globally.

Geospatial technology helps in understanding and mapping the patterns of vulnerability with planning climate adaptation strategies. Vulnerability analysis, or the degree to which people or the environment may be harmed, requires integrating three types of information about society and environment interactions, including: patterns of exposure to hazards, sensitivity, and resilience. Sensitivity includes the amount of damage expected from a particular event such as coastal flooding, a hurricane, or an excessive heat wave; and resilience includes the capacity to recover from the vagaries of climate change. Researchers use the spatial information technology to prepare society to withstand the challenges. Hotspot identification and analysis is a prime tool of geographic information sciences. Through geospatial technology use, governments can identify factors and hotspots responsible for global warming and climate change and locate areas affected by them. Governments can then act accordingly to save vulnerable populations. Thus, the use of geospatial technology can help in mitigating global warming problems and aftereffects.

Germany

GERMANY IS LOCATED in Central Europe, and in recent years has emerged as a leader in the fight to combat global warming. A modern nation of 82.4 million people, with a stable and diversified economy, Germany has a highly developed industrial, commercial, and agricultural infrastructure, all of which will face challenges as the climate begins to change. Like the rest of Europe, Germany expects to see more extremes in its weather patterns, with milder, wetter winters and hotter, drier summers. Steady distribution of rainfall throughout the year will likely give way to long dry periods, punctuated by sudden, heavy downpours. Most models project an average temperature increase of 0.18–0.81 degrees F (0.1–0.45 degrees C) per decade, and an increase in precipitation increase of 5–10 percent by 2050.

Agriculture will at first benefit from higher atmospheric concentrations of CO_2, and researchers do not expect any problem with crop yields in the foreseeable future, except in eastern Germany, where the sandy soil is more vulnerable to precipitation shifts. Forests, which cover a third of the country, may also fare well under rising temperatures. There is some concern, however, that precipitation extremes could stress the forest ecosystem and new insects and diseases could move as their ranges expand. Prolonged dry spells could also increase the risk of forest fires. Models predict a negligible sea level rise of 0.03–.034 in. (0.09–0.88 cm.) over the next century. Since Germany currently builds coastal structures based on an assumption of a 10–12 in. (25–30 cm.) rise over a century, this modest rise will pose no real problem. The government is planning on continuing to enhance sea walls and other defenses to protect against higher storm surges.

More intense storms could also lead to increased incidence of hail, wind, and flooding rains, putting infrastructure at some risk for damage or destruction. Shipping and air transport could also be affected by more frequent or heavier storms. While the popular summer resorts along the Baltic Sea are likely to benefit from warmer summers, the ski industry will sustain losses from warmer winters and reduced snow packs. The nation's water supply is not believed to be at risk, and there is little fear of new diseases moving into the region; in this respect, Germany will fare better than many other parts of the planet. Germany has taken a number of affirmative steps to mitigate carbon emissions and develop sustainable and renewable resources.

Ghana

LOCATED IN WEST Africa, Ghana was formerly the British colony of the Gold Coast, and has a land area of 92,098 sq. mi. (238,534 sq. km.), with a population of 23 million (2005 est.), and a population density of 215 people per sq. mi. (93 people per sq. km.). The country's economy has an extensive agricultural base, with 12 percent of the land arable, and a further 22 percent used for meadows and pasture, mainly cattle, but also sheep and goats. The cattle are responsible for some of the methane emissions. Forests cover 35 percent of the country, and the timber industry is regulated.

Ghana has had a relatively low per capita carbon dioxide emission rate, with 0.2 metric tons per person in 1990, rising to 0.37 metric tons per person by 2003. Some 77 percent of this comes from liquid fuels, the vast majority from the transportation sector, which makes up 42 percent of the country's carbon emissions. The remaining 23 percent of carbon emissions comes from cement manufacturing, and a negligible amount from solid fuels. The main reason for the extremely low per capita carbon emission rate is because 69.6 percent of Ghana's electricity production comes from hydropower, with the remainder from fossil fuels. There is also an efficient train service covering Accra, Kumasi, and Takoradi; and bus service connects the major towns.

Global warming is expected to lead to an increased rate of flooding in Ghana. This may provide the possibility for further mosquito breeding, leading to higher rates of malaria and dengue fever, and may also cause the spread of bilharzia. The Ghanian government of Jerry Rawlings ratified the Vienna Convention in 1989, and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. Ghana accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on May 30, 2003, which took effect on February 16, 2005.

Glaciers, Retreating

THERE ARE GLACIERS in all areas of the globe. Most glaciers are found in the polar regions, but many of the Earth's tallest mountains also have glaciers. Glaciers go through life cycles. They have growing years, moving years, and retreating years. For glaciers to form, very specific climatic conditions are necessary. They are usually found where there is enough snowfall for a snow pack to permanently accumulate, where summers are not warm enough for all of the snow to melt. In some regions, such as at the North Pole, the intense cold squeezes out moisture as rain or snow before it advances to the far north. This makes the Arctic region a cold desert because the cold prevents the accumulation of snow. However, in warmer areas, the greater amount of moisture combined with sufficiently low temperatures encourage snow and the possibility of glacier formation.

There are two major kinds of glaciers: continental glaciers and valley glaciers. Continental glaciers are often called ice sheets—the glaciers in Antarctica are continental ice sheets. For practical purposes, the entire continent is locked in a single combined glacier. It is also a slow growth glacier because the low level of moisture adds only small amounts of snow each year. Alpine glaciers form in high mountain areas. In Africa, Mount Kilimanjaro has a glacial field. There are many other glacial areas such as those in the mountains of western North America and South America. New Zealand's South Island has glaciers, as do the Himalayas and the Alps in Europe.

Glaciers form because every year more snow remains than there was the previous year, because not all snow melts during the summer. As the winter snow accumulates, its weight turns the snow beneath it into ice. The snow that remains is called firn. As more snow falls, it and the snow above it compress the firn into buried layers that become thickened masses of ice crystals. In the second phase of glacier life, they move or flow. The sheer weight of the ice causes continental glaciers to move outward from a central point. As the ice is deformed internally by the weight of the ice above it, a thin layer of water forms at the bottom and the glacier then follows gravity's pull down the path of least resistance. The water may be from summer melt or from the pressure.

If the mountain slopes upon which a glacier has formed are steep, its movement may be rapid. The moving ice has internal stresses that cause fracturing into cracks (crevasses) that form at the surface of the glacier. Moving glaciers also have a dramatic impact on the environment. They scour the surface beneath them and scrape the sides of the mountain where they are flowing like frozen rivers. They crush rocks into pebbles and soil. As a glacier passes, there is erosion and then deposition of the glacial debris as moraines, drumlins, and eskers. Glaciers eventually melt and leave behind rocky debris. They also leave scoured areas, valleys, and mountainsides. The causes of glacial retreat are increases in temperatures, evaporation rates, and wind scouring that promotes sublimation. In the summertime, glaciers undergo a natural retreat in the form of ablation. A glacier will grow and move as long as more snow accumulates than melts. When there is more melting than accumulation, the glacier will eventually decrease in size or disappear.

In the northern part of North America, the glacial remnants of the last ice age are visible in many places. From New York to Labrador in the east, there are scoured mountain valleys and mountaintops. In the midwestern states and provinces, the lines of moraines and other glacial debris deposits can easily be seen from the air. Farmers as far south as Iowa plow in fields that are composed of glacial soil and where composts are easily seen. The shores of the Great Lakes provide other evidence of previous glacial activity. The retreat of the glaciers since the last Ice Age has continued slowly, until recently. Today, there is evidence of rapid melting in the alpine glaciers. The snows of Mount Kilimanjaro may disappear by 2030 if the melting continues. Other alpine glaciers in North America and in many other locations are also in retreat.

The alpine glaciers seem to be melting the fastest because they are the smallest and the most exposed to the global rise in temperatures. For example, the Franz Josef Glacier in New Zealand retreated rapidly over a 15-year period during the 1950s and 1960s. Other glaciers are also in rapid retreat such as the Quelccaya, Huascaran, and Chacaltaya glaciers in the Andes. Glaciers on tropical mountaintops are among the retreating glaciers. Photographic evidence, from as recently as 10–50 years ago, provides irrefutable proof that glaciers are retreating rapidly. The retreat of glaciers threatens the world's water supplies because snowmelt from mountain glaciers will be reduced when the glaciers are gone. The loss would also mean the loss of species that have adapted to cold water. Fish and plant that are used for food would be lost as well. Also, if the continental glaciers melt, sea levels will rise.

Glaciology

GLACIOLOGY IS THE study of the formation and movement of glaciers and their response to climate change. It included studying the past positions of glacial ice, monitoring changes in present-day ice, and forecasting the future behavior of the world's glaciers and ice sheets. Because glaciers respond directly to changes in air temperature, they are one of the key indicators of climate change on the planet. Understanding the behavior of glaciers is important to understanding the effects of climate change. Although climate change is a central focus of glaciology, this discipline also incorporates aspects of geophysics, geology, climatology, hydrology, and geomorphology.

GLACIERS AS TOOLS TO RECONSTRUCT THE PAST

The landscapes left behind by retreating glaciers can be valuable tools for glaciologists to reconstruct the past positions and characteristics of glacial ice. End moraines, for example, are formed when sediment that is eroded and transported by glacial ice is deposited at the front of the glacier in piles of rock and soil. These moraines usually mark the maximum extent of the glacial terminus, or snout. Often, glacial valleys contain numerous sets of end moraines that correspond to either the last Ice Age or smaller, more recent advances, such as the Little Ice Age in that ended in the mid-1800s. Wood that is buried in these moraines can be carbon dated to help scientists determine the age of these landforms.

Glaciers also retain evidence of past climates within layers of accumulated ice. Because snow in the accumulation zone is progressively buried, glacial ice is older toward the bed of the glacier. Glaciologists drill cores through glaciers and ice sheets to sample ice of different ages. They measure the ratios of the isotopes of oxygen and hydrogen in the ice to gain information about past atmospheric temperatures. They also extract ancient air that is trapped in small bubbles deep within the ice. This can tell scientists about concentrations of greenhouse gases, such as carbon dioxide, in past climates. The levels of methane also reveal information about the level of biological productivity in the past, while traces of sulfur are indications of volcanic activity. If the time of the eruptions is known, these layers of volcanic material can be used to help date ice cores.

The oldest ice exists deep within polar ice sheets and many ice cores have been drilled in Antarctica and Greenland. The Vostok ice core from central Antarctica, for example, dates back more than half a million years and has provided a wealth of information about past atmospheric conditions. Ice cores from alpine glaciers in the world's major mountain ranges are not as old because this ice tends to flow more quickly and is much shallower than ice in polar ice sheets. These cores however, have provided glaciologists with a wealth of information about past climate change at lower latitudes (closer to the Equator). This information is invaluable because it provides proxy climate records for many centuries prior to the first recorded measurements of atmospheric conditions.

STUDYING PRESENT-DAY ICE

Glaciers are often referred to as global barometers because they respond rapidly to changes in air temperature. They are one of the most visible indicators of climate change on the planet and, thus, glaciologists can learn a lot about the world's climate changes by monitoring the way that land-based ice is growing or shrinking.

The most common way glaciologists monitor the health of a glacier is to measure the mass balance, or water budget. The mass balance of a glacier is found by measuring the rates of ablation (melting) compared to accumulation. The difference between the accumulation and ablation for a given year describes the annual net mass balance, which corresponds to the change in glacier volume. During cooler periods, the rate of accumulation usually exceeds the rate of ablation, and during warm intervals, the reverse occurs. Glaciers respond to these changing temperatures to try to attain a neutral mass balance, where accumulation equals ablation. They do this by retreating and thinning in warmer climates and advancing and thickening in colder climates. This ongoing fluctuation in glacial ice volume has a profound effect on the amount of liquid water that is available to the hydrological cycle. For this reason, mass balance measurements are a key tool for forecasting the water supply in mountainous regions.

Ground-penetrating radar is another commonly used technique to study glaciers. Glaciologists drag the radar over the ice surface to get a picture of the shape of the topography under the glacier. Because conditions under the ice play a huge role in the flow rate and behavior of glaciers, this technique is very useful for learning about the characteristics of the ice-bedrock boundary. Scientists often measure the speed of ice flow by placing markers (such as vertical stakes) in the ice and using a global positioning system (GPS) to track their movement.

Glaciologists have developed other tools to monitor ice over very large areas, such as the Greenland and Antarctic Ice Sheets. These include the use of satellite data to measure the changing surface area of the world's ice, and laser altimetry, which is used to measure changing surface elevations. Together, these tools can be used to remotely assess the mass balance of major ice sheets. While they will not completely replace ground-based observations, these techniques are effective because they allow a large amount of data to be collected in a short time. They also cost a fraction of the amount that is required to conduct field-based measurements in remote areas.

RESPONSE OF GLACIERS TO GLOBAL WARMING

Glaciologists use their knowledge of glacial dynamics to understand how the planet's ice is responding to climate change, and to predict how this response may change in the future. Because Antarctica and Greenland house a large proportion of the world's ice, these regions are a key focus for glaciological research. These glacial systems are the largest on the planet and, while they respond more slowly to changes in atmospheric temperature than alpine glaciers, the sheer volume of ice that they contain means that they could play a central role in future sea level rise. Glaciological research in polar regions focuses on large outlet glaciers that drain ice from the interior of the giant ice sheets to the coast. Scientists monitoring these glaciers have found that the flow rate has increased over the past few decades in areas such as the Siple Coast in Antarctica. This has contributed to the loss of ice sheet mass, and the collapse of ice shelves and floating glacier tongues. It has also led to concern that these glaciers may play a major role in any future collapse of the entire Antarctic ice sheet.

Although polar regions dominate the Earth's cryosphere (snow and ice), there is also a significant amount of ice stored at lower latitudes, closer to the Equator. These alpine glaciers are concentrated in the major mountain belts of the world, such as the Andes, the Rocky Mountains, the Himalayas, and the European Alps. Because these systems are smaller than those in polar regions, they respond more quickly to changes in the climate. For this reason, glaciologists also monitor these glacial systems closely and have been making mass balance measurements for more than 100 years in alpine regions. With only a few exceptions, glaciologists have found that alpine glaciers in both the northern and southern hemispheres are experiencing widespread retreat, and some have disappeared completely.

Glaciologists also use their knowledge of the physical laws that control the behavior of glaciers, along with past observations, to try to predict how glaciers will respond to different global warming scenarios. This is usually done using physical models, which incorporate natural laws. These models cannot fully represent all of the processes that occur in glacial environments, but they aim to produce a good approximation of glacial behavior. The models are tested to see if they can mimic the behavior of present day glaciers before they are used to predict future changes.

Global Atmospheric Research Program (GARP)

THE GLOBAL ATMOSPHERIC Research Program (GARP) was a 15-year international research program directed by the World Meteorological Organization and the International Council of Scientific Unions.

In 1962, after the successes of the 1957/58 International Geophysical Year, the General Assembly of the United Nations formally invited the International Council of the Scientific Unions to cooperate with the World Meteorological Organization in developing a program of research on atmospheric science. The Global Atmosphere Research Program (GARP) was the result of the work of a joint ICSU and WMO committee. The program was launched in 1967.

Led by Massachusetts Institute of Technology meteorologist Jule Charney, the Global Atmosphere Research Program played a crucial role in its pioneering influence in the use of satellites for continuous, global observation of the Earth and of computers for modeling global atmosphere circulation. The program produced some visionary collaborative experiments and results, notably the Atlantic Tropical Experiment, the first major experiment of GARP, whose goal was to understand the predictability of the atmosphere and extend the time range of daily weather forecasts to over two weeks. This experiment allowed to understand how tropical weather systems are organized and their connections with the overall tropical circulation. The experiment also provided insights into variations in surface temperature and other properties of the ocean. The experiment took place in the summer of 1974 in an experimental area that covered the tropical Atlantic Ocean from Africa to South America. The work had an international scope, and involved 40 research ships, 12 research aircraft, numerous buoys from 20 countries all equipped to obtain the observations specified in the scientific plan. The International Project Office located in Senegal acted as the director of operations. The Project Office was staffed by the nations involved. The Scientific Director was from the United States and the Deputy Scientific Director was from the Soviet Union. The operational plans were drawn every day taking into account the meteorological situation and each ship and aircraft carried out the plan. The data collected were analyzed by the nations participating in accordance with an overall plan and made available without restrictions to all scientists in the world. Research using these data still goes on today, more than three decades later, and it is estimated that over a thousand papers have been published based on the data collected during this short period in 1974. The experiment involved the world's best scientists, all types of engineers, technicians, pilots, ship captains, logistics specialists, computer specialists, as well as senior policy makers from science agencies and foreign ministries in a large number of countries. The experiment led on to the highly successful 1979 Global Weather Experiment which paved the way for the scientific foundation to restructure the WMO's operational World Weather Watch. Under Charney's leadership, GARP was the first truly international research program involving climate. Charney had always argued in favor of international cooperation in meteorology in spite of the divisive political climate of the Cold War years. The important goals reached by GARP did justice to his assertion that the lack of global observations and exchange between nations prevented examination of the global side of meteorology.

INTERNATIONAL RESPONSE

As a result of these efforts within GARP, in 1978, ICSU, WMO and United Nations Environment Program jointly organized an international workshop on climate issues, hosted by the International Institute for Applied System Analysis (IASA) in Vienna. This led to the first World Climate Conference in Geneva the following year. 300 scientists from all over the world analyzed the scientific evidence, and, for the first time, confirmed the long-term effects for global climate of atmospheric CO_2 levels. They also stressed the important role of the oceans as a major factor in the natural variability of climate on seasonal to inter-annual timescales. The ICSU and WMO closed the Global Atmosphere Research Program in 1980 and set up the World Climate Research in its place. The research carried out during GARP laid down the scientific basis for the achievement of global and long-range weather forecasts.

Global Environment Facility (GEF)

GLOBAL ENVIRONMENTAL FACILITY (GEF) is an independent financial organization that provides grants to developing countries for projects that benefit the global environment and promote sustainable livelihoods in local communities (mainly in six environmental areas: biodiversity, climate change, international waters, land degradation, the ozone layer, and persistent organic pollutants). After the Rio Convention, GEF was established to finance sustainable development in developing countries with funds from developed nations.

GEF has 177 members (also known as the GEF Assembly), which includes developed and developing countries, as well as those countries with economies in transition. Each country has a GEF representative known as a Focal Point, a designated government official who coordinates matters related to GEF governance to ensure that projects meet a country's priorities. The GEF Assembly meets once every four years to review the policies and operations of GEF. The GEF chief executive officer and chairperson leads the GEF Secretariat, which coordinates the implementation all GEF projects and programs.

The GEF Council, representing 32 constituencies (14 from developed countries, 16 from developing countries, and two from countries with transitional economies), functions as an independent board of directors, with primary responsibility for developing, adopting, and evaluating GEF programs. The council meets twice each year for three days and also conducts business by mail. All decisions are by consensus and its open-door policy towards non-governmental organizations and representatives of civil society makes GEF unique among international financial institutions.

The GEF Assembly, Council, and Secretariat approve of projects and policies, but the GEF does not implement projects. The United Nations Development Program, the UN Environmental Program, and the World Bank are some of the major agencies that are responsible for implementing and managing GEF programs. Other international organizations like the African Development Bank, Asian Development Bank, European Bank for Reconstruction and Development, UN Food and Agriculture Organization, Inter-American Development Bank, International Fund for Agricultural Development, and UN Industrial Development Organization have been added to the list of organizations executing GEF projects.

GEF-SUPPORTED PROGRAMS

GEF supports a number of programs. Renewable energy is one of the most promising substitutes for fossil fuels, which are responsible for the largest share of greenhouse gas emissions. GEF helps countries remove barriers to developing markets for renewable energies wherever cost-effective. GEF funds projects which promote the use of renewable energy, such as small hydropower generating plants, and the development of cost-effective solar voltaic cells. Such opportunities can be found in on-grid and off-grid situations, as well as in heating for industrial and other applications using renewable energy sources.

Using less energy saves money, and reduces greenhouse gas emissions. GEF supports market transformation of energy-efficiency appliances and widespread adoption of energy-efficient technologies in industry and building sectors.The transportation sector is the fastest growing source of greenhouse gas emissions. GEF supports projects that promote a long-term shift towards low emission and sustainable forms of transportation. Eligible activities include things such as: public rapid transit, which encompasses bus rapid transit, light rail transit, and trolley electric buses; transport- and traffic-demand management; non-motorized transport, and better land-use planning.

The Climate Convention guidance to the GEF on adaptation has evolved through a series of staged approaches. Originally, the GEF supported initial studies, vulnerability and adaptation assessments, and capacity building. More recently, the UN Framework Convention on Climate Change has negotiated with the GEF to support pilot and demonstration projects in the field of adaptation. Under its strategic priority Piloting an Operational Approach to Adaptation, the GEF supports projects that provide real benefits and may be integrated into national policies and sustainable development planning. In addition, the GEF supports adaptation activities through the Least Developed Country Fund and the Special Climate Change Fund.

In addition to renewable energies and energy efficiency, new technologies are critical to help prevent dangerous levels of greenhouse gas emissions, while allowing for economic development. GEF provides support for such new technologies that are not yet cost effective. The current portfolio ranges from large-scale solar power plants, to distributed power generation in fuel cells, to building-integrated solar photovoltaics.

Donor countries, usually developed countries such as the United States and Japan, contribute funds to GEF. Since 1991, GEF has provided $6.8 billion and generated over $24 billion in co-financing from other sources to support over 1,900 projects that produced global environmental benefits to more than 160 developing countries and countries with economies in transition. In 2006, 32 donor countries pledged $3.13 billion to fund operations for four years.

Natural Resource Consultant

Global Industrial and Social Progress Research Institute (GISPRI)

THE GLOBAL INDUSTRIAL and Social Progress Research Institute (GISPRI) is located in Tokyo, Japan. According to the Institute, "GISPRI's core purpose is to provide research and analysis in the area of global environment and natural resources, international systems, interaction between industry/economy and culture/society to deliver comprehensive policy proposals for the international community, both at home and abroad."

The Japanese Minister of International Trade and Industry established GISPRI December 1, 1988, in response to the recognition that Japan was emerging as a leading global nation and therefore had a responsibility to the international consortium. Japan aimed to increase research exchange. There are three main initiatives of GISPRI: Joint Research, Policy Proposals, and Research and Study. Joint Research encompasses collaboration between Japanese institutes and research institutes abroad, to share knowledge as well as human resources. Policy Proposals are arranged by the Global Industrial and Social Progress Policy Forum, and focus on international issues that Japan can address locally or through international cooperation. Research and Study is the main branch that is concerned with the environment; specifically, this branch examines the relations between industry and society, and how these interactions impact the global environment. Other, smaller initiatives of GISPRI include local and international symposia and the GISPRI newsletter.

The umbrella of GISPRI's Research and Study includes two chief areas. The first area is International Order, Culture, and Society (IOCS). IOCS is concerned with "sustainable social structure and its governance." The goal of those working with IOCS is to develop communication between developed and developing countries, to foster cooperation that will protect the environment as industrialization spreads. A major study of this area analyzed "Japan and Chinese Economy After its Accession to the WTO," 2002–03. An additional research focus under IOCS is the emerging relationship between industrialization and culture, especially the significance of nonprofit organizations (NPOs). In 2003, Japan's prime minister was presented with the results of research entitled "The Statement for the Cooperation between NPOs, Businesses, and Governments for Building a New Socioeconomic System."

The second area under the Research and Study umbrella is Global Environment and Resources (GER). GER research focuses on the necessity for sustainable resource management, recognizing the fact that if society continues to use up resources at an increasingly rapid rate, the cultures that depend on those resources will be faced with a shock once the resources are exhausted. To thwart such an occurrence, GISPRI, through its GER research, has organized a 2050 Sustainability Research

Committee (SRC). This committee will examine ways to align development with environmental responsibility and sustainability.

Another principle focus of the GER researchers at GISPRI is to develop ways to include the United States, currently the world's largest emitter of greenhouse gases, and other emitting nations to the path of sustainable environmentalism during economic development. The GER works to promote environmental responsibility, utilizing Kyoto Mechanisms that came from the Kyoto Protocol of 2005. GISPRI is managed by an executive director and other directors, most of whom serve on the boards of leading electric, gas, and other corporations in Japan. A chairman oversees the executive director and other directors. The Intergovernmental Panel on Climate Change released its Fourth Assessment Report in 2007, and GISPRI participated in the generation of this report.

Globalization

GLOBALIZATION'S BEGINNINGS ARE located in the theories of modernization and dependency from the 1950s and 1960s. The notion of globalization implies the internationalization of the world's communities in economic, cultural, environmental, and financial ways. Globalization can be understood as a series of processes. One of these processes is the way in which social, economic, political, and economic activities occur across national boundaries. The decisions that affect people in one part of the planet, will affect societies in other areas of the globe. Globalization is also the process of consolidation of all the networks between societies linked by global systems such as the global economy, digital technology, and culture. Global interactions are enhanced by global telecommunications systems, especially through satellite technology. Finally, globalization can be understood as a magnification of the impact of events. For example, if a hurricane hits the United States or a tsunami hits Asia, the whole world becomes aware of this crisis and its importance is amplified.

There are also many theories of globalization. One of these is the notion of hyper-globalization. Proponents of this theory believe that globalization is a political development that has emerged due to the fact that describing the world in terms of nation-states is no longer appropriate.

As all nations are subject to the vagaries of the global market, the idea of boundaries becomes defunct. Globalization has de-nationalized economies, and has made all nations participants in a global world. Hyper-globalizers believe the shift to globalization represents a fundamental divide from previous social, political, and social arrangements.

Others argue that globalization is not a new development, and that nation states still have an important role to play in international politics. They argue that nations have always been economically interdependent, and that global world trade therefore simply serves to intensify individual connections. Proponents of this perspective of globalization ultimately argue the idea of globalization as a Western construction designed to embed Western supremacy and economic dominance. Others take a transformalist position and view globalization as a powerful influence, transforming modern society economically and politically. A new world order is emerging, in which state sovereignty has to adapt to new world conditions and where global institutions such as the United Nations, European Union, or the World Trade Organisation need to be incorporated into national decision-making processes.

At a cultural level, globalization has led to what some term the homogenization of culture, that is, a diminishing of cultural diversity due to global trends being set and transmitted through technology, art, fashion, and film making. The global influence of stations such as CNN have led to a merging of many different cultures into one that is predominantly influenced and shaped by the Western world. Economically, the production of goods has become more globalized. For example, car parts are manufactured in different countries, and items such as cars and fridges are becoming transnational goods, which all societies can access with money.

While this has advantages, it also can create conditions of global uncertainty and impacts across the world if one market or another fails or stumbles. For example, if there is a housing and interest rate crisis in the United States, this will have impacts on economies in other countries such as Britain, Australia, and New Zealand. Some argue that the world is also moving towards a global political order, based on liberal democracy and with a mutual commitment to market capitalism and individual rights. Global institutions such as the United Nations already rule on many international issues, such as human rights and the environment.

GLOBALIZATION AND THE ENVIRONMENT

The impact of globalization has put added pressure on the environment. For example, World Bank figures show that deforestation for cropping accounts for up to 20 percent of the world's global carbon emissions. Increasing trade has also encouraged fishing, destruction of forestland, and the spread of pollution to previously unrecorded levels. There are serious equity issues embedded in the treatment of the impact of these environmental issues, and the distribution of the impact.

Detractors of globalization further argue that the free trade system that is a characteristic of globalization has particular impact on the environment, because it creates a demand for and a monopoly around genetically modified products. Moreover, the trend of globalization to patent and appropriate intellectual property rights within market mechanisms causes loss of species diversity, and imposes a monoculture on the world and its environment.

Climate change is an issue that affects all societies on the planet. Global warming is a result of global agricultural and industrial processes, all of which serve to meet the needs of the global marketplace. The consequences are also global, with all regions of the world predicted to experience some form of change as a result of global warming. One of the characteristics of projected climate impacts is that the effects will not be evenly distributed. For example, many developing countries such as Bangladesh that do not proportionally contribute largely to the global emissions will sustain critical problems as a result of flooding from sea level rise. Global warming has the potential to cause economic and social disruption around the globe, but the main burden of negative impacts will fall on poor developing tropical countries, while more affluent and developed countries in temperate zones will experience fewer or less severe negative impacts. Some reformers advocate a global climate agenda that ensures that global equity issues are addressed.

ADDITIONAL ENVIRONMENTAL PROBLEMS

Other examples of global environmental problems include acid rain, the dumping of wastes in international waters, and the depletion of climatic ozone. The loss of species, biodiversity, and resources will continue to have global implications. Global institutions are working to resolve environmental problems. Many of these institutions have emerged within the umbrella of the United Nations (UN) and include agencies such as the International Union for the Conservation of Nature, the UN Educational, Scientific and Cultural Organisation, and the UN Environment Program.

Some examples of joint commitments made in the interests of the global community include the Kyoto Protocol for Climate Change, the Montreal Convention (which dealt with ozone issues), The UN Law of the Sea (1972), and the Basel Convention (1989) that binds countries to agreements relating to the transport and disposal of hazardous wastes.

Global Warming

GLOBAL WARMING IS a term that is used to refer to an increase in Earth's average surface temperature. It is due mostly to the release of greenhouse gases (GHGs) into the atmosphere by human-fuelled activities such as increased fossil fuel consumption leading to the release of carbon dioxide (CO_2), the increasing use of automobiles, the use of nitrogen base fertilizers, and rearing and breeding large methane-belching cattle. Greenhouse gases such as carbon dioxide, nitrous oxide, water vapor, halocarbons (chlorofluorocarbons and hydrofluorocarbons), methane, and ozone have the capability of absorbing infrared radiation from the Earth's surface, thereby altering the heat balance of the Earth.

The gases later warm the Earth's surface by emitting trapped energy. When GHGs absorb radiation, the stratosphere becomes warm and then re-emits infrared radiation back to the Earth's surface. This warming of the Earth's troposphere is commonly known as the greenhouse effect. Global warming potential (GWP) is usually expressed in relation to carbon dioxide, which is given a relative global warming potential of one. Methane, nitrous oxide, and hydrofluorocarbons are assigned a GWP of 23, 296, and 12,000 respectively. This means that methane is 23 times as potent a GHG as carbon dioxide, and nitrous oxide is 296 times as potent as carbon dioxide.

Many human processes ranging from industry, transportation, power stations, agriculture, fossil fuel development and usage, to residential and commercial activities have variously led to the production of high amounts of greenhouse gases, such as carbon dioxide, methane (CH_4), nitrous oxide (N_2O), water vapor, and chlorofluorocarbons (CFCs). Of these activities, agriculture contributes the largest amount of methane (40 percent) and nitrous oxide (62 percent), while the combination of industrial processes, power stations, fossil fuel processing and development, with residential and commercial activities contributing over 82 percent of the total carbon dioxide produced by the entire human activities.

CARBON DIOXIDE

Carbon dioxide is the primary driver of global warming. It is freely available in the Earth's atmosphere, released by man and other animals, and used up by plants in the processes of respiration and photosynthesis. CO_2 is a product of the combustion of carbon related compounds such as fossil fuels and organic matter; it can be produced synthetically by acidification and decomposition of metallic carbonates, among other methods of chemical reaction. However, CO_2 is produced industrially through different processes of combustion of carbonaceous fuels, decomposition of calcium carbonates, fermentation, and from gas wells. It can also result from the oxygenation of the product of the incomplete combustion of automobile and generator fuels.

It has great industrial uses in the food, oil, and chemical industries. Of all the GHGs, it occupies the center stage of the world's basic discussion on global warming and climate change because of its effect on the environment. Human activities have contributed to a significant increase in atmospheric levels of CO_2. These concentrations have increased by 33 percent, from around 280 parts per million (ppm) as recently as the late 1700s, to 316 ppm in 1959, to 373 ppm in 2002. In the stratosphere, it is highly stable and could exist in the atmosphere for more than 100 years. This stability period means it cannot be eliminated from the Earth's atmosphere, but can only be indirectly reduced by reducing the activities producing it.

Carbon dioxide's importance in greenhouse effect is based on its ability to absorb much of the electromagnetic radiation below the visible light wavelength, trapping heat radiation that attempts to escape from the Earth, thereby causing an increase in the Earth's temperature. It is reported that doubling of CO_2 produces a temperature rise between 2.7–9 degrees F (1.5–5 degrees C), leading to a warming of between 0.9–3 degrees F (0.5–1.7 degrees C). Also, it has been established that CO_2 has significant effect in increasing the global surface temperature of the Earth's atmosphere, and of the GHGs (excluding water vapor), it is the most powerful, with a radiative forcing of 1.5 $W/m.^2$.

METHANE

Carbon dioxide is not the only GHGs increasing in its stratospheric level. Methane is also increasing in concentration. Methane is considered as an important greenhouse gas. It is believed to be the second most powerful greenhouse gas (excluding water vapour), and its concentration in the stratosphere affects the Earth's heat balance, and thus temperature. Methane

Major research findings have pointed to changes in climate temperature, including widespread melting of snow and ice and rising global mean sea level. Mountain glaciers, snow cover, and Arctic sea ice levels have also fallen.

is a natural gas with a chemical compound consisting of one carbon and four hydrogen atoms bonded covalently together, the simplest alkane, relatively abundant and gaseous at normal temperature and pressure. The Earth's crust contains huge amounts of the gas, produced anaerobically by biomethanation, and also released to the atmosphere by mud volcanoes. It is colorless and odorless, a major component of fossil fuel, about 97 percent by composition, having different uses ranging from industry, power generation, to manufacturing processes. Apart from it being a major component of natural gas, it is obtained from the anaerobic digestion of organic matter, manure, sewage, and solid and biodegradable wastes.

In the Earth's atmosphere, it adds to global climate alteration. Although not as stable as CO_2, having a stability period of 10 years, it is however, 100 times stronger than CO_2 in its greenhouse effect. A ton of methane is reported to have 25 times the temperature effect of the same size of CO_2 on the environment after every 100 years, and accounts for 20 percent of the total radiative forcing of all the combined GHGs. However, the cumulative effect of CO_2 is more than that of methane because of the enormous amount of it present in the atmosphere, with methane having a large effect on the environment over a short period of 10 years in comparison to the small effect of CO_2 over a longer period of over 100 years. The effects of methane include the absorption of infrared radiation, affecting the troposheric and stratospheric ozone (O_3).

NITROUS OXIDE
