Nitrous oxide is another GHGs whose atmospheric levels have continued to rise because of human activities. It is also referred to as dinitrogen monoxide and is a colorless, odorless, covalently bonded gas that can be produced synthetically and biologically. It is a by-product of feedlots, auto emissions, and modern agricultural practices, whose atmospheric levels have increased by 17 percent since the mid-16th century. It is also emitted from processes ranging from wastewater treatment, gas combustion, industrial processes, fertilization, and microorganism's reactions in soil and in the ocean. It has a stability period of 150 years, and is about 200 times as potent a greenhouse gas as CO_2.

Today, human-fuelled activities contribute 33 percent of nitrous oxide emissions into the atmosphere. Although the quantity of N_2O present in the atmosphere in comparison to CO_2 is very small, its effect as a greenhouse gas is much more potent; one molecule of N_2O has a heat absorbing ability equivalent to 200 molecules of CO_2. It is reported that while NO_x is partially responsible for increased ozone (O_3) production as part of photochemical smog production in urban areas near the Earth's surface, it also plays a role in its destruction in the stratosphere, where the O_3 would have been helpful in absorbing excessive ultraviolet radiation. N_2O is converted to NO in the atmosphere, which on reaching the stratosphere reacts with O_3 to result in its depletion. It is however noted that the gas absorbs thermal radiation at the same wavelength as methane. The concentration of oxide in the atmosphere is presently increasing above the pre-industrial level at a rate of approximately 0.25 percent per year, due largely to anthropogenic biomass burning and bacterial oxidation of fertilizer nitrogen; it absorbs light in a broad continuum from and including 260 nm to 182 nm.

WATER VAPOR

Water vapor is also considered a greenhouse gas. This is the gaseous form of liquid water, and is enormously abundant in the atmosphere, much more than other GHGs. There have been a lot of research arguments on the impact of water vapor on the atmosphere, but over the years, it has come to be known as the most important greenhouse gas. It strongly absorbs thermal radiation with wavelengths less than eight μm and greater than 18 μm.

HALOCARBON GASES

Another group of greenhouse gases, the halocarbon gases (CFCs) are synthetic-anthropogenic molecules that contain chlorine, fluorine, and carbon atoms bonded together. They add greatly to the atmosphere's heat-absorbing ability by actively absorbing radiation in the atmospheric radiative window of seven to 12 μm. They are non-soluble, inert, and have long stability period, capable of being broken up by photolysis to release chlorine, which in turn damage the ozone layer. Of all the chlorofluorocarbons, the significant CFCs are CFC-11 (trichlorofluoromethane) and CFC-12 (dichlorofluoromethane). The atmospheric residence time of CFC-12 is 102 years and its 100-year GWP relative to CO_2 is about 8,500, while CFC-11 has stability period of 50 years and a 20-years GWP of 5,000. Some countries like the United States and Sweden have taken steps to reduce the quantity of CFCs in the atmosphere in line with the Montreal protocol.

There are other gases that adversely affect the Earth's atmosphere, creating global warming concerns. Such gases include per-fluorocarbons (PFCs), sulphur hexafluoride (SF_6), and pollutants such as SO_2. SO_2, on the other hand, is a gas that emanates as a result of human activities from combustion of coal and the exhaust of cars. It acts to cool the atmosphere, contrary to other GHGs, however, its effects as a regulatory gas to the global warming effects of the GHGs is limited by its life span on the Earth's surface, which is not more than a week.

GLOBAL WARMING EFFECTS

Human-induced warming over recent decades is already affecting many physical and biological processes on a global scale. Major research findings have pointed to changes in climate temperature, including increases in global average air and ocean temperatures, widespread melting of snow and ice, and rising global mean sea level. Due to this changing climatic condition, much of the world's population is expected to face serious water shortages by the turn of the century, food production is expected to decline in low-altitude areas, and desertification will lead to food shortages. There are reported cases of increased intensity of tropical cyclones in the north Atlantic within the past 25–30 years, and storms with heavy precipitation have also increased. Mountain glaciers, snow cover, and Arctic sea ice have also fallen.

The report of the Intergovernmental Panel on Climate Change (IPCC) in April 2007 reveals that the rising temperature of the global environment may result in the altered spatial distribution of some infectious disease vectors, meaning that the rate of transmission of such disease like malaria in Africa and other parts of the world could increase. It is also reported that diseases such as those carried by insects, ticks, and other insect vectors are likely to be affected by environmental changes because these creatures are themselves very sensitive to vegetation, temperature changes, humidity, and rainfall.

There is the likelihood of continuous enhanced coastal erosion, increased farming seasons, increased plant growth, and increased flooding as currently observed in different parts of Asia, western Europe, and west Africa. There would also be more hot days and nights, and extreme variations in the amount of rainfall across the globe, where high altitude and generally wet places will tend to receive more rainfall, while tropical regions and generally dry places will probably receive less rain. This increase in rainfall will come in the form of more rainy days; in between these periods there will be longer periods of light or no rain, bringing about increasing frequency of drought. Hurricanes will also probably increase due to warmer ocean surface temperature.

Animal and plant species have begun dying off or changing sooner than predicted because of global warming. Global warming might spark the mass extinction of endangered species, eroding biodiversity. Several scientific reports have pointed to trends of animal populations moving northward as a result of alteration to their natural habitat; of species adapting slightly because of climate change; of plants blooming earlier; and of an increase in pests and parasites.

Global warming will potentially stifle life-giving microscopic plants that live in the surface layer of the marine ecosystems, thereby cutting marine food production and accelerating climate change. Phytoplankton are not only the foundation of the marine food chain, but every day they take more than 100 million tons of CO_2 out of the atmosphere. As global warming raises the surface layer of the ocean, it becomes lighter and, therefore, separated from the cooler depths from which the phytoplanktons get many of their nutrients. This reduces their assemblage, not only reducing the food in the oceans, but also reducing the amount of CO_2 they take from the air and, therefore, accelerating the climate warming process.

INDIRECT EFFECTS OF GLOBAL WARMING

Apart from the direct effects of global warming on the global climate, there is the issue of the indirect effects of it on the sociological, political, and economic climate of nations. It is reported that the social, economic, and physical infrastructural indices of a geographical region has evolved from the adaptation of all that region's society to the prevailing climate and to the hydrological conditions brought about by that climate over a finite time period. In cases, therefore, when the frequency of occurrence and magnitudes of phenomenon such as typhoons, floods, and droughts have altered the habitability of that region and affected the social and economic activities of its dwellers, there is bound to be the development of unwanted and unexpected stresses.

Due to these direct effects on the global climate, nations worst hit by some or few of the elements of global warming effects are most likely to suffer from increasing under population, as gradually, people begin to move away from areas of incessant flooding, drought, and erosion, to areas of calmness and freedom from such environmentally dictated occurrence. This would invariably lead to the overpopulation of neighboring towns, cities, and countries, creating attending situations associated with such phenomenon. Issues of over population have over the years been linked to over-use of available natural and developed resources. As the average population of a place begins to grow, higher demand would begin to be placed on living factors such as energy, water, space, food, good health facilities, shelter, and security. The result is that more waste would be produced due to increased human presence and activities.

There would also be the challenge of higher demand placed on available water resources, and serious deforestation as a result of people felling trees and clearing grounds for shelter and other human related activities. Forest reserves would be taken over by people, and wildlife would be seriously endangered. This could lead to the problem of erosion and water pollution, as particles of erosion could be washed into fresh water resources, creating an additional need for governments to clean up the water and make it safe for domestic use. In effect, this would bring about a depletion of available resources, carrying with it some environmental issues of degradation and mismanagement.

The problem of the environment would be further aggravated, creating a recycling of environmental disturbances and furthering the effects of global warming. In Africa and some other developing countries, over population has resulted in serious famine and poverty; there have also been cases of close to zero health care, with people suffering from serious curable and incurable diseases. More so, as people migrate from areas hit by global warming impacts to other places, there could be a greater instance of disease transfer. Diseases such as polio and malaria, which the world has been trying to curb, could upsurge. Human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS) is another human vectored disease that could increase due to huge migration of people. There could also be greater territorial wars, international disputes, and disrespect for boundary policy if the impacts of global warming are not addressed globally. Thus, global warming does not only affect the climate of nations; it also affects the sociological, political, and economic standards of nations.

Goddard Institute for Space Studies

THE GODDARD INSTITUTE for Space Studies (GISS) is part of NASA's Goddard Space Flight Center. It is one of the laboratories in the Earth Sciences Division and is a component of Columbia University's Earth Institute. The focus at GISS is the study of global climate change. Dr. Robert Jastrow established GISS in 1961 to conduct basic research in the science of space. He served there until 1981. GISS's early tasks included the study of other planetary atmospheres using data collected by space probes and images captured by earthbound telescopes. The success of these endeavors led to its development into a world-class center for atmospheric modeling of Earth's atmosphere. Today, the mission of GISS embraces the scientific study of climate change.

Dr. James Hansen currently directs the institute, with research broken up into two major areas: human influences, and natural changes in the environment across varying time frames. The second is categorized by long-term events, such as long-term ice ages, annual occurrences such as El Niño, and isolated events like volcanic explosions. Study in these areas and analysis across a wide range of timeframes fulfills key research objectives of GISS, the prediction of atmospheric changes and the impact on climate change. Tools relied upon include satellite and spacecraft observations. The data gleaned from this process defines the input to developed models used to predict oceanic, landmass, and atmospheric interactions. Coupled with previous information on Earth's changing climate and 20th century insights into the observed workings of other planetary atmospheres, GISS analysts are beginning to understand the evolution of Earth's atmosphere.

In support of this role, GISS allocates its resources across program areas, which include atmospheric chemistry, planetary atmospheres, Earth observations, radiation, climatic events, and model development. GISS resources include personnel at the Goddard Space Flight Center who coordinate with NASA colleagues at the Laboratory for Hydrospheric and Biospheric Sciences, the Laboratory for Atmospheres, and the Earth Observing System science office. Links with Maryland area universities, in particular with

Columbia University, provide almost half of the talent needed to fulfill the GISS mission of providing the critical perspective from space in the quest to monitor and predict climate change. Columbia University supports NASA through their Center for Climate Systems Research (CCSR), the Earth Institute, and the Lamont-Doherty Earth Observatory.

In May 2007, GISS publicly reinforced the fact that greenhouse gases are directly responsible for moving Earth's climate to "critical tipping points." The conclusion, derived from paleoclimate history, satellite observations, and use of predictive climate models, suggests dire consequences for Earth. GISS posits that Arctic ice, the West Antarctic ice sheet, freshwater sources, and the habitat of many species, such as the polar bear, are at risk due to global warming. The spring study determined that the 0.6 degree C rise in temperature over the past 30 years is primarily due to the corresponding increase in greenhouse gases. GISS reported that carbon dioxide concentrations in the atmosphere, for example, are rising by about two parts per million each year. The tipping point occurs when amplified effects brought on by incremental warming suddenly accelerate this steady rise. The resulting rapid rise in temperature occurs as sunlight is absorbed to a greater degree by the dark ocean waters and is not reflected back into space by the disintegrating ice sheets.

Another study published in May 2007, assists meteorologists with future temperature projections. GISS researchers predict that by the 2080s, summertime heat in the eastern United States will rise from an average in the low-to-mid-80s to one in the low-to-mid-90s. GISS notes that the past few decades have witnessed most locations in the world warming, with areas of high latitude particularly feeling the temperature rise. These warming trends are felt most in Alaska, Siberia, the Arctic Ocean, and the Antarctic. In fact, the five warmest years since the end of the 19th century are 2005, 1998, 2002, 2003, and 2006.

GISS conducts numerous other measurements and studies related to climate change. Some recent work includes investigations into how aerosol pollutants affect climate, the possibility of a massive carbon dioxide release from the ocean depths into the atmosphere, and the positive effects of dust and other pollutants blocking sunlight. The organization provides the science behind climate change to enable policy makers to enact the best legislation to mitigate the potential devastating affects of global warming.

Robert Karl Koslowsky
Independent Scholar

Gore, Albert, Jr. (1948–)

FORTY-FIFTH VICE PRESIDENT of the United States from 1993 to 2001 in the Democratic administration of President Bill Clinton, Al Gore's political career climaxed with his nomination to run as the Democratic candidate for the presidency in the 2000 election. In one of the most divisive elections in American history, Gore won the popular vote by a margin of more than 500,000 votes, but lost the Electoral College (271–266) to his Republican opponent George W. Bush.

After his failure to win the presidency, Gore, who has always been concerned with green and environmentalist issues, has devoted most of his time to ecological causes. He has focused particularly on global warming with his Academy Award-winning documentary *An Inconvenient Truth* (2006), and with the organization of the Live Earth benefit concerts in July 2007. Because of his role in bringing the problem of global warming to public attention, Gore has been nicknamed, not always flatteringly, the "Noah of Modern Times," and "The Environment Evangelist." His commitment against global warming made him a co-winner of the Nobel Prize for peace in 2007.

Gore was born on March 31, 1948, in Washington, D.C. His father was a Democratic congressman and senator from Tennessee. Gore attended St. Albans School and, in 1965, he enrolled at Harvard University, majoring in English, but later switching to government. He graduated with honors from Harvard in June 1969 with a Bachelor of Arts degree in government. Gore was then recruited into the Army and was

Albert Gore, Jr., has sometimes been called "The Noah of Modern Times," and "The Environment Evangelist."

sent to Vietnam as a military reporter. Upon his return to the United States in 1971, he started to work for the Nashville newspaper *The Tennessean*, and enrolled at Vanderbilt University to study philosophy and law.

Gore was elected to the U.S. House of Representatives starting in 1976 for three consecutive terms before winning a seat in the Senate in 1984. In 1991, he was among the 10 Democratic senators who voted in favor of American military involvement in the Persian Gulf War. The following year, Bill Clinton, the Democratic presidential nominee, chose Gore to be his running mate, and Gore became vice president following Clinton's victory against George Bush in 1992.

In 1993, Gore was instrumental in engineering the passage of the North American Free Trade Agreement. In the 1990s, Gore launched the GLOBE project, an educational scheme that made extensive use of the internet to make students aware of environmental problems. He also campaigned, although unsuccessfully, to have the Kyoto Treaty ratified by the U.S. Senate. He symbolically signed it in November 1998.

In June 1999, Gore announced his intention to run for the presidency. As a moderate Democrat, he focused his campaign on themes such as the economy, healthcare, and education. As his running mate, Gore selected Senator Joseph Lieberman, the first Jewish American to be on the presidential ticket. The election proved one of the closest in American history. During the election night, Florida became the key state as the candidate who would get the state's 25 electoral votes, would also have a narrow majority in the electoral college. Gore initially conceded defeat as the state was assigned to Bush by television networks, but, later in the same evening, he withdrew his concession, enthused that returns from Florida pointed to an increasingly slim margin for Bush.

For five weeks, the election results remained undeclared as the two candidates fought legal battles for a possible recount of the votes. Although the Florida Supreme Court passed a resolution in favor of Gore's demand for a recount, the Democratic candidate publicly conceded the election after the Supreme Court of the United States in *Bush v. Gore* ruled 5 to 4 that the Florida recount was unconstitutional and that no constitutionally valid recount could be completed by the December 12 deadline, effectively ending the recounts. Gore strongly disagreed with the court's decision, but decided to offer the concession of defeat for the sake of the American nation.

After his defeat, Gore refused to run again in the 2004 presidential election and has instead devoted his efforts to campaign for the preservation of the environment and to spread awareness about global warming.

In 2004, he launched Generation Investment Management, a firm that invests in companies taking a stand on global issues such as climate change. In June 2006, Gore founded the Climate Project (TCP), based in Nashville, Tennessee, to increase public awareness of the climate crisis at a grassroots level throughout the United States and abroad. Gore came to the forefront when he starred in the documentary *An Inconvenient Truth*, directed by Davis Guggenheim, where he argued that global warming cannot be regarded as a merely political issue, but should be treated as a moral challenge. The documentary intertwines events in Gore's life and his increasing commitment to environmentalist causes with data on the evidence of anthropogenic global warming. Released in May 2006, the film went on to become one of the highest-grossing documentaries in American history. It was well-received by both film critics and scientists, although global warming skeptics such as Reid Bryson have criticized it as an over-exaggeration. The documentary is used in science school curricula around the world. Gore also authored a companion book to the film which became a bestseller.

On July 7, 2007 Gore was one of the chief organizers of the Live Earth concerts, which took place on all seven continents to lobby individuals, governments, and corporations to take actions to solve the global warming problem. The event reached an unprecedented audience through internet and television broadcasting, but was disapprovingly dubbed as "Private Jets for Climate Change," for the amount of emission caused by the transportation of the bands and the audiences. Gore was also criticized as political opponents pointed out that the event would launch his 2008 presidential candidacy, a fact that he has vehemently denied.

Greece

OCCUPYING THE SOUTHERNMOST part of the Balkan Peninsula and more than 1,400 islands, Greece is an ancient land of great beauty and diversity. The culture of classical Greece was a shaping force in the art, literature, philosophy, and politics of the Western world. Modern Greece is a nation of 11 million people, 60 percent of whom live in urban areas. Athens alone is home to more than three million, and more than 50 percent of Greek industry is located in Athens. The population explosion into Athens and other urban areas that began in the mid-20th century has intensified concerns about air pollution and its effects on human health and the environment.

The Kyoto Protocol, to which Greece is a signatory (along with more than 20 other international environmental agreements), allowed the country to increase CO_2 emissions 25 percent 1990–2010, but Greece has already exceeded the allowed increase and is expected to generate an excess 15 million tons beyond the target of 139 million by 2010. An increase of nearly double the maximum allowed is predicted by 2020. Coal-burning thermoelectric stations produce approximately 66 percent of Greece's electricity. During a period when other nations have built nuclear power plans and/or exploiting renewable sources of energy, Greece's use of coal for electricity production has increased. The World Wildlife Fund has designated two of the nation's power stations, Agios Dimitrios and Kardia, as the dirtiest in Europe; they produce the largest number of grams of CO_2 per kilowatt-hour. These plants and others in Greece burn lignite, or brown coal, which produces higher levels of CO_2 emissions than black coal.

The European Union (EU) has challenged Greece's violation of its greenhouse gas emissions allowance and promised consequences if the goal of 20 percent energy from renewable sources by 2010 is not met. A 2006 Yale University study ranked Greece 10th among EU nations in its overall environmental health. The Greek parliament passed new laws in 2007 that provided government support for renewable energy initiatives such as wind farms, and offered incentives for private investment in renewable sources. Solar energy remains a largely untapped resource. Whether or not these new initiatives will balance the country's dependence on fossil fuels, particularly lignite, remains to be seen.

Emissions from vehicles in crowded urban centers have also increased greenhouse gas emissions in Greece. Transport consumption of energy increased by nearly 50 percent 1982–92. The country is making a concentrated effort to address this problem. The extension of the rapid transit system in Athens, with around 25 new stations to be added 2008–18, and an additional line to be added after 2018, should help to control automobile emissions within the Athens area. Thessaloniki, Greece's second largest city, began construction of a rapid transit system in 2006 that is expected to be completed in 2012.

Despite these measures, air pollution and CO_2 emissions in Greece became a greater problem in the summer of 2007 when forest fires raged between late June and late August, claiming more than 60 lives and destroying more than 470,000 acres of forests and farmland. The nation's olive crop was ravaged in the detruction. Experts estimate damages at more than $1.6 billion, or 0.6 percent of Greece's Gross Domestic Product. Living trees absorb CO_2, but burning trees release the gas into the air. Scientists say that it is too early to know how the summer fires affected emissions, but many fear deforestation will magnify the effect of greenhouse gas emissions. Because Greece is the only country in the EU without a national forest registry, any burned land can be reclassified and sold to developers. With environmentalists preducting that global warming in the Mediterranean has begun, the fear is that a hot summer, a winter drought, and strong winds may make the Greek inferno of 2007 a common occurence. While non-human sources of CO_2 are exempt from the Kyoto Protocol and, consequently, will not add to the pressure on Greece, the costs of the devastation will certainly deplete both human and economic resources.

Green Buildings

GREEN BUILDINGS REPRESENT commercial or residential buildings that are designed, constructed, maintained, and operated with energy-efficient engineering systems, responsible use of water, and recyclable materials. These buildings are becoming increasingly popular because of their environmental, economic, and social benefits due to responsible use of natural resources. As the Earth's population is increasing exponentially, the building stock that houses the population is also increasing at a similar rate. At present, in the developed countries, buildings are using approximately one-third of the primary energy and roughly two-thirds of the electricity. As a result, even modest improvements in current building practice can result in significant energy savings. Even more important is the consequent reduction of greenhouse emissions due to reduced energy consumption during the building lifecycle, which includes not only construction and operation, but also the demolition process.

Examples of green building practices include use of wind and sun for energy, ventilation, and lighting. An appropriately-oriented building, can, with its window openings, promote natural ventilation, so the use of air conditioning systems becomes unnecessary when outdoor weather is mild.

At the same time, natural lighting can reduce the need for electricity, but the window openings need to be designed to provide sufficient lighting levels without glare. The use of local materials for buildings reduces the cost of material transportation, and the use of the natural and recyclable material reduces the cost of building demolition. The building wastewater can be treated for irrigation or used as "gray water" for non-potable purposes to reduce the impact on water treatment plants.

Green roof technology has emerged as a solution that can reduce the stormwater runoff, building energy consumption, and the heat island effect in cities. A rating system from the Leadership in Energy and Environmental Design (LEED) is used for evaluation and comparison of green buildings' performance. This LEED system was developed by the U.S. Green Building Council (USGBC), and includes the following five evaluation areas: sustainable site development, water savings, energy efficiency, materials selection, and indoor environmental quality. Each of these areas has multiple evaluation criteria that potentially affect human and environmental health.

Green Cities

GREEN CITIES ARE designed and operated to have a minimal environmental impact. Green cities embrace design, construction, and operation of urban environments that are environmentally friendly, less-toxic, less-wasteful, and work more with nature than conventional cities. Pedestrian-friendly green cities are built for people, bicycles, and mass transit (as compared to conventional cities often constructed to optimize automobile transportation). Green cities are powered as much as possible by a combination of renewable energy sources such as wind, geothermal, and solar energy.

Green cities can also be known as eco-cities, eco-friendly cities, earth-friendly cities, environmentally preferable cities, and sustainable cities. Although it is unlikely that any modern city has obtained true sustainability, green cities have sustainability and even restoration of the natural environment as a goal. All cities are on a green to gray continuum, where gray represents the polluted post-industrial fossil-fuel powered city and green represents the way the area was before human intervention, the green economy based on ecologically favorable practices, or a mixture of both. The location of any city on the spectrum of gray to green will soon be able to be quantified by a forthcoming rating and certification scheme for neighborhood environmental design, Leadership in Energy and Environmental Design for Neighborhood Development (LEED-ND), developed by the U.S. Green Building Council, Natural Resources Defense Council, and the Congress for the New Urbanism. LEED-ND integrates the principles of smart growth, urbanism, and green building.

Green cities often are built on new urbanism principles, also known as traditional neighborhood design, neotraditional design, and transit-oriented development. New urbanism is an American urban design movement that arose to reform all aspects of current sprawling real estate development and urban planning, from urban retrofits to suburban infill. New urbanist neighborhoods are designed to contain a diverse range of housing and jobs (mixed use), and to be walkable. This movement seeks to restore a civil realm to urban planning and a sense of place to communities. It is a tangible response to the failed modernist planning in the United States that has resulted in unchecked suburban sprawl, non-human scale, automobile dependence, and the abandonment and pollution of the urban centers of many modern cities.

The green city represents the ultimate challenge in urban and human planning. The city must be planned so that all the elements that make it up (people, technology, nature, and material byproducts) are harmonized in aesthetic, safe, and sustainable relationships. Putting urbanism and nature together provides humanity with an opportunity to create cities that are healthy, civilizing, and enriching places in which to live. Green cities are not only designed and constructed, they must be governed and operated in an environmentally conscious manner to remain green. Green city governments use environmentally preferable purchasing programs, commercial and residential green building incentives, composting and recycling services, public transit incentives, carpooling coordination, car sharing programs (public or private), and other tools to reduce the impact of the operation of the city on the environment.

There are several advantages to living in a green city. Green cities are easily navigated by people on foot and by public transport because they are designed to the scale of the pedestrian and seek to promote a symbiotic relationship between urban development and public transportation. This reduces family transportation costs, congestion, and eliminates stressful and time-wasting automobile commutes. Those living in green cities run errands and commute using their own bodies for locomotion, therefore, they benefit from improved physical wellness. Inhabitants of green cities also enjoy health benefits because of reduced air and water pollution. Reduced air pollution improves outdoor air quality, reduces air-pollution related illness and deaths, reduces smog, and smells better than conventional cities. Reduced water pollution improves drinking water, provides opportunities for outdoor water activities (such as swimming and boating) and enables local fish to be eaten. Green cities encourage green building for construction of both homes and work places, which in addition to improving indoor air quality, saves residents and owners money on operation due to improved energy and water efficiencies. Green cities support local food and regional agriculture, and many green cities even have community gardens where residents grow fresh fruits and vegetables. This fresh produce again improves the health of the residents and in general tastes better than less fresh food. Green cities are also literally green. They promote the rebuilding of essential soil and water resources, while increasing plant and animal biodiversity. This nature, which can be found within the city, improves mental health of the occupants.

These advantages make green cities very desirable places to live. This is reflected in the increased property values found in green cities and the aggressive competition to be listed among the environmental leaders by the *Green Guide* on Earth Day. The top 10 green cities are awarded for providing energy-efficient, least polluting, and healthy living spaces, and whose green achievements set the standard for others. These standards are currently of large importance due to the lack of federal direction. Cities across the United States and the rest of the world are taking environmental stewardship into their own hands and reducing their environmental impact. In relation to climate change, city mayors working to lower greenhouse gases best exemplify this: several hundred have signed the U.S. Mayors Climate Protection Agreement.

Green Design

GREEN DESIGN, SOMETIMES referred to as sustainable design or ecological design, is a process by which products are created to be more sustainable, and last longer. The goal is to makes changes during the design and manufacturing phases so that the end products are as environmentally benign as possible. This, in turn, will reduce the ecological footprint of those using such items. In terms of green design in building construction and land use planning, there is significant potential to reduce the amount of carbon emitted in the development process and in day-to-day operations. Those implementing green design often follow a systems approach and readily utilize several sustainable design principles. The national Leadership in Energy and Environmental Design (LEED) certification program awards architects and builders for using green design methods. On a broader scale, land use planning techniques can be followed to design environmentally sustainable communities. Finally, there are some technologies and polices that advance the goal of green design.

The systems thinking approach to product development and certain green design principles are usually incorporated into the design and manufacturing phases when creating environmentally sustainable products. The systems thinking approach, also referred to as the life cycle approach, considers the environmental impacts of the materials and procedures used to create the product, the effects of the product while in use, and then the impacts of the product as it is disposed of and decomposed.

This method promotes the use of recycled materials and nontoxic substances in production. The product should then be environmentally benign while in use and easily broken down to recyclable and innocuous components at the end of its use.

There are a variety of green design principles that can be incorporated into the planning and implementation stages of production. First, the materials used to create the product should be given careful consideration. Materials that can be easily recycled at the end of the products' life cycle are desirable. Also, components that are nontoxic should be selected. Finally, to ensure that products or buildings are sustainable, renewable materials should be utilized. In the end, material selection must be balanced with cost. While using entirely sustainable materials is environmentally sound, this practice may cause the product to be prohibitively expensive. Successful manufacturers are able to find creative ways to employ sustainable materials without significantly increasing the price of the product.

Next, the reliability should be considered when creating green designs. Products that are durable and can withstand daily use are more advantageous than those that may need to be replaced in the short term. The longevity of a product is not only useful from a green design perspective, but also it makes the best economic sense. A third principal often considered in green design is energy use. This principle is two-dimensional. First, materials should be selected that do not require a lot of energy to make. Transportation of raw materials must be taken into account. Next, the product itself should not require much electricity to function. There are several programs available to have energy efficient products labeled so that consumers can easily identify them. An example of the is the Department of Energy and Environmental Protection Agency's ENERGY STAR labeling and marketing campaign for appliances.

Finally, green design focuses on creating items with shared uses. These consist of items that can be used my many individuals over the lifespan of the product. For instance, silverware has more shared use potential than plastic ware. The shared use principle may also encourage the same user to utilize the product for many different tasks, such as vacuum that is also able to wet-wash hardwood floors. In general, using a system approach and following certain principles when engaging in product design will lead to less energy and resource consumption.

The U.S. Green Building Council (USGBC) oversees a nationally accepted green design program for commercial and residential buildings. This program is referred to as the Leadership in Energy and Environmental Design (LEED) certification program. A systems approach is used and performance must be achieved in five categories: sustainable site development, water savings, energy efficiency, materials selection, and indoor environmental quality. Buildings are rated in each of these five areas and must achieve a specific number of points for different certfications. The lowest level of certification is when a building is simply considered LEED Certified. The next level is bronze certfication, then silver certification, followed gold certification, and finally the highest level is platnium certification. In 2007, only 14 states had buildings that were platnium certified.

On a larger scale, green design methodology can be used during land-use planning. Sometimes called sustainable development, land-use planning integrates urban planning, housing development, and transportation theory with environmental understanding. This may include using energy efficient lighting for buildings and street lamps or creating neighborhoods in which all amenities are easily walkable. Wildlife corridors and green spaces are usually left intact to protect native and migratory species.

Finally, green technologies are becoming more available in all communities. Wind turbines and photovoltaic cells are more common on peoples' properties and allow individuals to live off-grid or to net-meter excess energy. Many home textiles such as carpets and furniture coverings emit less volatile organic compounds (VOCs) than before. Water-saving fixtures like faucets, toilets, and showerheads are becoming the standard. The installation of these products, however, may be more expensive than conventional products. This development is slowly changing as the market turns toward homes that value human and ecosystem health.

Green Homes

GREEN HOMES ARE designed and operated to have a minimal environmental impact. They are constructed using green building techniques, which increase the efficiency of the homes and their use of energy, water, and materials, and reduce the homes' impacts on human health and the environment, through better siting, design, construction, operation, maintenance, and eventual removal. The green attributes of green homes generally include, but are not limited to, reduced toxicity, re-usability, reduced waste, energy and water efficiency, high recycled content, intelligent design, responsible manufacturing techniques, and reduction of personal environmental hazards.

The green building techniques needed to construct green homes are sometimes called sustainable building or environmental building. A similar concept is natural building, which focuses on the use of natural materials that are available locally. Green homes may also fall under the classification of sustainable design and green architecture; however, while the initial design of a home is important in making hbba green home, the actual operation, maintenance, and ultimate disposal or deconstruction of the home also have very significant effects on home's overall environmental impact.

There are several advantages to living in a green home. First, through the use of proper materials and attention to natural ventilation, green homes reduce exposure to mold, mildew, and other indoor toxins, and thus have better indoor air quality than standard homes. Homes with high indoor air quality are more comfortable and healthier places to live, particularly for families with young children. Second, because of increased efficiency, green homes reduce operating costs by using less energy and water. Finally, green homes in the aggregate have the potential to radically reduce environmental impacts on the local and global environment by reducing both pollutants and greenhouse gas emissions.

Green building is increasingly governed and driven by standards, such as the Leadership in Energy and Environmental Design (LEED) rating system developed by the U.S. Green Building Council. LEED for Homes has been developed, which is a voluntary rating system that promotes the design and construction of green homes. LEED certification recognizes and rewards builders for meeting the highest performance standards, and gives homeowners confidence that their home is durable, healthy, and environmentally friendly.

Fortunately, the net cost of owning a green home is comparable to that of owning a conventional home. This is possible, because although some green design practices cost more than conventional design, many cost less (particularly over the lifecycle) and when all practices are aggregated in smart, integrated design, they provide the green benefits without increased costs.

DESIGN FEATURES OF A GREEN HOME

Multiple design features work in tandem to make comfortable, efficient, and economic green homes.

Conventional homes are getting larger, while the average family size/occupancy decreases. Smaller homes that use space efficiently, are well-organized, and are filled with a prudent number of possessions, can not only be beautiful and cozy, but also use much less energy to heat and cool.

A home located on existing water, sewage, and roads will have less of an environmental impact than one that is not. Ideally, a green home would also be located close to community resources and public transportation in order to minimize automobile travel. Finally, homes should be in a compact development to allow for more open, green spaces.

Landscaping of a green home is designed to minimize fertilizer, herbicide, pesticide, and water use. Trees are also planted to provide shade (passive cooling for the home). Permeable paving is used to recharge groundwater and reduce surface run off. Finally, non-toxic methods of insect and pest control should be used.

Rainwater from the roof is harvested and graywater reuse systems are installed in a green home. High efficiency fixtures (toilets, showers, and faucets) are used. In some cases, even composting toilets or living machines treat human wastes.

In order to maintain high indoor air quality, all combustion devices (space heating, fireplaces) need to have proper venting, and air systems must have a method of heat recovery (such as heat exchangers). Materials such as paints and glues used in the homes also contribute to indoor air quality; green homes use products with low VOCs (volatile organic compounds), which helps maintain healthy air quality, not only for those living in the house, but also for those working on the construction of the home. Green homes also have good air-filtering, radon protection, humidity control, and protection from vehicle emissions.

Durable materials used in the construction are sourced locally to avoid unnecessary transportation. All wood is Forest Stewardship Council certified, and products are chosen from an environmentally preferable product list, which favors recycled and recyclable materials and rapidly renewable materials. Waste during construction is minimized, and waste is recycled during construction and during use (for example, through curb-side recycling and back-yard composting).

A green home is very energy efficient and meets the requirements for an Energy Star rating for the entire home, but also contains Energy Star appliances, windows, furnace, air-conditioning, and lighting. To earn the Energy Star rating, homes must meet guidelines for energy efficiency set by the U.S. Environmental Protection Agency, which typically make them 20–30 percent more efficient than standard homes. Green homes are well-insulated, their ducts are tight, and the thermal envelope is sealed to reduce air infiltration.

A green home is run by renewable energy, utilizing orientation and window placement for passive solar heating and natural ventilation/cooling, and has a solar domestic hot-water system. In addition, the green home may have solar photovoltaic panels, wind turbines, micro-hydro, or combined heat and power systems.

The physical design of the house can also lend a great deal to a green home's efficiency. Through careful attention to sizing and placement of glazing, room layouts, and positioning of various architectural elements, a wide range of benefits can be reaped. These benefits include an increase in natural day-lighting, solar heat gain or loss (based on climate), and better cross-ventilation.

Green homes are designed, built, and operated so that by using energy, water, and building materials intelligently, modern society can live well without needlessly damaging the environment.

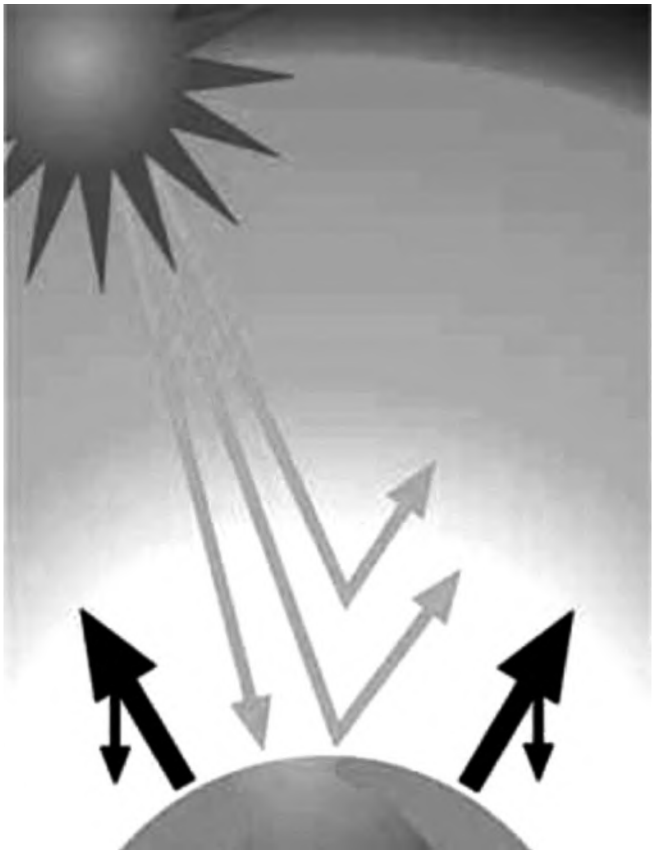
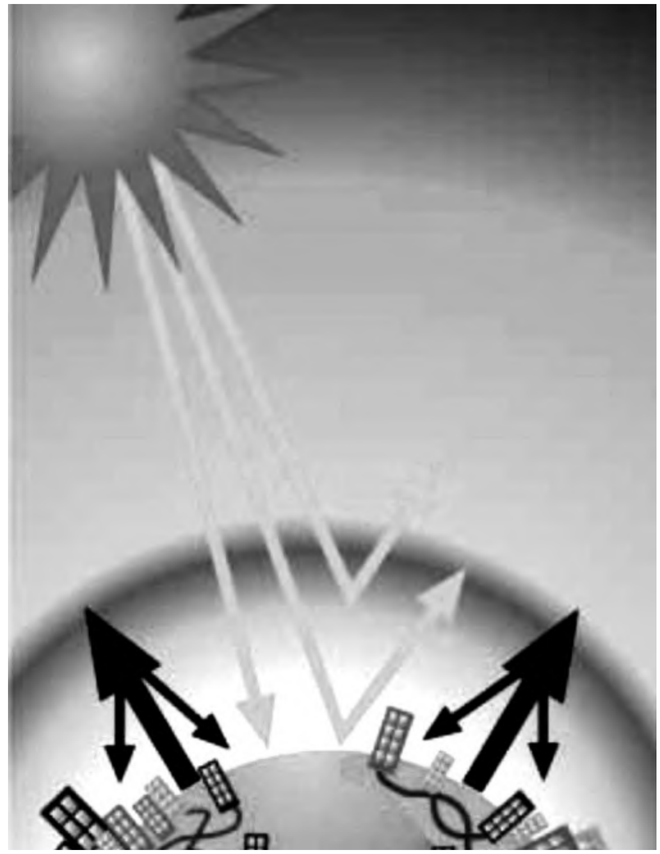
Greenhouse Effect

HUMAN ACTIVITIES CAN disrupt the balance of the natural system that regulates the temperature on



Most of Earth's heat is re-radiated toward space, but some is trapped by greenhouse gases in the atmosphere. This is a natural effect that keeps Earth's temperature at a level necessary to support life.



Human activity—particularly burning fossil fuels (coal, oil, and natural gas) and land clearing—is generating more greenhouse gases. Scientists are convinced that this will trap more heat and raise Earth's surface temperature.

Earth. This natural regulating system is known as the greenhouse effect. As human societies burn fossil fuels, and adopt it to increasingly sophisticated and mechanized lifestyles in the developed world, the amount of heat-trapping CO_2 and CH_4 in the atmosphere has increased. By increasing the amount of these heat-trapping gases in the atmosphere, humankind has enhanced the warming capability of the natural greenhouse effect.

This human influence (in addition to the natural release of these gases) on the natural warming function of the greenhouse effect has become known as the enhanced greenhouse effect. It is this human-induced enhanced greenhouse effect that causes environmental concern. This enhanced greenhouse effect has the potential to warm the planet at a rate that is unprecedented. Greenhouse gas effects due to natural phenomena have existed from the very beginning of the Earth. The rate has increased over time due to increased human activity such as industrialization, deforestation, increased fossil-fuel-based transportation, and increased agriculture to satisfy the increased population.

Another factor that is causing significant change in the atmosphere is the rising levels of carbon dioxide, due to increased burning of coal and oil, which traps more heat in the atmosphere, thus warming the Earth. This phenomenon began with the advent of the Industrial Revolution of 1800s, and has been increasing ever since. Work was done by hand and by animal power before the Industrial Revolution, but was done by fossil-fuel burning machines since the Industrial Revolution, resulting in generation of higher amounts of CO_2 and its subsequent release to the environment. It is difficult to predict the precise effects of doubling the concentration of CO_2 in the atmosphere, but doubling CO_2 should increase global temperatures.

Also, increased production of rice and growing numbers of domestic animals to feed the increasing population have resulted in increased emissions of CH_4. During the last two centuries, the concentrations of CO_2 and CH_4 (both greenhouse gases) have increased faster than at any other time in the recorded history of mankind, leading to enhanced greenhouse effect.

RESULTS OF ENHANCED GREENHOUSE EFFECT

The expected continued temperature rise due to climate change is linked to the observed build-up of greenhouse gases in the atmosphere. This will cause further warming of Earth's surface over the long term. Whether or not global warming has already begun, and if it is a direct result of the enhanced greenhouse effect, is still uncertain. The Intergovernmental Panel on Climate Change (IPCC) raised the question through the fourth report of IPCC to the United Nations (UN) in 2007. The IPCC's chairperson commented that the world still has time to reverse global warming. The decision by the Nobel Peace Prize committee to award the 2007 prize to the UN IPCC, together with former U.S. Vice President Al Gore, demonstrates that the committee considers climate change a threat to peace and that the global warming is taking place.

The enhanced greenhouse effect has already led to some severe weather patterns such as: 11 of the last 12 years (1995–2006) rank among the 12 warmest years ever recorded since global surface temperatures were measured (1850). Over the last 100 years (1906–2005), there has been an increase in surface temperature of 1.3 degrees F (0.74 degrees C), which is larger than the 1 degree F (0.6 degrees C) increase given in the Third Assessment Report for the 1901–2000 period. And the warming trend over the last 50 years (.23 degrees F, or 0.13 degrees C per decade) is nearly twice that for the last 100 years.

Temperatures in the higher atmosphere and in the oceans (to depths of at least 1.8 mi. or 3,000 m.) have also been rising, along with the water vapor content of the atmosphere. Mountain glaciers, snow cover, and ice caps have declined, on average, in both hemispheres, contributing, in part, to the rise of global sea level. The Arctic and Antarctic ice caps have also contributed to the observed rise of sea level, which amounted to a rise of 6.6 in. (17 cm.) in total over the course of the 20th century.

At continental, regional, and ocean-basin scales, numerous long-term changes in climate have been observed. These include changes in Arctic temperatures and ice, widespread changes in precipitation amounts, ocean salinity, wind patterns, and aspects of extreme weather including droughts, heavy precipitation, heatwaves, and the intensity of tropical cyclones. Some aspects of climate have not been observed to change. The difference of temperature between day and night, for example, has remained the same, since daytime and nighttime temperatures have risen by the same amount. However, even when expected natural short-term variability, such as unusually cold winters are taken into account, global temperature trends show that the Earth has warmed over the long term.

To summarize, the enhanced greenhouse effect is leading to change in atmospheric composition and climate change during the 20th century: global-average surface temperature has increased (1 degree F, or 0.6 degrees C); temperature in the lowest 8 km. increased in the past four decades, global-average sea level has risen (0.3–0.6 ft., or 0.1–0.2 m.), snow and ice extent decreased with widespread retreat of glaciers, and precipitation has increased (up to 1 percent per decade).

Since 1750, there has been an increase of: CO_2 (31 percent), CH_4 (151 percent) and N_2O (17 percent), and present CO_2 levels probably were not exceeded in the past 20,000 years.

Greenhouse Gases

THE IDEA THAT some gases trap thermal radiation like the glass of a greenhouse was first proposed by Jean Baptiste-Joseph Fourier in 1827. However, this analogy is not strictly correct, because greenhouses warm the air in their interior mainly by blocking convective mixing with the outside, not by trapping thermal radiation. However, in spite of this, gases that are relatively transparent to solar radiation and relatively opaque to thermal radiation are known as greenhouse gases. On Earth, water vapor (H_2O) is the most important greenhouse gas. Other important gases are carbon dioxide (CO_2), nitrous oxide (N_2O), chlorofluorocarbons (CFCs), methane (CH_4), and ozone (O_3). Anthropogenic emissions are important sources of all greenhouse gases, except water vapor. However, the atmospheric water vapor content increases with increases in surface temperature. Therefore, the atmospheric concentration of water vapor increases with anthropogenic emission of greenhouse gases. The increase in atmospheric water vapor content induced by anthropogenic emissions in responsible for a large fraction of the greenhouse effect.

CARBON DIOXIDE

Carbon dioxide (CO_2) is a colorless and odorless gas consisting of one carbon and two oxygen atoms. CO_2 is produced when carbon compounds are burned in the presence of oxygen. It is produced during forest fires and the combustion of fossil fuels. CO_2 is also produced by the decay of organic matter and volcanic eruptions. Other important sources of carbon dioxide are emission by the oceans and respiration by humans and animals. Important sinks of carbon dioxide are absorption by oceans, photosynthesis, and plankton and plant growth. Because the sources and sinks of carbon dioxide varied significantly during the Earth's history, its atmospheric concentration also varied significantly. There is evidence that the concentration of carbon dioxide was very high in the Earth's early history, then declined steadily and reached a quasi-steady value of about 280 parts per million. The concentration varied around this value with climate fluctuations.

However, the huge increase in man-made emissions of carbon dioxide that came with the Industrial Revolution has been making its concentration to increase steadily since the end of the 18th century. Today, the concentration of carbon dioxide has already exceeded 350 parts per billion and continues to increase at the rate of more than one part per million per year. The atmospheric concentration of carbon dioxide has been continuously measured at Mauna Loa, Hawaii, since 1957. It shows a clear annual cycle, resulting mainly from changes photosynthesis and a steady increase since the measurements started. The atmospheric concentration of CO_2 before this record started can be measured from bubbles of air trapped in ice cores. They show a steady increase since the beginning of the Industrial Revolution.

Human-induced emissions of carbon dioxide have increased dramatically and steadily since the end of the 18th century.

TOXIC GASES

Nitrous Oxide is a non-toxic gas consisting of one oxygen and two nitrogen atoms (N_2O). The main sources of nitrous oxide are natural processes in soils and the ocean, chemical fertilizers, and deforestation. Ice core data suggests that the atmospheric concentration of N_2O was approximately constant before the Industrial Revolution started. The annual increase in the atmospheric concentration of N_2O is estimated to be about 0.3 percent, according to the IPCC.

Chlorofluorocarbons (CFCs) are non-toxic gases composed primarily of carbon, hydrogen, chlorine, and fluorine. They are used mainly as cleaning agents, refrigerants, fire retardants, and in aerosol sprays. Since they are chemically inert in the troposphere, they have a long residence time, and reach the stratosphere where they are photodissociated by ultraviolet radiation. Then, free chlorine atoms destroy ozone catalytically. Thus, besides being important greenhouse gases, CFCs are responsible for destroying the ozone layer that protects humans from harmful ultraviolet radiation.

Methane is an odorless, non-toxic, flammable gas consisting of one carbon and four hydrogen atoms (CH_4). Mainly anaerobic or oxygen-deprived processes produce methane. It forms when the digestion of organic material by bacteria releases single carbon atoms. The main sources of methane are wetlands, the combustion of fossil fuels, animals, rice plantations, biomass burning, landfills, termites, and the oceans. Methane is removed from the atmosphere primarily by reaction with hydroxyl radicals (OH). The atmospheric concentration of methane has also been steadily increasing since the beginning of the Industrial Revolution. The atmospheric concentration of CH_4 has been increasing at the rate of about 1 percent per year.

Ozone (O_3) is formed via the dissociation of molecular oxygen by ultraviolet radiation. It is the most photochemically active greenhouse gas. Ozone is an important greenhouse gas because it strongly absorbs ultraviolet radiation. About 90 percent of the atmospheric ozone is found on the stratospheric ozone layer. However, the ozone concentration in very polluted areas can exceed the stratospheric levels.

The concentration of water vapor increases exponentially with temperature. This fact and the presence of water reservoirs such as lakes and oceans make the opacity of the atmosphere a strong function of surface temperature. Thus, global increases in temperature (global warming) produce a positive feedback in the climate system. Increases in the surface temperature causes increases in the amount of atmospheric water vapor that produce further increases in the surface temperature. This positive feedback makes the greenhouse effect increase dramatically with temperature. Above a critical value of the solar forcing, the atmospheric water vapor feedback becomes so large that equilibrium is not possible and a runaway greenhouse occurs. In fact, there is evidence that the dependence of the concentration of water vapor on temperature might lead to multiple climate equilibria.

Greenland Cores

GREENLAND IS THE largest island in the world. Most of Greenland is covered with an enormous ice cap that is almost three times the size of Texas. The ice cap covers about 90 percent of the island. It is so heavy that its weight has depressed the center of Greenland to about 1,000 ft. (304 m.) below sea level. The Greenland icecap contains one-eighth of the total global ice-mass. Most of the remaining ice mass is in Antarctica. Some parts of northern Greenland are ice-free because it is too cold for snow to form. In some southern parts, the area is too warm for ice to accumulate. The ice cap has been created by the accumulated weight of snowfall through hundreds of thousands of years. The shrinkage in the ice cap, since it was first measured in the 1950s, is due to global warming.

Scientists who specialize in paleoclimate research have drilled two ice core samples in the center of the Greenland ice cap. The core samples were drilled to a depth of 2 mi. (3.2 km.). The ice cores are in an area where winter snowfall has constantly added depth to the ice cap over thousands of years. The ice caps have been studied as an environmental record of the climate, regionally and globally, for the last 100 thousand years. Strictly speaking, the ice cores report what occurred climatically only where the samples were taken. However, extrapolations provide an estimate of global weather conditions, and, thus, a record of the Earth's climate through several ice ages.

Plant materials in the cores are some of the oldest plant material currently available on the Earth. The plant materials reveal that the climate of the Earth was much warmer hundreds of thousands of years ago than today. The age of the plants, as well as the insect life found, is between 500,000 and 1 million years in age. In addition, remains of boreal forests were found. The implications of the plant and insect materials in the ice cores indicate that the ice cap perhaps did not exist perhaps as long as 2.5 million years ago. However, in more recent geological ages, the ice cap did not completely disappear during interglacial periods.

As the snow accumulations have compressed over the millennia, they have also been squeezed into ice, which has trapped air bubbles. The ice cores, composed mostly of water, also contain isotopes of oxygen and hydrogen, the two elements in a water molecule. The air bubbles, the isotopes, and the organic material in the ice cores have given scientists materials that are enabling them to create a picture of the climate of the Earth over the last 1 million or more years. The heavier isotopes have a lower vapor pressure, so they condense more rapidly as temperatures cool than is the case with normal water molecules. The concentration of isotopes is an indication of the temperature at the time of the precipitation of the water molecule under study.

Concentrations of different gases in the air bubbles trapped in ice core samples record the levels of greenhouse gases in the atmosphere over a long stretch of geologic history. The concentrations of carbon dioxide, methane, and nitrous oxide reveal the greenhouse gas levels that are used to interpret the climatic changes over the last 1 million years. Some of the trace molecules in the samples were aerosols, which are indications of vast volcanic activity. Other inclusions in the ice core sample may be dust or volcanic ash, pollen, and radioactive elements. Ice core samples from Greenland can be compared with the results from ice core samples taken from Antarctica and from other major glaciers around the world. The conclusions of scientists have included inferences about solar variability, forest fires, and the water drawn from the sea through evaporation.

The depth from which an ice core sample is taken is important for stating its age. The newer parts of the core samples have thin annual layer lines, while samples from deeper depths of the ice cap are so compressed that age determination has to be made with different criteria. The ice core samples since the end of the last Ice Age, about 12,000 years ago, show variations in snowfall. This has led to the conclusion that the climate at that time was getting colder because there was less moisture in the air to fall as snow. Samples from different parts of Greenland have revealed greater differences than were expected. Evidence of volcanism that affected the climate has been found in ice core samples that have sulfate concentrations from about 9,000 years ago. The sulfate concentrations are indicators that volcanoes played a role in global cooling. However, currently, the ice cap is rapidly melting.

Greenland Ice Sheet

THE GREENLAND ICE Sheet contains about 10 percent of the world's fresh water, and is vulnerable to mass loss by climate warming; if it were to melt, it would cause a 24 ft. (7.4 m.) rise in global sea level. The ice sheet covers 82 percent of the total area of Greenland. It is a huge ice dome, with two main peaks: one at 3,220 m. at the summit (about 72 degrees N, 29 degrees W), and the other at 9,350 ft. (2,850 m.) in the south at about 64 degrees N, 44 degrees W. The ice sheet is up to 1.8 mi. (3 km.) thick in the middle, and its great weight depresses the underlying crust, which assumes the concave shape of a saucer. The ice sheet has waxed and waned in response to natural changes in solar radiation and other climatic factors over millennia: during the last Ice Age, which peaked about 20,000 years ago, it expanded to form the Laurentide Ice Sheet covering much of North America.

Various processes contribute to the accumulation (growth) and ablation (decay), and, therefore, the net mass balance, of the ice sheet. Accumulation comes mainly as precipitation (snowfall), although there is also condensation of water vapor (such as hoar frost) onto the surface. Ablation includes surface melt water runoff, iceberg calving, evaporation, and sublimation (direct conversion of solid ice to vapor). Under present climatic conditions, annual accumulation and ablation roughly balance, with about half the ablation from runoff and the other half from iceberg calving. However, iceberg calving happens only at the margins of the ice sheet, where ice streams flow outward to reach fjords and/or the sea, and can be ignored for the bulk of the ice sheet further inland. Surface mass balance is used to denote all accumulation and ablation processes, except iceberg calving. Overall (net) mass balance includes ice flow (dynamics) as well as surface mass balance processes: the ice sheet naturally deforms and flows outwards under the force of gravity. When studying Greenland Ice Sheet behavior over periods longer than about a decade, dynamical readjustment (effectively a long-term memory) of the ice sheet to changes since the last Ice Age has also to be considered.

The ice sheet is divided into an accumulation zone and an ablation zone, separated by an equilibrium line. Accumulation exceeds ablation at higher elevations (accumulation zone), and vice-versa at lower elevations (ablation zone). The much higher summer temperatures at lower elevations near the ice sheet margin explain this. The exact height of the equilibrium line varies with location according to climatic and geographic factors, ranging from about 300 m. above sea level in the north to about 1,800 m. above sea level in the south. Summer melting occurs over about half the area of the ice sheet. However, just above the equilibrium line, over more than two-thirds of the total area, the limited summer snowmelt mostly percolates into the local snow pack and refreezes, so net runoff there is negligible.

The surface mass balance of the ice-sheet margin is most sensitive to slight (several-degree) changes in summer temperatures, which substantially affect surface melt runoff. This part of the ice sheet is therefore particularly sensitive to climatic changes, such as global warming. Marginal melt rates are locally up to around 5–10 m. per year. These would be enhanced with future warming, which would radically affect the mass balance of the whole ice sheet, even though the area of significant melt covers only a relatively small fraction by area. Summer cooling in coastal southern Greenland between the late 1950s and early 1990s may explain the mid-late 20th-century re-advance of the ice sheet margin after retreats of a few km. in some places since the 19th century. This evaluation of changes in the ice margin is based on analysis of old maps, photos, and expedition reports, and cannot be expressed accurately as volume change, which can only be determined by modern altimeter surveys from aircraft and satellite.

MONITORING OF THE GREENLAND ICE SHEET

Several means have been used to assess the current state of balance of the ice sheet to effectively model its response to natural- and human-induced climatic change. Observational methods include direct meteorological and glaciological measurements at the ice-sheet surface with weather stations, ablation stakes and ice cores, and remote sensing by satellite radar, gravity surveys, and airborne laser. It is essential to establish the ice sheet's current state of mass balance and climatic sensitivity, and detect any early-warning signs that might signify its future response.

Despite much effort, the Greenland Ice Sheet is still poorly-sampled by direct glaciological measurements, although it appears that there have been relatively large fluctuations in surface mass balance over the early 21st century. However, a Greenland Climate Network of automatic weather stations and an extensive ice-core network have been established across the ice sheet in the 1990s, providing much-needed meteorological and glaciological measurements across the interior regions.

Airborne and satellite laser-altimetry data analyses indicate substantial volume losses from the ice sheet since around 1993. Various recent analyses of gravimetric (GRACE) satellite data suggest particularly high mass losses 2002–06; the largest mass losses are generally indicated from low elevations (less than 2,000 m.) and especially in southeast Greenland, with partly compensating mass gains at higher elevations (over 2,000 m.). Other altimetry data suggest that there has been substantial growth of the ice-sheet interior in the last 15 years, which may be partly attributable to increased atmospheric moisture and precipitation and/or shifting storm tracks forced by enhanced greenhouse gases. There are considerable discrepancy among these pioneering observational estimates. Moreover, most of the observational studies have data spanning less than a decade, so they have yet to provide a convincing timeframe of how the Greenland Ice Sheet might be responding to long-term climatic change, most notably the evident Arctic and global warming since the 1970s.

Outlet glaciers have typically thinned by several meters per year since the 1990s. Satellite radar interferometry reveals widespread acceleration of Greenland margin glaciers, a pattern progressing northward since 1996, with an accompanying doubling of the ice sheet's volume deficit, although it is too early to say if these changes are exceptional. Some of these margin changes are the likely response to recent climatic warming through infiltration of surface melt water and lubrication of the glacier bed, speeding up glacier flow and mass loss. Notably, several key glaciers in southern Greenland (such as Jakobshavn Isbrae, Helheim, and Kangerdlussuaq) have shown dramatic accelerations, retreats and/or breakup of their floating tongues. This thinning of the Greenland Ice Sheet margin could account for at least 10 percent of the total increase in global sea level during this period.

Studies have shown that the Greenland Ice Sheet experiences rapid changes over periods of just a few years, and some of these could be in response to climate change. Scholars are currently focusing on surface ablation and glacial dynamics in the marginal (edge) regions of the ice sheet, and their sensitivity to summer warming.

Recent relatively high summer temperatures (1995–2005) are associated with increased net ice loss over Greenland. However, recent warm summers are not unprecedented as they are similar to those experienced an early-20th-century warm period (1918–47). Nevertheless, most computer-model predictions of future climate suggest that sustained warming around the margins will lead to a negative mass balance and give a positive contribution to sea level. The latest Intergovernmental Panel on Climate Change (IPCC) prediction is for a Greenland Ice Sheet contribution to sea-level rise of 1–13 cm. during the current century. The ice sheet could respond more rapidly to continued warm temperatures via hydraulic acceleration, but at the moment, the physical response mechanisms are too poorly understood to be included in the IPCC projections.

Greenpeace International

GREENPEACE INTERNATIONAL IS an environmental organization that uses creative confrontation, usually in the form of media spectacles, to draw attention to specific environmental problems. Abrupt climate change caused by human-induced global warming is atop the organization's list of concerns. Scientists predict that if humans continue to burn fossil fuels at present rates, global warming will have catastrophic effects on existing ecosystems, natural landscapes, plant and animal populations, and human life. Greenpeace, which is a nongovernmental organization supported by charitable grants and membership fees, is at the forefront in the struggle to convince governments, businesses, and individuals that global warming is a real threat, and in finding ways to lessen human dependence on fossil fuels. From its headquarters in Amsterdam, the Stiching Greenpeace Council gathers almost three million supporters, directs activities in 27 national and regional offices located throughout the world, and promotes local and regional actions that include media-luring confrontations that produce image bites and aggressive lobbying of politicians and businesspersons.

The problems of global warming and climate change have only recently become central targets for Greenpeace. The testing of nuclear weapons galvanized the founding of the organization in Vancouver, British Columbia, in 1972. Several American expatriates and Canadians joined hands to prevent the United States from testing nuclear bombs along the Aleutian coast of Alaska. Originally called the Don't Make a Wave Committee, after the potential tidal wave the explosions could raise in the North Pacific, the group sailed twice into the testing area of Amchitka, only to be turned away by the U.S. Navy. The U.S. government eventually discontinued the Aleutian Islands testing program as a consequence of Greenpeace's spectacular confrontations and the media attention they received. Since then, Greenpeace has been a pro-environmental force to be reckoned with, promoting greater knowledge of environmental issues including deforestation, air and water pollution, whaling, over-fishing, and genetically modified food crops.

In the late 1970s, Greenpeace International consolidated what was then an informal association of smaller groups carrying out actions in the name of Greenpeace. Headquarters were moved to Washington, D.C., and the organization refitted a fishing trawler, renaming it the *Rainbow Warrior*. The image of Greenpeace activists maneuvering their rubber dinghies in between industrial harpooner and terrific whale is representative of their purpose and determination.

Greenpeace's most famous stance came against the French nuclear testing program in the South Pacific beginning in the late 1970s, when activists sailed again into an exclusive zone, but this time encircling the Moruroa Atoll, the French test site. Again, they were rebuffed, but not so subtly. The French military rammed their yacht, the precursor to the *Rainbow Warrior*, and dished out a beating of the crew that was seen on television screens throughout the world. This raised more than a few eyebrows, and membership dollars. In 1985, Greenpeace set sail again for the atoll, but this time with the stout *Rainbow Warrior*. While docked in Auckland Harbor, New Zealand, French intelligence agents bombed the ship, killing a photojournalist. The French government of François Mitterand was humiliated and testing halted.

Greenpeace activism was significant in propelling several important international policies, furthering the goals of environmental conservation and preservation. They include the Protocol on Environmental Protection to the Antarctic Treaty (1991) that imposes a 50-year moratorium on the mining of resources on the continent; and the Comprehensive Nuclear Test Ban Treaty (1996) now signed by 177 states including the United States, China, France, and Russia. During the summer of 2007, Greenpeace began construction of another ship on Mt. Ararat, in eastern Turkey, where Noah's Ark is said to have rested after the biblical deluge. This may some day join their present fleet of five ships.

Grenada

THIS CARIBBEAN ISLAND, with some much smaller islands located in the Windward Islands, has a land area of 132.8 sq. mi. (344 sq. km.), and a population of 103,000 (2005 est.). Grenada has a population density of 672.2 people per sq. mi. (259.5 people per sq. km.), making it 44th in the world in terms of population density. Some 15 percent of the land is arable, with a further 3 percent used for meadows or pasture. Unlike many other Caribbean islands, Grenada still relies heavily on agriculture; it is the second largest producer of nutmeg in the world, and agricultural output makes up some 90 percent of the exports from the country.

GOVERNMENT AND TOURISM

Since the 1990s, the Grenada government has been trying to increase the number of tourists visiting the country. Many tourists visit the coral reefs around the island, the most popular of which lie to the southwest of the main island. This has led to an increase in carbon dioxide emissions per capita, with Grenada ranking 114th in the world, with 1.2 metric tons per person in 1990, rising steadily until 1997, when it reached a peak of 2.1 metric tons per capita. After falling, this figure rose again, surpassing this level slightly in 2001. Almost all the carbon dioxide emissions in the country come from liquid fuels, with all electricity generation in the country coming from fossil fuels.

As the temperature of the seawater rises, coral bleaching occurs, threatening the tourism industry. Hurricane Ivan hit Grenada on September 7, 2004, causing widespread damage and killing 39 people. The Grenada government of Nicholas Braithwaite took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and signed the Vienna Convention in the 1993. The government of Keith Mitchell accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on August 6, 2002, with it taking effect on February 16, 2005.

Gross National Product

THE ECONOMIC MEASURE of countries is determined by accounting. Industrialized nations tend to use Gross Domestic Product (GDP) as their chief economic indicator to allow for easier comparison with other countries standardized accounting systems. The GDP measures the value of all within-the-country products and services, including production by foreign companies/individuals and excludes overseas income and investments. In comparison, the Gross National Product (GNP) is the total dollar value of all final products and services produced for consumption during a particular time period, including the country's global personal, industrial, and government spending and investments, with allowances factored in for depreciation and indirect business (sales and property) taxes. The GNP includes income from overseas sources that would be figured in the GDP of another country.

Climate change will affect the direct economy of a country through production, services, and resources, and will influence global trade and financial markets. The atmosphere is a global resource; it is not limited to one nation in terms of addressing greenhouse gas emissions, determining the economic consequences of climate change, but must factor in losses experienced by the economies of other countries.

In addition to disrupting weather patterns, with increased frequency of hurricanes and other extreme weather events in determining economic costs and benefits (losses in one nation may be a benefit in another nation with changing agricultural, migration and tourism, energy and heating/cooling). Economic costs must include damage associated with the impact of climate change including loss of land, loss of forested areas, loss of species, loss of water quality and supply, increased healthcare costs from heat, air quality issues, and the spread of tropical diseases. Economic benefits would factor in increased production of technology for wind, solar, and biogas energy production; and increased money flow in the construction sector for building dikes, levees, infrastructure, and buildings in previously uninhabited areas

According to estimates presented by the 2006 Stern Review, climate change could cause a 5 percent reduction in the global GNP, whereas only 1 percent of global GNP would be needed to stabilize green-

A population at risk: The economic costs of global warming include the loss of land, forested areas, species, water quality and supply; increased healthcare costs from heat; air quality issues; and the spread of disease.

house gas emissions. In general, economic models predict developing nations would experience greater economic losses (reduced GNP growth) by reducing the use of fossil fuels and substituting more expensive energy sources. A limitation of the economic models is putting a dollar amount on resources with more than a market value that cannot be assessed without difficulty and multiple value judgments of the extent of damage including social, cultural, and ecological values. To estimate these costs, economists use models that show how economic output is produced from inputs such as labor, capital, and resources.

PREVENTION AND ADAPTATION

Preventive measures for limiting the extent of global warming from the greenhouse effect include reducing emissions and enhancing carbon sequestration. Adaptive measures include construction to protect against the effects of climate change, improving water resources, and improving cultivation practices or shifting crops to the match the plants' ideal weather conditions for maximum production.

There is also a shift to previously underutilize or unused commodities like carbon taxes (levied exclusively on carbon-based fossil fuels). Such a tax would raise the price of carbon-based energy sources, giving consumers incentives to conserve energy and to shift demand to alternative sources. Demand may shift from carbon-based fuels with a higher proportion of carbon, such as coal, to those with relatively lower carbon content (such as natural gas). Other techniques include: carbon credits (with each nation allocated a certain permissible level of carbon emissions and the ability to sell leftover allocations to nations who have exceeded their allocation limits), subsidizing noncarbon-based fuel providers instead of fossil fuel providers, research and development expenditures promoting the commercialization of alternative technologies, and promoting the transfer of technology to developing nations. Any measures taken to prevent global climate change will have economic effects, both positive and negative, on gross national product (GNP), production, employment, and investment.

Gross Primary Production

TERRESTRIAL GROSS PRIMARY productivity (GPP) is a collection of complex processes performed by photosynthetic organisms that result in the conversion of light energy and water into chemical energy and the subsequent biochemical fixation of carbon dioxide into sugars. Because the supply of organic carbon exerts a dominant control on the activity of heterotrophic organisms, from bacteria to ungulates, GPP is a central process regulating the structure and functioning of ecosystems. Further, during terrestrial photosynthesis, plants transpire large quantities of water, and so GPP impacts both water and carbon cycles, and thus local, regional, and global climate. In turn, changes in climate will impact GPP at local to global scales.

Plants are responsible for most terrestrial GPP, which on an annual basis amounts to some 120 Gt carbon (1 Gt = 10^{15} g.), or about 17 percent of all carbon in the atmosphere. About half of the assimilates derived from GPP are lost back to the atmosphere through respiration processes that support important plant functions, including: nutrient uptake from soil, reduction of nitrate to the plant-available form of ammonium, phloem loading (the active export of assimilates from leaves to the rest of the plant), and for some plant species fixation of atmospheric nitrogen into ammonium. Following export from leaves the remainder of GPP is allocated to the construction of living biomass, which is often described as net primary production (NPP, or GPP less the carbon respired for construction and maintenance purposes). This carbon is allocated to a diversity of sinks within the plant, including long-lived components (above and belowground wood growth) and short-lived components (foliage and fine root production). A large fraction of GPP is allocated belowground to support symbiotic fungi and bacteria. Ultimately, all NPP will be released as CO_2 back to the atmosphere through heterotrophic utilization of plant biomass following senescence, leaching, herbivory, or exudation from roots.

The major drivers of GPP and thus NPP include climate (temperature, water, and light availability), soil fertility, species composition, and vegetation age. Ecosystem-level plant production varies widely across the terrestrial biosphere, with the highest rates where it is warm, wet, and soils are fertile; and the lowest rates where it is cold, dry, and soils are infertile. Given the important control that climate has over GPP, it is expected that climate change will impact global patterns of plant production. Interactions among driving variables will also influence how ecosystems respond to changes in climate, with responses depending on geography. Warming in colder climates will generally result in increased plant production, while warming in already warm climates may have little, or even negative impacts on GPP. Similarly, where moisture is limiting to plant productivity, warming, even with no change in rainfall, will result in declining GPP because of increased water losses to evaporation. Warming will also impact disturbance regimes (such as fires and hurricanes) that impact GPP and NPP through drastic changes in vegetation.

Guatemala

THE NORTHERNMOST OF the Central American republics, Guatemala has a land area of 42,042 sq. mi. (108.890 sq. km.), with a population of 12,728,111 (2007 est.), and a population density of 348.6 people per sq. mi. (134.6 people per sq. km.). Some 12 percent of the country's land area is arable, with another 24 percent used for meadows and pasture, and 35 percent is covered with forests. The mainstay of the economy is coffee, the largest cash crop in the country.

Underdeveloped, Guatemala has made only a small contribution to global warming and climate change. It has an extensive public transportation system, mainly using former U.S. school buses. Guatemala has one of the lower rates of carbon dioxide emissions per capita in the world, with 0.6 metric tons per person in 1990, rising steadily to 0.89 metric tons in 2003. The vast majority of the carbon dioxide emissions from the country come from liquid fuel (92 percent), with just under 8 percent from the manufacture of cement, and a negligible amount from gaseous fuels. Most of the carbon dioxide emissions are for electricity, with 50.3 percent of the electricity production rates in the country from fossil fuels, and 44.5 percent from hydropower. Guatemala also has a high rate of carbon monoxide emissions.

Increasing sea temperatures have caused worry from conservation groups that this change might affect the beaches at Monterrico, which have extensive mangrove wetlands, and are often visited by sea turtles. Increasing sea temperatures are also likely to lead to flooding, with the possibility of increased risk of malaria and dengue fever. The Guatemalan government of President Marco Vinicio Cerezo Arévalo ratified the Vienna Convention in 1987. The government of President Jorge Serrano Elías took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and the government of President Álvaro Arzú Irigoyen signed the Kyoto Protocol to the UN Framework Convention on Climate Change on July 10, 1998, which was ratified on October 5, 1999, and went into effect on February 16, 2005.

Guinea

GUINEA IS A republic in west Africa, formerly known as French Guinea, whose capital and largest city is Conakry. Its total land area is 245,857 sq. km (94,926 sq. mi.), slightly smaller than the size of Michigan. It has 200 mi. (320 km.) of coastline. The total land border is 2,112 mi. (3,399 km.). The population of Guinea is 8.8 million (2005 est.). The name Guinea is also used for the region of most of Africa's west coast south of the Sahara desert and north of the Gulf of Guinea. The climate of Guinea is monsoon and subequatorial. Maximum daily temperature (91 degrees F, or 33 degrees C) occurs July–August. Minimum daily temperature (79 degrees F, or 26 degrees C) occurs March–April. The historical maximum/minimum temperatures were 115/ 39 degrees F (46.1/3.9 degrees C). Precipitation is highest (around 157 in., or 4,000 mm., per year) along the coastal line. Precipitation peaks in the wet season (July–August); in the dry season (March–April) it falls to around zero.

Seasonal and interannual-to-multidecadal variability of temperature and precipitation in Guinea is under control of Intertropical Convergence Zone (ITCZ) evolution, as is shown by Gennady Dvoryaninov et al. The linear trend of surface air temperature and precipitation 1920–90 is insignificant for most months because of strong superimposed interannual-to-multidecadal variations. For instance, typical magnitude of interannual-to-multidecadal variations of precipitation exceeds 20 in. (500 mm.) per year. Inter-annual variability of climate of Guinea is under the influence of El Niño/La Nina events. They impact Guinea's climate through the atmospheric bridge, resulting in a change of intensity of ITCZ and west African monsoons. Transient and early mature El Niño phases are usually accompanied by more dry conditions there. Multi-decadal variability of climate of Guinea significantly depends on Atlantic multi-decadal oscillation, in which warm phases coincides with warmer conditions in Guinea.

Guinea's territory has a curved shape, with its base at the Atlantic Ocean, inland to the east, and turning south. The base borders Guinea-Bissau and Senegal to the north, and Mali to the north and northeast; the inland part borders Côte d'Ivoire to the southeast, Liberia to the south, and Sierra Leone to the west of the southern tip. A humid and tropical country, Guinea comprises an alluvial coastal plain, the mountainous Fouta Djallon region, a savanna interior, and the forested Guinea Highlands, which rise to 5,800 ft. (1,770 m.) in the Nimba Mts. Fouta Djallon highland region in central Guinea. The Niger, Senegal, and Gambia rivers rise there. The largest rivers of Guinea, with inflows into its coastal zone, are Cogon, Fatala, and Concure. Their discharge is changeable. For example, monthly average discharge of Concure (1957–84) varied from 1770 cu. m. per second (in the wet season) to less than 20 cu. m. per second (in the dry season). There are high-amplitude inter-annual variations of Concure discharge. Its maximum is met in August, when it reaches 2,800 cu. m. per second. Sea surface temperature in the coastal zone of Guinea varies from 25.4 degrees C (in March) to 27.1 degrees C (in August). Upwelling is not typical phenomenon for the Guinean coastal zone, as opposed to that of Senegal.

Guinea-Bissau

THE FORMER COLONY of Portuguese Guinea, the Republic of Guinea-Bissau has a land area of 13,948 sq. mi. (36,125 sq. km.), with a population of 1,586,000 (2005 est.), and a population density of 114 people per sq. mi. (44 people per sq. km.). Forests cover 38 percent of the country; some 11 percent of the land is arable, and 38 percent is used for meadows and pasture. Largely because it is an undeveloped state, with many of its people living in poverty, Guinea-Bissau has one of the lowest rates of per capita carbon dioxide emissions in the world, with 0.2 metric tons per person in 1990, falling to 0.18 metric tons by 2003. All the electricity production in the country comes from fossil fuels, with all the carbon dioxide emissions in the country coming from liquid fuels.

Much of the country is low-lying, with a significant number of offshore islands, and coastline that would be flooded if global warming and climate change led to a rise in water levels. Bissau, the capital, is also liable to flooding from the Rio Géba. The government of João Bernardo Vieira took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and the government of interim President Henrique Rosa accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on November 18, 2005; it went into effect on February 16, 2005.

Gulf Stream

OCEAN CURRENTS AFFECT not only the temperature, but also the precipitation on land areas adjacent to the ocean. A cold ocean current near land causes the air just above the water to be cold, while the air above is warm. There is very little opportunity for convection, thus denying moisture to nearby land. Coastal deserts of the world usually border cold ocean currents. Contrary to this, warm ocean currents, such as Gulf Stream, bring moisture to the adjacent land areas.

The Gulf Stream, together with its northern extension towards Europe, the North Atlantic Drift, is a powerful, warm, and swift Atlantic Ocean current that originates in the Gulf of Mexico, exits through the strait of Florida, and follows the eastern coastlines of the United States and Newfoundland (Canadian island) before crossing the Atlantic Ocean. It carries a huge amount of warm water to northerly lands, which has enormous significance to inhabitants of those areas; without it, northern Europe would be much colder and drier.

At about 30 degrees W, 40 degrees N, it splits into two, with the northern stream crossing northern Europe, and the southern stream (Canary Current) recirculating off western Africa. The Gulf Stream influences the climate of the east coast of North America from Florida to Newfoundland, and the west coast of Europe. Warm water brought to Europe's shores raises the temperature by as much as 18 degrees F (10 degrees C) in some places.

GULF STREAM ORIGINS

The origin of the Gulf Stream is debatable. One group of scientists believes that the Gulf Stream is driven both by the rotation of the Earth and by a deep-water current called the thermohaline circulation. Another group of scientists accept the theory propounded by Henry Stomme in 1948, that the Gulf Stream is a wind-driven phenomenon. Heating and cooling affect its temperature and other properties, but not its basic existence or structure. Stomme theorized that as long

A NASA satellite image shows the Atlantic Ocean, off the shore of Georgia and the Carolinas, where the Gulf Stream current curves out to sea away from the North American continent.

as the sun heats the Earth and the Earth spins, there will be winds, and there will be a Gulf Stream.

There is some speculation that global warming could decrease or shut down thermohaline circulation, and therefore reduce the North Atlantic Drift. The time frame for this might happen is unclear; estimates range from few decades to a few hundred years. This could trigger localized cooling in the north Atlantic and lead to cooling (or lesser warming) in that region, particularly affecting areas such as the Scandinavian countries and the United Kingdom. The slowdown, which climate modelers have predicted will follow global warming, has been confirmed by the most detailed study yet of ocean flow in the Atlantic. Most alarmingly, the new research reveals that a part of the current, which is usually 60 times more powerful than the Amazon River of South America, came to a temporary halt during November 2004.

Recent research has shown that changes are occurring in the Gulf Stream. According to scientists, in the absence of the Gulf Stream and its two northern branches, the north Atlantic Drift and the Canary Current, the weather in the United Kingdom could be more like that of Siberia, which lies on the same latitude. According to Peter Wadhams of the University of Cambridge, changes are occurring in the water of the Greenland Sea. Historically, large columns of very cold, dense water in the Greenland Sea, known as chimneys, sink from the surface of the ocean to about 9,000 ft. (2,743 m.) below, to the seabed. As that water sinks, it interacts with the warm Gulf Stream current flowing from the south. However, the number of those chimneys, according to Wadhams, has decreased from about a dozen to just two. That is causing a weakening of the Gulf Stream, Wadham asserts, which could mean less heat reaching northern Europe. It is possible that the coastal areas of western Europe could be converted into deserts. However, this would require much more extensive research on changing land use patterns in coastal areas.

Harry Bryden, of the National Oceanography Centre in Southampton, presented his findings to a conference in Birmingham on rapid climate change. Bryden's research group stunned climate researchers in 2006, with data suggesting that the flow rate of the Atlantic circulation had dropped by about 6 million tons of water a second 1957–98. If the current remained that weak, Bryden predicted, it would lead to a one degree C drop in the United Kingdom in the next decade. A complete shutdown would lead to a 7–11 degree F (4–6 degree C) cooling over 20 years.

Bryden's study prompted the United Kingdom's National Environment Research Council to set up an array of 16 submerged stations spread across the Atlantic, from Florida to northern Africa, to measure the flow rate and other variables at different depths. Data from these stations confirmed the slowdown in 1998 was not a "freak observation," although the current does seem to have picked up slightly since then. Richard Seager, who presented his research to the New York Academy of Sciences on "The Gulf Stream: European Climate and Abrupt Climate Change," expressed similar views. Seager states that a slowdown of the Gulf Stream and ocean circulation in the future, induced by freshening of the waters caused by anthropogenic climate change (via melting of glaciers and increased water vapor transport into high latitudes) or simply by warming, would introduce a modest cooling tendency. This would leave the temperature contrast across the Atlantic unchanged. In fact, the cooling tendency would probably be overwhelmed by the direct radiatively driven warming from rising greenhouse gases.

Guyana

GUYANA'S LOW-ELEVATION COAST hosts the majority of its population. It is predicted to become one of the world's top 10 most impacted nations from sea level rise in terms of the percentage of the population and extent of urban area implicated. Ranging from a low estimate of 16 percent to a high estimate of 103 percent, Guyana is expected to have one of the greatest losses in gross domestic product in the Caribbean as a result of climate change. One of the poorest countries in the western hemisphere, Guyana remains reliant on foreign assistance to mitigate potential consequences. Researchers have demonstrated an urgent need to update flood control. Irrigation technologies also need rehabilitation. The name Guyana is Amerindian for "Land of Water," but the country may be losing its fresh groundwater. It has been suggested that this may contribute to coastal subsidence.

The capital city Georgetown is located along Guyana's 270-mi. (434 km.) coast. Three quarters of the national population of 765,000 lives within 20 mi. (32 km.) of the sea. This same area hosts most agricultural production. Drainage is a major problem, and agricultural irrigation systems must control seawater intrusion. The centerpiece of the outdated drainage and irrigation infrastructure is the East Demerara Water Conservancy (EDWC) Dam. This structure was developed in 1880 and holds a volume of more than 100 sq. mi. (259 sq. km.) of water, but it is currently believed to over-top and seep. Defective intake contributes to dry season water shortages.

Sea level rise in Guyana is believed to be two to five times higher than global averages. It was measured at an excess of 0.3 in. (10 mm.) annually 1951–79. Research suggests that this trend has continued. Major floods in 2005 and 2006 demonstrated an inability to clear water. The impact of the flood in 2005 has been estimated at 60 percent of GDP. Many biodiverse ecosystems exist in Guyana, including mangroves in low-lying areas. Guyana hosts an extensive tropical forest that makes up a northern portion of the Amazon rainforest. In 2000, forests covered over 70 percent of the country, but multinational timber and mining concessions have accelerated deforestation.

Guyana ratified the United Nations Convention on Climate Change in 1994 and the Kyoto Protocol in 2003. The country has compiled an extensive climate change action plan. It is part of the Caribbean Planning for Adaptation to Global Climate Change Project. Georgetown hosts the administrative headquarters of the Caribbean Community (CARICOM). CARICOM is involved in climate change vulnerability assessments and adaptation programs.

As many countries in the region, including Guyana, rely heavily on fossil fuel, CARICOM oversees research on alternative energy. A bagasse cogeneration project is the first initiative in the nation under review for support from the Clean Development Mechanism.

Hadley, George (1685–1768)

GEORGE HADLEY WAS an English lawyer, physicist, and meteorologist who first accurately theorized a hypothesis for the trade winds and the associated north-south circulation pattern now known as the Hadley Cell. This piece of information was particularly important in Hadley's times, as it helped the journeys of English vessels toward North American shores. Hadley was intrigued that winds that should have blown northward had, instead, a western course.

Hadley was born on February 12, 1685, in London, England to Katherine FitzJames and George Hadley. He was part of a family of six children and his father was the high sheriff of Hertfordshire. George was initially overshadowed by the fame of his brother John, the inventor of the octant. He studied law, but soon found out that he preferred physics to legal work. For 7 years he was in charge of the meteorological observations for the Royal Society.

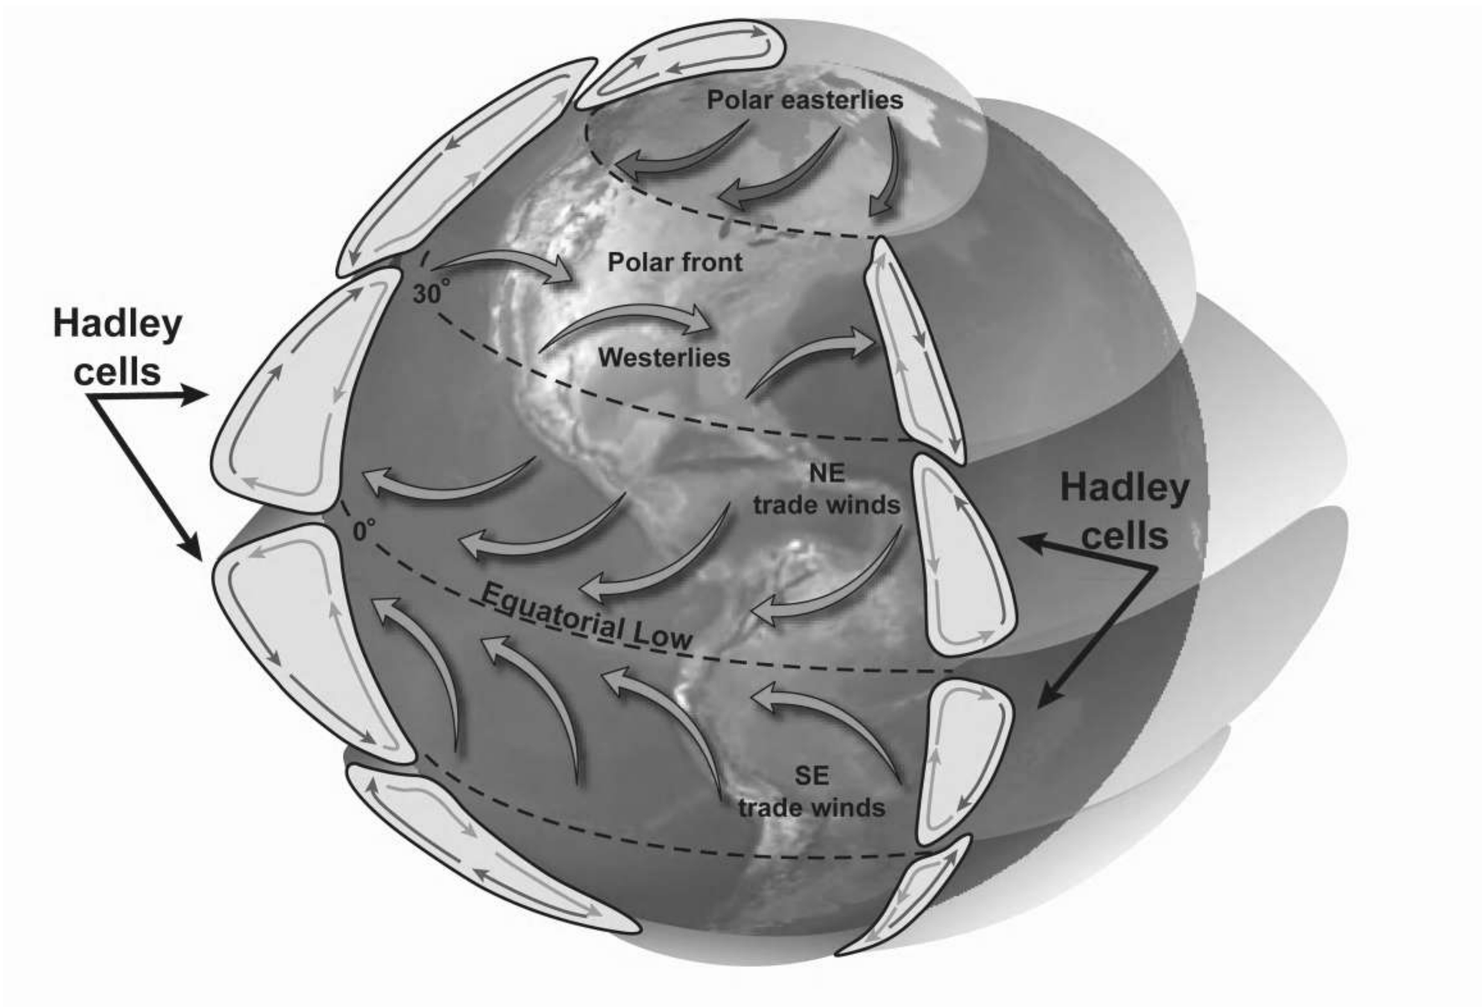
Yet, his fame rests on his work of the 1730s, when Hadley was able to complete Edmond Halley's theory of trade winds. Halley had failed to explain completely the westward component of the trades. In his famous paper "Concerning the Cause of the General Trade Winds," published in 1735, Hadley related the direction of trade winds to the rotation of the Earth.

The meteorologist started from the well-known fact that air at the equator is heated more strongly than at any other place on Earth. Air above the poles is cooler than at any other location. Therefore, it is speculated that surface air near the equator will ascend into the upper atmosphere and, above the poles, descend from the upper atmosphere to ground level. In order to balance these vertical movements of air, Hadley also assumed that air flows across the Earth's surface from each pole back to the equator and, in the upper atmosphere, from above the equator to above the poles.

This movement of air is called a convection cell, where convection describes the transfer of heat carried by a moving fluid. Yet, Hadley knew that his model was too simplified to explain the motion of the winds, which obviously do not blow from north to south in the Northern Hemisphere and from south to north in the Southern Hemisphere. He then explained that winds actually tend to blow from the east or west because of Earth's rotation.

The movement of the planet causes airflows that would otherwise be from the north or south to be diverted to the east or west. Because of his fame, Hadley was elected a Royal Fellow in 1745. He died on June 28, 1768.

A century after Hadley first proposed his theory, the French physicist Gaspard Gustave de Coriolis



Hadley Circulation provides westward windflow at the Earth's surface and eastward jet streams at higher altitudes. The circulating air patterns create convection currents in four global locations—each current is called a Hadley cell.

devised a mathematical description detailing how an object, in motion on a rotating body, follows a curved path in relation to any other body on the same rotating body.

Hadley Circulation

HADLEY CIRCULATION IS a type of atmospheric circulation following a stereotypical pattern in the para-equatorial region. Atmospheric circulation and ocean circulation together are the major mechanisms for global heat distribution. As ocean circulation refers to movement of waters, atmospheric circulation defines large-scale air movements around the globe. The principle tropical current known as Hadley Circulation affects jet streams, subtropical deserts, trade winds, and tropical rainbelts. Hadley Circulation provides westward windflow at the Earth's surface and eastward jet streams at higher altitudes.

The circulating air patterns create convection currents in four global locations—each current is called a

Hadley cell. The pattern of air movement is toward the Earth (prograde) at higher latitudes (in the subtropics) and backward (up from the Earth) at lower latitudes (near the equator). The movement occurs near the Earth's surface—within 6.2–9.3 mi. (10–15 km.). Its span across latitudinal markers remains within thirty degrees north or south of the equator. In this way, a Hadley cell moves heat from the equatorial region to regions within 30 degrees of latitude in either direction. Moisture is moved along with the heat.

In a Hadley cell, the air rises to the atmospheric tropopause, which is the region at the top border of the troposphere and thus the bottom border of the stratosphere. The troposphere is the lowest atmospheric region and is where all weather takes place. At the equator, it reaches up to 11 mi. (18 km.) from the earth's surface.

The next atmospheric layer is the stratosphere, extending to 31 mi. (50 km.) from the Earth's surface. This characteristic air circulation results from the Sun's rays heating the air at the level of the equator. Solar heating is strongest at the equator and weakest at the north and south poles, due to the direction of the Sun's rays, and therefore currents of atmospheric circulation due to solar heating are more prominent at the equator.

Hadley Circulation was first described by George Hadley (1685–1768) to explain the science behind the trade winds. It was to replace a flawed model that had been presented by Edmond Halley (1656–1742). George Hadley was an early 18th century meteorologist by hobby and lawyer by trade.

In fact, Hadley's theory was imperfect as well. It was corrected by American meteorologist William Ferrel (1817–91) at the end of the 19th century, but by this time Hadley's name had stuck. The Hadley Circulation is traditionally defined as resting on the equator; in fact it rests on the "thermal equator," or the Sun's zenith.

Haiti

THE REPUBLIC OF Haiti is located on the western part of the island of Hispaniola in the Caribbean. It has a land area of 10,714 sq. mi. (27,750 sq. km.), a population of 8,528,000 (2005 est.), and a population density of 758.1 people per sq. mi. (292.7 people per sq. km.). 20 percent of its land is arable, with a further 18 percent used for meadows and pasture. Haiti's farmland is divided into more than 500,000 farms, many of which are subsistence farms. Less than 4 percent of the country is still forested, a figure that is quickly declining because of the heavy demand for charcoal, and wood for construction.

Deforestation and flooding from global warming, and rising water levels have contributed to soil erosion, leading to major efforts to reduce the cutting down of trees. The Haitian Environmental Foundation has tried to replace charcoal cooking stoves with ones using briquettes of secondhand paper. U.S. aid workers are trying to replace 50,000 wood stoves with oil-fired burners each year.

Also badly affected by hurricanes, deforestation, and pollution, Haiti remains heavily underdeveloped, and, as a result, has one of the lowest rates of carbon dioxide emissions per capita in the world. Currently, Haiti ranks 181st, with 0.21 metric tons per person emitted in 2003, which is double the level achieved in 1990. Much of this rise has been accounted for by the rising level of prosperity among the middle class of the country, leading to increased use of private cars instead of reliance on the taptaps, the brightly colored pickup trucks still used for public transport in rural areas. There has also been a rise in the demand for electricity, much of it either for general household use or for air conditioning. Fossil fuels provide 68.9 percent of the electricity production in Haiti, and 31 percent comes from hydropower.

The Haitian government of the provisional president Joseph Nérette took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and the government of René Préval ratified the Vienna Convention in 2000. The provisional government of Boniface Alexandre accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on July 6, 2005, which took effect on October 4, 2005.

Justin Corfield
Geelong Grammar School, Australia

Hansen, James (1941–)

DIRECTOR OF THE National Aeronautics and Space Administration (NASA) Goddard Institute for Space Studies in New York and adjunct professor in the Department of Earth and Environmental Studies at Columbia University, James Hansen has come to the public attention in contemporary debates about global warming for his harsh critique of the environmental policies pursued by the George W. Bush Administration. He has also unequivocally stated that, because of such criticism, it is increasingly difficult for him to speak freely about the emission of greenhouse gases and global warming. In 2005 and 2006, Hansen claimed, in several interviews with the *Washington Post* and the *New York Times*, that officials at NASA headquarters were ordering the public affairs staff to review his coming lectures, papers, postings on his mailing lists and website, and requested interviews from journalists. This was due to his critical statements made during a lecture at the American Geophysical Union in San Francisco in December 2005. In Al Gore's Academy Award-winning documentary, *An Inconvenient Truth* (2006), Hansen has repeated the charge of having been manipulated. Since the late 1980s, Hansen has been issuing public statements about the long-term threats deriving from heat-trapping emissions, dominated by carbon dioxide. To Hansen, these are an unavoidable byproduct of burning coal, oil and other fossil fuels.

Born on March 29, 1941, in Denison, Iowa, Hansen was educated at the University of Iowa where he obtained a B.A. in Physics and Mathematics with highest distinction in 1963, an M.S. in Astronomy, in 1965, and a Ph.D. in Physics, in 1967. He took part in the NASA graduate traineeship program from 1962 to 1966 and, at the same time, between 1965 and 1966, he was a visiting student at the Institute of Astrophysics at the University of Kyoto and in the Department of Astronomy at the University of Tokyo. After serving as a Postdoctoral Fellow at the Leiden Observatory in the Netherlands, in 1969, and as a Research Associate at Columbia University, from 1969 to 1972, Hansen joined the Goddard Institute for Space Studies. He has directed the Institute since 1981, and has worked as an adjunct professor at Columbia since 1985. As a college student, Hansen was first attracted to the James Van Allen Space Science Program, but later focused on planetary research dealing with climate change on Earth resulting from anthropogenic changes of the atmospheric composition.

One of Hansen's main research interests is radiative transfer in planetary atmospheres, especially interpreting remote sounding of the Earth's atmosphere and surface from satellites. Analyses of such data could constitute one of the most effective ways to monitor and study global change on the Earth. Hansen is also interested in the development and application of global numerical models for the purpose of understanding current climate trends and assessing potential human impacts on climate.

In the 1980s, Hansen was one of the first scientists to point out that the process of global warming was already taking place and that its effects would be visible beginning in the 1990s, not 2020, as most of his colleagues argued at the time. He suggested in his paper, "Global Warming in the Twenty-First Century" (2000), an "alternative scenario" for global warming and its possible solution. In it, Hansen claims that we should focus on non-CO_2 gases and black carbon in the short run, giving more time to make reductions in fossil fuel emissions. According to his alternative scenario, the current warming up of temperatures is largely due to non-CO_2 gases. Hansen stresses the role of climate-cooling aerosols emitted with fossil fuel burning in offsetting CO_2 warming and he points out that non-CO_2 gases, taken together, are responsible for roughly 50 percent of greenhouse gas warming. In "Defusing the Global Warming Time Bomb" (2003), Hansen has further developed his ideas on climate change, reaching the conclusion that human actions now far surpass the impact of natural elements in changing the climate. He has pleaded for an urgent and unprecedented international cooperation to control climate change. Hansen has predicted that 2016 will be the global tipping point (also known as the runaway effect) for global warming, if the human population is unable to reduce greenhouse gases.

Although he describes himself as a "middle-of-the-road" conservative, Hansen publicly endorsed John Kerry in the 2004 Presidential Election. This decision was motivated by his disillusion with the environmental policies pursued by the Goerge W. Bush Administration. Hansen is also particularly critical of the U.S. responsibility for the global warming phenomenon. He has repeatedly stressed that determining responsibility for climate change should not be limited to current emissions. The effect of greenhouse gas emissions on climate is determined by accumulated emissions over the lifetime of greenhouse gases in the atmosphere.

If we take into account past emissions, the United States can be described as the largest single cause of climate change, even after its current emissions are surpassed by China and other developing countries. According to Hansen, there are concerted efforts to mislead the public about issues of climate change and to dismiss the problem of global warming as a hoax. On the contrary, he points out that the phenomenon is very real, and that changes needed to keep it in check do not require hardship or reduction in the quality of life, but will also allow an improvement of life conditions such as cleaner air and water, and the growth of high-tech industries.

Harvard University

HARVARD UNIVERSITY, IN Cambridge, Massachusetts, is the oldest school of higher education in the United States. Founded in 1636, in the Massachusetts Bay Colony, the school was named Harvard College in honor of John Harvard, a clergy member who left half his fortune and his library to the college. Harvard University remains a private school governed by a corporation, the president, and fellows of Harvard College. Harvard offers undergraduate, graduate, and professional study in many academic disciplines (such as law, medicine, business, and education) in several schools and centers.

EARTH SYSTEMS STUDIES

The approach to teaching and research related to Earth systems, including climate, is integrated throughout the departments and inclusive of all disciplines. Many academic courses related to climate studies or atmospheric sciences are taught by the Faculty of Arts and Sciences (FAS), founded in 1890 by the merger of the College Faculty (also Faculty of the Graduate School) and the Scientific School Faculty. The FAS includes Harvard College (undergraduate), the Graduate School of Arts and Sciences, School of Engineering and Applied Sciences, and Division of Continuing Education, including Harvard Extension School. Environmental courses are offered to undergraduates and graduates across numerous schools and departments and with neighboring schools, Massachusetts Institute of Technology (MIT) and Tufts University, including the various sciences, economics, business, philosophy, religion, literature, and law.

The options for graduate students include combining science and engineering. Those interested in life science have opportunities to work with chemists, physicists, and computer scientists to study and simulate biological processes. Engineers and physical scientists observe and apply natural principles and processes to create human-made materials and products. The Graduate School of Arts and Sciences offers a Master of Science, Master of Engineering in Applied Mathematics, Applied Physics, Computer Science, and Engineering Sciences, and a Doctor of Philosophy in Science, Technology, and Management (with Harvard Business School). Instead of traditional academic departments and degrees by specific research area, these graduate programs rely on the convergence of engineering, applied sciences, and technology, and allow for specialization, including studies in Environmental Sciences and Engineering.

HOLISTIC MODEL

The Department of Earth and Planetary Sciences relies on a holistic model of the Earth, incorporating physics, chemistry, astronomy, and biology to study the intimate link between human life and the Earth and its systems. In addition to bringing together a variety of disciplines for scientific discovery, the department incorporates colleagues in social sciences and humanities to address societal issues pertaining to the human/Earth interrelationship.

The facilities include laboratories with instruments for a wide range of analyses, libraries, and lecture rooms of the Department of Earth and Planetary Sciences in the University Museum and in the David and Arnold Hoffman Laboratory of Experimental Geology. A variety of external research facilities and sites are available to students for research, including the seismograph station at the George R. Agassiz Station of the Astronomical Observatory in Harvard, Massachusetts, about 25 mi. (40 km.) west of Cambridge. Harvard also has reciprocal instructional and credit-granting arrangements with MIT and the Woods Hole Oceanographic Institution for graduate students.

Examples of research conducted by the Department of Earth and Planetary Sciences are showcased by the ecological measurements taken at Prospect Hill in Harvard Forest in Petersham, Massachusetts and on a privately owned site adjacent to Prospect Hill. On specifically sized (10 m. radius) plots, scientists record tree growth, woody debris, litter-fall, leaf litter decomposition, leaf-area increment, foliar nitrogen content, soil respiration, and soil moisture. Also at the Harvard Forest is the Fisher Museum, open to the public. The exhibit includes dioramas on central New England forests' history, conservation, and management. The museum also has self-guided interpretive trails. These trails connect the museum to the research forest.

MILLIONS OF YEARS

The goal of study in atmosphere, ocean, and climate dynamics at Harvard is to understand the Earth's weather and climate, over timescales of days to million years, by studying the systems controlling the circulation of both the atmosphere and the ocean. Of special interest is finding sources of variability (such as irregularity of El Niño, periods of ice ages, and precipitation patterns). Ongoing research includes programs for improving weather prediction and El Niño prediction.

A variety of research projects at Harvard Forest include measuring nitrogen oxide concentrations at Harvard Forest, a study of carbon and nitrogen in the soil, along with soil temperature and moisture; and soil respiration with soil temperature and moisture. In relation to climate science, a study by one research group working at the Harvard Forest includes collection of data on greenhouse gas concentration and flux, and carbon storage. Another group has measured ozone-depleting and/or greenhouse gases above the forest canopy at Harvard Forest since 1996. In the experimental and theoretical laboratory, researchers perform work on ozone chemistry in the stratosphere/troposphere.

Atmospheric and climate dynamics research topics include the study of past and present weather, and processes for creating climate models, global atmospheric and oceanic circulations, atmosphere-ocean exchange of energy and water, as well as studies on exchange of carbon dioxide and reactive gases with the biosphere, life-cycles of aerosol particles, and the effects of changes in atmospheric composition on climate. Additional opportunities for students include the Atmospheric Chemistry Journal Club to bring together the various groups in atmospheric chemistry for discussion and collaboration on atmospheric science topics. Past topics have covered "Scientific Consensus on Climate Change" and "Saturation of the Southern Ocean CO_2 Sink due to Recent Climate Change".

RESEARCH INSTITUTES

Some of the many research institutes at Harvard focus on modeling to better understand life systems and the universe, including climate. At the Kavli Institute for Bionano Science and Technology, technology meets life and biology. The institute harnesses a variety of academic disciplines to address behavior and function of biological systems. FAS began the Center for Imaging and Mesoscale Structures in 1999, the center was renamed the Center for Nanoscale Systems and became part of the larger National Nanotechnology Infrastructure Network in 2004, for availability to researchers on a local and national basis. The focus of CNS is to integrate nanoscale components into large and complex interacting systems to study how small structure behavior varies from the larger system and objects.

At the Harvard University Center for the Environment (HUCE), the complexities of environmental dynamics requires an integrative approach. To meet this need, HUCE brings together faculty members and students from a wide range of academic disciplines (the sciences, engineering, public health, government, business, economics, and law) to research complex environmental problems with the potential for global impact. In addition, the center sponsors symposia, public lectures, and informal student convocations to connect everyone with an interest in the environment.

Edwin Land founded the Rowland Institute for Science in the early 1980s. In 2002, the institute merged with Harvard University. The institute focuses on experimental science over a wide range of academic disciplines (current research includes physics, chemistry, and biology). The facility support includes a laboratory, a precision machine-shop including a welding facility, an electronics engineering lab to fabricate custom instrumentation, and a library/information center.

In 1998, the Harvard Institute for International Development and the Kennedy School of Government established the Center for International Development (CID) at the Kennedy School. The goal of CID is to support sustainable international development research, by bringing together academics and researchers from across Harvard's schools and with international colleagues. The complex issues (including managing climate change and environmental issues) related to global development require input from a variety of views. The Sustainability Science Program presents the dynamics of human-environment systems to encourage practical application through research, innovation, policy, and management. The center offers a Master in Public Administration in International Development degree to prepare students.

The Harvard Green Campus Initiative (HGCI) started in 2000 to focus on making Harvard an example of sustainability. HGCI staff and students develop services for money-saving and environmentally-friendly results, including building upgrades, construction, and design; greenhouse gas reduction; procurement; renewable energy; reduced waste and recycling; and environmental training and education. Using a business model, HGCI seeks challenging solutions to complex problems within time, economy, and social policy. Strategy is based on value to assure that each program is financially and organizationally viable and makes a difference in improving the environment.

A few examples of the success of HGCI include construction (green building projects with energy performance 30 to 50 percent above code and 90 percent recycling of construction waste); Green Living programs (a 40 percent increase in recycling and 10 to 15 percent reduction in energy use); campus-wide green cleaning service; the use of biodiesel in Harvard buses; Waste Management and Recycling Service achieving 45 percent recycling rate; and a Commuter Choice Program to encourage use of public transport and bicycling. The goal of HGCI and working partners is to continue to demonstrate the viable approach of sustainability within the context of business and economy. As part of an extensive cooperation, an International Students' Committee (ISC) office at Harvard University connects Harvard students with St. Gallen University in Switzerland to support the St. Gallen team members planning and participation in the St. Gallen Symposium.

Hawaii

AN AMERICAN STATE in the central Pacific, Hawaii consists of eight large islands and hundreds of islets stretching more than 1,500 mi. (2,414 km.). Located about 2,500 mi. (4,023 km.) from the mainland of the United States, this 50th state is unique in composition. Less than 6,500 sq. mi. (16,835 sq. km.) of total land area is divided 48 percent for conservation and 47 percent for agriculture. The division reflects the two largest industries of the state, tourism and food processing, with tourism contributing substantially more to the state's economy. In 2006, more than 7.5 million visitors spent $12.4 billion in Hawaii. Tourism generates more than 25 percent of the state's tax revenues. The economic crisis that Hawaii faced after 9/11, a crisis categorized as the most severe in Hawaii's history, made clear how dependent the state is on tourism, and tourism is dependent upon the island paradise that Hawaii's image promises. Hawaii has begun to take steps to preserve that image.

Changes, many of them attributed to global warming, are already threatening the paradise. In Honolulu, the average temperature has increased by 4.4 degrees F (2.5 degrees C) over the last century, and precipitation has decreased some 20 percent in the last 90 years. The Intergovernmental Panel on Climate Change projects increases in temperature by 3 degrees F (1.6 degrees C) or more by the beginning of the next century. Such warming would likely lead to an increased number of extremely hot days, and could also lead to increases in the intensity of thunderstorms.

The rising sea levels that accompany warmer temperatures create additional problems. The sea level is already increasing by 6–14 in. (15.2–35.5 cm.) per century. Erosion has been an ongoing problem for the islands for half a century. Some sources say that as much as 2 percent of the state's coastline is critically eroding, with losses ranging from 0.5–1 ft. (0.15–0.3 m.) per year. Nearly 25 percent of Hawaiian beaches have been significantly degraded. In the mid-1990s, Whale-Skate Island, a primary breeding ground for monk seals, started eroding. By 1998, the island had disappeared completely, placing this species in jeopardy.

Researchers note that most of Hawaii's plant and animal species are found only in the islands. The remote, unpopulated islands are home to some of the largest seabird colonies in the world. The state is also the world's leading site for extinct and endangered species. Approximately 70 percent of U.S. extinctions have happened in Hawaii, and more endangered species per square mile can be found in Hawaii than in any other place on the planet. While some experts are cautious about attributing such changes to global warming, others argue that climate change is at least a contributing factor.

HAWAII'S UNIQUE ENERGY PROFILE

Hawaii's isolation from the mainland United States and its non-energy intensive economy make the state's energy profile distinctive. Per capita energy consumption is among the lowest in the nation, and the state ranks 51st in its carbon dioxide production. However, the state's energy needs are growing; they increased by 18 percent 2003–04. Over one half of the state's energy consumption can be attributed to the transportation sector, particularly the jet fuel consumed by military and commercial flights. Only Alaska consumes more jet fuel. Hawaii burns very little coal (only 14 percent of its energy), but it is the most oil-dependent of the 50 states. Nearly 90 percent of the state's petroleum is imported.

Hawaii began to address the problems of climate change actively in 1989, when the state legislature voted to create the nation's first energy performance contracting program designed to foster the development of public-private partnerships that would increase the use of more energy-efficient technologies. In 2004, Hawaii enacted a law that required the state's public utilities to provide 8 percent of their electricity from renewable sources by December 31, 2005. The act required an increase of 10 percent renewable sources by 2010, with an annual increase of 1 percent until a 20 percent increase is attained in 2020. The act also mandated that the Department of Land and Natural Resources and the Department of Business, Economic Development, and Tourism foster development of renewable energy projects within the private sector. According to the U.S. Department of Energy, Hawaii ranks 5th among the 50 states in the use of non-hydro renewable energy.

In 2006, Hawaii Governor Linda Lingle signed into law four bills that were part of the Energy for Tomorrow program. The first law raised the income tax credit for certain renewable energy technologies, making this tax credit permanent, and provided incentives to support the production of biodiesel and cellulosic ethanol. It also created the Hawaii Renewable Hydrogen Program to move the state toward a renewable hydrogen economy. Other laws included in the package appropriated funds for solar power systems in public schools, required 20 percent of the state's new vehicles to be hybrids or alternative fuel vehicles, with the percentage increasing in subsequent years, established a public benefits fund for energy efficiency programs, and authorized the state's Public Utility Commission (PUC) to set penalties for failing to meet the state Renewable Portfolio Standard (RPS). A final act appropriated monies to reauthorize the Hawaii Energy Policy Forum and charged that reconvened group with developing an action plan.

The state's most ambitious move came in 2007 when Hawaii, following California's example, became the second state in the nation to place a statewide, enforceable limit on greenhouse gas pollution. A task force was given until the end of 2009 to develop the regulations that will allow the state to reduce greenhouse gas emissions to 1990 levels by 2020. The state Department of Health and Department of Business, Economic Development, and Tourism will assist the task force. Critics point to the exclusion of emissions from air transportation, despite that sector's high contribution to CO_2 emissions.

Health

GLOBAL WARMING AND climate change may produce a wide variety of harmful impacts on human health. Although the magnitude and timing of climate change and the effects of human adaptation are not known with certainty, some inferences have been drawn from existing models. These models attempt to use historical scientific data and current global or regional trends to estimate a range of possible future outcomes. There remains significant disagreement in both scientific and political circles regarding trends in global warming, potential threats posed by change, and the need for mitigation effort. Five major potential outcomes of global warming and climate change associated with significant health consequences include increases in ambient temperature, weather extremes, shifts in infectious disease patterns, changes in air quality, and resource pressures associated with migration and adaptation.

BACKGROUND

Public health practitioners and medical researchers in government, academia, and other agencies around the world are studying possible health impacts of global warming and associated climate change. There is a growing body of literature used to help understand current trends and extrapolate future trends, representing the work of experts from many disciplines, working to understand health effects. Increasingly, this research takes place through collaborative partnerships or organizations comprised of experts from across the globe. Two examples of these types of collaborative efforts are research conducted by the World Health Organization (WHO) and the Intergovernmental Panel on Climate Change (IPCC).

Both direct and indirect health effects can occur from transient heat increases, extreme weather events, water availability and quality, changes in air quality and atmospheric protection, infectious diseases, and the interplay of these factors. Although some impacts may be positive, such as the possibility that increased winter temperatures may result in lower seasonal morbidity and mortality in some areas, the overall impact of global warming and climate change on human health is expected to be negative. This imbalance is partly attributed to the likelihood that climate changes over the next several centuries will outpace local and regional capacity for adaptation in many areas.

There are many uncertainties and challenges in accurately predicting the health effects of global warming and climate change. Partly, this is because the overall outcomes depend extensively on other factors that impact human health and compound their effects. These factors include population expansion, energy production, pollution or misuse of land and water resources, deforestation, and urbanization. Another complication in predicting the health effects are the many ways in which health impacts may be offset by continuing scientific advances in medical care, pharmacology, and public health. This may prove especially important with improved access and resources in developing countries.

Effects of global warming and climate change are expected to vary by population socio-demographic characteristics and by geographic area. People in developing countries are particularly vulnerable, in part, because of the reduced resources for planning and responding to changes, often due to geographic location. People who live in areas that are prone to extreme weather events, such as coastlands and lowlands, are more likely to be adversely affected. In many areas, people who contribute the least to global warming and climate change (through energy consumption and waste production) will be the most vulnerable to its effects. In both developed and developing countries, the poor, elderly, very young, and chronically ill are more vulnerable than healthier or more affluent people. Finally, there are many areas that are currently only sparsely populated, due to marginal water and food resources. With relatively small changes in average annual temperature or shifts in rainfall patterns, many of these areas will no longer support sustained human activity. Other areas that are currently too cold or arid may become more hospitable, but migration requires tremendous amounts of resources, and often requires travel across semi-permeable political (or cultural) boundaries.

TEMPERATURE INCREASES AND EXTREMES

Average temperature has increased globally over the past few decades and is expected to increase between 2.5–10.4 degrees F (1.4–5.8 degrees C) by the end of the 21st. century. An increase in mean temperature occurs in the context of fluctuating local, regional, seasonal, and other patterns. This translates to higher temperatures at the extreme, which in turn, are directly related to short-term human illness and death. For context, the estimated average temperature for the most recent ice age was approximately 7.2–9 degrees F (4–5 degrees C) below the mean temperature over the subsequent 10,000 years to the present. Research in this area has been especially controversial because of evidence of historic variation in temperature and difficulty establishing valid associations, in the context of global environmental complexity. Increasing mean temperature may be the most direct and measurable component of global warming and climate change, and health effects may be more related to extremes (both hot and cold) than to overall increased temperature.

Many scientists have proposed that the most significant impact of increasing mean temperatures will be the related disruption of regional and global weather patterns, driven, in part, by alterations in oceanic and atmospheric temperatures and currents. Relatively minor shifts in major currents, such as the Gulf Stream and El Niño, produce significant changes in the frequency and intensity of local storms and rainfall patterns.

It is expected that there will be both direct (or more immediate) impacts, as well as indirect impacts, of temperature changes and extremes. The most direct and observable effects are heat strokes and deaths related to heat extremes. Indirect effects are more debatable and difficult to attribute to any one cause, but one possibility is decreased health related to decreased physical activity, and more time spent indoors in air-conditioned environments. Some research has also shown associations between higher temperatures and violence in urban areas.

In summer 2003, a two-week heat wave in Europe killed tens of thousands of people. It was estimated that summer temperatures averaged 6.3 degrees F (3.5 degrees C) above baseline, perhaps the hottest season in several hundred years. Lessons learned include highlighting the vulnerability of elderly and health-impaired individuals, and the disparate impact of temperature extremes on poor people and resource-poor communities. This event was particularly important for future planning, because it highlighted the continuing inadequacy of mitigation plans and available resources in developed countries. Another compounding factor is the increased ambient temperature of urban areas, which can result in a significant contribution to morbidity and mortality during peak heat events.

Increases in average ambient temperature are also expected to contribute to melting of ice caps and glaciers, which currently reflect large amounts of incident radiation (albedo), potentially leading to further global warming and climate change that may negatively impact health at regional and global levels.

EXTREME WEATHER EVENTS

Flooding, drought, and environmental degradation associated with climate change may lead to population displacement and more environmental refugees. Sea-level rise is likely to affect low-lying coastal populations, especially in countries where economic means do not allow construction of sea defenses and other counter-measures. Human populations have tended to concentrate in major cities over the past 150 years, and many of the largest population centers are located on low-lying oceanfront terrain, often with an associated major river delta.

As with heat changes and extremes, there are expected to be both direct and indirect health effects of extreme weather events. Direct health impacts include injury and mortality associated with these events. There are potentially many more indirect effects, such as increases in vector-borne diseases associated with flood waters, the spread of infectious diseases in sewage runoff and poor drinking water in the aftermath of these events, and increases in mental illnesses due to community displacement, loss of property or lives, or anxiety. In late August 2005, hurricane Katrina formed over the Bahamas and

While some inferences have been drawn from existing models, more studies are needed for a better understanding of the health impacts related to global warming and climate change. Very little is known about its long-term consequences on health.

crossed the Gulf of Mexico, where it strengthened before reaching landfall along the Gulf Coast, including the New Orleans metropolitan area. Because New Orleans had been built in low-lying areas (in some cases below sea level) at the Mississippi delta, it was particularly vulnerable to the breaching of its protective levees. Nearly all of the city levees broke in at least one place, flooding large parts of the city and completely disrupting the community support system. It is estimated that over 1,800 people died, and over one million were displaced by the storm. Two years later, it was estimated that approximately one-third of the population had not returned to the area and both public and private services to remaining citizens had not returned to pre-hurricane levels.

Regarding drought, changing water patterns may put severe strain on human populations that do not have access to resources for diversion of rivers or development of major reservoirs. In areas that do have resources, the environmental impact of drought may be significantly exacerbated by human activity.

INFECTIOUS DISEASES

Perhaps the earliest measurable changes in human population health related to climate change are relatively rapid shifting of patterns in bacterial, viral, fungal, and parasitic diseases. As living organisms strive to adapt to changes in temperature and weather over time, pursuing both immediate survival and longer-term access to resources, shifts occur in the geographic range of plants, animals dependent on plants, animals dependent on animals, and associated disease patterns. For example, vector-borne diseases are caused by microorganisms that are transmitted by spending part of their life cycle in an animal that then interacts with humans. Diseases may appear in previously unaffected areas in one of several ways, including migration of the vector to newly-warmer or wetter ecosystems.

In its quest for a meal, the mosquito must penetrate the skin of animals and access blood, in the process providing access to organisms harbored in its mouthparts. Malaria (*Plasmodium* genus, *Anopheles* genus mosquito) and dengue fever (dengue virus, *Aedes* genus mosquito) are two major diseases transmitted in this way. Malaria is endemic to tropical areas, largely because the lifecycle of the *Anopheles* mosquito depends on warm, humid climate and pools of warm standing water for maturation of eggs; the malarial parasite itself does not reproduce in colder temperatures. Global and regional rises in average temperature are expected to extend the range into higher altitudes and more northern latitudes. In Central and South America, researchers have documented an increase in malaria associated with warmer temperatures that occur during El Niño affected periods.

Challenges in measuring regional and global infectious disease changes as they relate to temperature and climate alterations are compounded by many other (sometimes interrelated) human activities. For example, diseases with rapid human-to-human transmission may quickly jump large geographic obstacles such as oceans and mountain ranges through rapid transport capability and increases in overall mobility (travel) of human sub-populations.

Water-borne (especially diarrheal) infectious diseases could increase due to changes in temperature and rainfall patterns. Increasing coastal water temperatures may give rise to more frequent toxic algal blooms. Food-borne diseases, such as salmonellosis, also increase in incidence in warmer months, and may have a significant impact in many areas.

AIR QUALITY

Weather and climate changes can affect the mix and level of contaminants in the air. This has important consequences for health, according to a growing body of research showing associations between poor air quality and adverse health effects. In particular, cardiovascular conditions such as cardiac arrhythmia, and respiratory conditions, such as asthma, have been associated with poor air quality. For asthma, temperature increases can affect the levels of aeroallergens, such as pollen and mold, which can exacerbate symptoms in allergy and asthma sufferers. The combination of heat and urban pollutants interact to form the urban heat island effect. This refers to the increase in temperatures in urban areas, compared to surrounding rural areas, as a result of less tree coverage, and more use of heat-absorbing materials, such as rooftops and roadways in urban areas. Increases in temperature cause an increase in ground level ozone, a principal component of urban smog.

Atlanta, Georgia is a comparatively well-studied example of a large urban area affected by ground-level ozone and smog pollution. The increases in congestion, vehicle traffic, drought, and development of the built environment over the past several decades have interacted to increase temperatures, ozone, and smog in the city. In the summer months, Atlanta often exceeds air quality standards for ozone and particulate matter set by the U.S. Environmental Protection Agency. The Georgia Environmental Protection Division reports daily air quality levels in metro Atlanta and issues Smog Alert warnings for days when measured pollutants are projected to exceed a certain level. The purpose of alerts is to warn people with respiratory conditions and other vulnerabilities to limit exposure. In 2006, metropolitan Atlanta was issued 42 smog alert days, as well as 236 days of moderate-risk air pollution warnings for vulnerable groups.

ADAPTATION AND MITIGATION

Although it is difficult to determine the extent of the health impacts of global warming and climate change, both currently and in the future, there are several adaptation and mitigation measures that can be taken to lessen potential impacts. On the adaptation side, these include improved design of homes, buildings, and other land and water structures to withstand extreme weather events. In some cases, relocation of populations away from low-lying flood plains and other geographic areas that are especially susceptible to extreme weather events should also be considered.

On the mitigation side, more health studies are needed for a better understanding of the health impacts of global warming and climate change. Although research on health effects has increased in the 21st century, very little is known about the contribution to global warming and climate change to ill health beyond immediate and observable impacts. A related need is for better disease and environmental surveillance data on an ongoing basis, particularly in developing countries. Many developing countries lack even basic environmental-monitoring capabilities or disease-tracking systems. Another need is for the implementation or improvement of disaster response planning, including educational intervention and outreach. Each of these efforts requires financial resources. Finally, research and innovation on ways to reduce the human contributions to global warming will play an important role in adaptation and mitigation strategies. A notable area is the reduction of fossil fuel use and increasing the availability and use of renewable energy technologies. The relationship between the human population and the environment is dynamic, so if there is a change in the environment, it will require an adaptation across a broad and diverse range of resources and local and environmental challenges.

Heat, Latent

LATENT HEAT IS energy in the form of heat released or absorbed by a substance during a phase change of the substance. The amount of latent heat involved with condensation/evaporation and freezing/melting are different under different temperatures and pressures. As temperature increases, latent heat of vaporization decreases, but that of fusion increases. Water is not the only substance that has three different phases at a normal temperature range in the universe, but it is the most abundant substance like this on Earth. A larger amount of latent heat is involved with the phase change of water. Through this transfer of latent heat, the water cycle determines surface and atmospheric conditions, as well as atmospheric circulation. Evaporative cooling and condensation heating moderate the surface temperature. Without this cooling and heating, daily temperature range would be significant, much like that of planets such as Mars or Venus, or of blacktop asphalt in summer.

The atmosphere is a dynamic heat system designed to transfer heat from one place to another. Latent heat involved in the phase change of water plays essential roles in the transfer of heat. Just as much latent heat is released in the atmosphere through a phase change as the latent heat is absorbed at the Earth's surface. The latent heat fluxes and the transfer of sensible heat between the equator and the poles are major components of the energy balance of the Earth. The latent heat flux in the atmosphere is huge. Latent heat flux involved in the phase change of water drives the atmospheric circulation and plays essential roles in global climate.

Latent heat is also an important factor to better comprehend weather systems, because it is a primary source of energy that develops, promotes, and sustains severe weather systems, such as thunderstorms and tropical cyclones. Latent heat supplies weather energy. As water condenses, latent heat from the water molecule is released into the air, heats the air, makes it lighter, and makes it rise fast. As the air rises, more air flows in and promotes storms. In this process, some latent heat is changed into the kinetic energy that accelerates the speed of water molecules and powers up severe weather systems. Recent global warming increases the ability to evaporate and hold moisture in the atmosphere. As a greater amount of water vapor exists in the hot air, more latent energy is available to be released into severe storms. Another critical aspect of global warming is that it will increase variability of extreme weather, although the overall average of the atmospheric condition changes little. Thus rare, but extreme weather, often much beyond what we experience today, will be more common.

Controversy exists concerning if latent heat adds to global warming, increasing it, or tends to act as negative feedback for global warming, slowing it down. A small change in atmospheric composition and chemistry can induce considerable climate alteration. The proponents of global warming argue that water vapor absorbs more infrared radiation than any other atmospheric gas and induces the largest greenhouse effect of the global climate. Growing latent heat flux in the atmosphere increases the amount of clouds, helping retain more heat, which would lead to more evaporation of water and the addition of more water vapor into the atmosphere, which leads to more heat in the atmosphere, and so on, in a positive feedback cycle. Opponents of global warming argue that a growing amount of clouds would increase the Earth's albedo, which would decrease the amount of solar radiation that reaches the Earth's surface. A decrease of solar radiation received would cool the Earth's surface, instead of heating it, in a negative feedback cycle.

Clouds contribute approximately 50 percent of Earth's planetary albedo. Change in latent heat flux in the atmosphere not only determines weather, but also induces global climate change. Aside from the climate change, latent heat is also responsible for the atmospheric humidity that affects human comfort. Despite uncertainties in the understanding the global climatic system, there is evidence that indicates that the Earth's atmosphere and overall environment are warming, such as sea-level rise, polar ice caps receding, increasing weather extremes, and more severe storms. Neither positive nor negative feedback cloud forcing has reached the point where it can offset the warming or cooling effects.

Heat, Sensible

IF THE MOVEMENT of energy to or from a substance can be sensed (for example, with a thermometer) as a rise or fall in temperature, then it is referred to as sensible heat. By contrast, if the movement of energy to or from a substance has a different result, such as evaporation, there will be no change in temperature. In this case, the energy is held dormant in the substance for release should the substance revert to its initial state (for example, via condensation). For this reason it is called latent heat. Changes in the sensible heat content of a substance (such as air) result in temperature changes, but latent heat movements (such as by evaporation) do not. The rate of sensible heat flow (sensible heat flux) is often referred to as dry heat flux, whereas the rate of latent heat flow is often referred to as evaporative heat flux. Climate is characterized by how available energy at the Earth's surface is distributed between sensible and latent heat.

Energy that drives global climate originates from the Sun as shortwave radiation. Some of it is absorbed by the Earth and heats the surface. The surface, in turn, radiates this energy as longwave (infrared) radiation to the atmosphere. Greenhouse gases in the atmosphere absorb some of this energy and radiate it back to the surface. The net result, or net allwave (long and short) radiation at the surface, is energy available to heat the air via the sensible heat flux, or to be used to evaporate water via the latent heat flux (which includes the transpiration from the leaves of plants). For example, in summer at mid-latitudes, or year round at low latitudes, more solar energy is absorbed at the surface during the day than is lost by longwave radiation. Surplus energy is transported as both sensible and latent heat from the surface to the atmosphere by eddies of air (convection).

A rise in the concentration of greenhouse gases in the atmosphere leads to more energy retained at the surface of the Earth. This additional energy could be used either to heat the atmosphere by way of the sensible heat flux (increased warming), or evaporate additional water via the latent heat flux (increased humidity). If moisture is freely available at the surface, the latent heat flux will always be larger than the sensible heat flux, meaning that energy otherwise available to heat the atmosphere is used to evaporate moisture. The resulting warming of the atmosphere would be less, in this case, than if all the additional available energy was accounted for by the sensible heat flux alone.

The heating of air by the sensible heat flux at the Earth's surface causes the air to become buoyant and, as a result, rise and mix with the cooler air aloft. Moisture, as well as sensible heat from the surface, is entrained in this convectional mixing of air. As a result, the mean annual global climate impact of increased energy available from an enhanced greenhouse effect will manifest itself both as an increased sensible heat flux (warming) and increased evapotranspiration via the latent heat flux. The latter is hidden heat energy that can be transported great distances by wind and over time without loss. The impact on climate may occur in regions far from its source. This hidden heat energy does not radiate back to space until condensation occurs and returns the heat to the air.

Heinz Center

FOUNDED IN 1995, in honor of late Republican Senator H. John Heinz, III (1938-1991), the Heinz Center is a nonprofit institution dedicated to improving the scientific and economic foundation for environmental policy through collaboration in different sectors among industry, government, academia, and environmental organizations.

Senator Heinz was always active as a politician in initiatives to preserve the environment and to understand the impact of human actions on it. By the mid-1980s, Heinz claimed that human actions were damaging the environment and, with Democratic Senator Tim Wirth, he set up Project 88. The Project contributed to the landmark legislation Clean Air Act Reauthorization passed by the Senate in 1990. Heinz also introduced bills to encourage the recycling of newspapers, motor oil, and other hazardous wastes.

The Senate version of the Clean Air Act reauthorization bill included a Heinz amendment protecting the right of local communities to fix strict limits on radionuclide emissions from nuclear facilities. Heinz was one of the main supporters of legislation to require banks to encourage sustainable growth in developing nations by considering the environmental implications of projects they finance. Heinz also proposed legislation to protect groundwater and ensure proper maintenance of above-ground storage tanks, and cosponsored a bill to curtail global warming. Heinz was a firm believer that many environmental problems went beyond national borders, so he was a founding member of GLOBE (Global Legislators Organization for a Balanced Environment) International, created in 1989 as a forum for the world's policy-makers to exchange environmental ideas and concerns. He also chaired GLOBE-US. Heinz served in the U.S. delegation to the Interparliamentary Conference on the Global Environment in 1989. In his capacity as a member of the national board for Earth Day, Heinz sponsored a variety of organizations with educational missions. He co-chaired the Alliance to Save Energy, served as a board member to the Environment and Energy Study Institute, and, along with Senator and future Vice-President Al Gore, supported EarthTech 90, a fair of environment-friendly technology on the National Mall in 1990.

To carry out the environmentalist legacy of Senator Heinz, the center focuses on issues that confront policymakers regarding the environment. The diverse membership of the center's board of trustees, its steering committees, and all its committees and working groups, mirror its guiding philosophy that aims to involve all relevant parties to offer solutions to the complex issues surrounding environmental policymaking. Industry, environmental organizations, academia, and government are the four components that the center attempts to involve in each of its program areas and projects. All four sectors are actively involved in all aspects of environmental policymaking, from the identification of a problem, through the suggestions of recommendations, to implementation of a policy. The cooperation between these four sectors produces solutions to the environmental challenges that face the United States and the world. The center, thus, gathers leading policymakers and practitioners from government, industry, environmental organizations, and universities to work together to identify pressing environmental challenges and to agree upon ways of meeting those challenges.

THREE PROBLEM AREAS

The center has identified three program areas: the state of the nation's ecosystems, global change, and the sustainable oceans, coasts and waterways. The report on the state of the nation's ecosystems is the most comprehensive document on the condition of U.S. lands, waters, and living resources. The report supplies business leaders and the general public with essential information concerning local, state, and national environmental policy. It provides decision-makers a scientific basis to decide on the best course of action, without putting forth prescriptive recommendations. The focus of the project is on ecosystem indicators, agreed upon by hundreds of experts from universities, government agencies, corporations, and environmental organizations. Funded by the federal government, foundations, and corporations, the report also emphasizes key gaps in data that must be filled to allow a complete picture of ecosystem conditions. One of these missing data has been identified through a national "carbon storage" indicator. Also, as part of the report, the center has formed an air quality working group that has the task of identifying the suite of chemicals that pose the greatest risks to human and ecosystem health.

The Global Change Program stems from the consideration that global changes in climate pose challenges to policy-makers in both developed and developing countries. The Global Change team analyzes policy responses to global environmental changes, both in terms of limiting change and in terms of adapting to it. The Global Change program includes domestic and international collaborators. Both its present and past projects have tackled issues that are relevant for global warming. For example, the "Evaluation of Technology Policies to Help Lower Emissions of Greenhouse Gas" (1999) assessed the effectiveness of policies to accelerate the development and adoption of new technologies for lowering emissions of greenhouse gases. The "Lowering Emission of Greenhouse Gases Through Emission Trading" (1988) examined alternative plans to include emissions trading into a potential U.S. program for lowering emissions of greenhouse gases such as carbon dioxide. Researchers analyzed how different potential trading systems worked under realistic conditions, and provided advice to Congress and the Administration on the cost-effectiveness of the major options. The Heinz Center plays a major role in the international Global Energy Assessment (GEA) project, an effort to provide essential information for global energy policy development and future energy strategies. GEA is structured around four main areas of analysis: major global issues and energy, energy resources and technological options, possible sustainable futures, and policies advancing energy for sustainable development.

A major project of the Global Change Program is the Eco-thresholds initiative, which was established to explore the subject of defining acceptable levels of greenhouse gas concentrations and to determine how to anticipate and deal with rapid changes in ecosystems. Started in 2005, Eco-thresholds is the result of the cooperation of the Heinz Center with The Nature Conservancy and the Joint Global Change Research Institute. The project has gathered members of the scientific and policy communities to explore the science behind thresholds and their implications for decision-making. The Eco-thresholds project aims to enhance collaboration among government, business, academia, and environmental nongovernmental organizations to define key issues caused by abrupt changes in ecological systems. The project also intends to promote long-term cooperation among the sectors and stakeholders to cope with threshold changes in natural, managed, and socioeconomic systems. Finally, the participants will discuss acceptable levels of greenhouse gases necessary to limit those threshold changes that cannot be dealt with through management actions. In addition to the Eco-thresholds initiative, the center sponsors the program "Methane 2100" to document the global distributions and concentrations of methane, a greenhouse gas, in the atmosphere, by sensors aboard a polar retrograde orbiting satellite. The third area of intervention by the center is the Sustainable Oceans, Coasts and Waterways Program to devise policies to stop the decline in quality and sustainability in these vital areas.

Historical Development of Climate Models

CLIMATE MODELS ARE computational tools used to study the dynamics of the climate system and predict future climate changes. Climate models have developed historically through the growth of mathematical techniques, computational capacity of computers, data of present and past climates, and theories of component climate processes. Climate models have progressed from very simple models for regional weather prediction, to sophisticated general circulation models that simulate interactions of the atmosphere, oceans, land surfaces, ice, and biosphere. Climate models are of great relevance because they examine the effects of increased atmospheric CO_2 on the Earth's average temperature. As such, climate models have been the primary source of data used by scientific communities and government organizations to draw conclusions about global warming.

EARLY MODELS

As developed in the early 1920s, the first proper model of climate-related events was a mathematical technique used for numerical weather prediction. This model treated a local weather area as a grid of cells. Using a set of basic equations, the model could, in principle, calculate how differences in pressure between adjacent cells determined wind speed and direction across the represented weather area. Lewis Fry Richardson, a pioneer of numerical weather prediction, attempted to apply the model to actual weather conditions. Richardson's attempt was unsuccessful because he was unable to perform calculations faster than the weather occurred.

During the late 1940s and early 1950s, computers were developed that could reliably perform complex calculations much faster than human beings. American meteorologists used computers to build models of weather simulation, one of the earliest of which was run on a computer named ENIAC. This particular model divided North America into a grid of cells. Taking the known weather conditions for each grid, the model calculated how air should move across the cells. When compared to the real weather that emerged, the model proved partially accurate, though the applicability of the model was limited by computational capacity and scientific knowledge of weather and climate processes.

As scientists developed more successful weather models, scientific focus expanded during the 1950s and early 1960s to include the development of simple climate models. In the earliest of these models designers analyzed the effects of geography and topography of mountain ranges on airflow across North America. They also simulated how energy and momentum moved through the atmosphere, and were able to predict wind patterns with some accuracy. Additionally, simple models began to represent equilibrium in the atmosphere by incorporating calculations for balancing incoming solar radiation with outgoing radiation reflected from the Earth. By the mid-1960s, these developments gave some degree of credibility to climate modeling; models could now simulate coarse processes of the Earth's atmosphere.

GENERAL CIRCULATION MODELS

In the late 1960s and early 1970s, computers advanced to the point of performing complex calculations in short timescales. Better observational data and measurements were made available through satellites and ground measurements. These conditions facilitated the emergence of three-dimensional atmospheric general circulation models, which represented climate as a comprehensive system. As they developed, general circulation models treated the atmosphere as layers and incorporated processes of convection, evaporation, and rainfall. The models could simulate the transfer of radiation vertically through the atmosphere, the reflectivity of sunlight from snow and ice, and basic seasonal changes. During this period, oceans were represented in models and coupled with the atmosphere, though these early models treated the ocean as a slab, without any unique dynamics of its own. General circulation models permitted analysis of how the movement of radiation through the atmosphere was affected by water vapor and CO_2.

Throughout the 1970s, Syukuro Manabe built and enhanced a climate model to analyze the relationship between CO_2 changes and climate change, a concept known as climate sensitivity. Specifically, the model investigated how a doubling of atmospheric CO_2 concentration would change temperature. The first estimates indicated that temperature would increase by approximately 3.6 degrees F (2 degrees C). In this way, models raised awareness among the scientific community that rising CO_2 in the atmosphere could lead to increases in the Earth's temperature, a phenomenon known as greenhouse warming.

By the 1980s, atmospheric general circulation models permitted analysis of climate component processes occurring on smaller spatial and temporal scales. Also, models of this period coupled the atmosphere and oceans in a complex way by simulating the exchange of heat between both components. Coupled models could simulate changes in sea ice, as well as the emergence of deserts and rainfall areas. As the use of coupled models advanced, research into atmospheric changes in CO_2 revealed serious consequences for the processes driving the overturning of ocean waters, which could potentially cease with higher levels of CO_2.

MODELS AND CLIMATE CHANGE ANALYSIS

Models provided information that ultimately increased public concern about the Earth's climate. As a result, the validity of models themselves became an issue of increasing importance. By the 1990s, projects were initiated in which models were systematically compared to one another, in relation to a growing and uniformed body of climate data. Such projects provided the science of climate modeling with a form of quality control and a standard of reproducibility of results. Using data about conditions during the most recent ice age (which were gained primarily from ice-core measurements), one way of testing the validity of models was to see how well they could simulate the climatic and oceanic conditions characteristic of glacial periods. An additional test of validity involved using models to predict consequences of unique, real-time events, such as climatic responses to volcanic eruptions. Models were successful in these various tests. Models gained further credibility as they served as the primary source of data for the newly-formed Intergovernmental Panel on Climate

Change (IPCC). In the mid-1990s, the IPCC used climate model data to draw its conclusion that a human influence on climate had been detected.

Models that have developed over the past several years are extremely complex. Relative to the simple models that emerged in the 1950s, current models can carry out simulations in much shorter time periods and represent many component processes simultaneously, including the atmosphere, oceans, glaciers and ice sheets, land surfaces, and biological and chemical activities linked with human economic life. Models now inform understanding of a range of possible future climatic changes and their impacts. Current models that simulate the present climate and account for CO_2 show a severe risk of future global warming. Based on these data, the broadly accepted view among scientists, policymakers, and the public is that rising CO_2 levels are warming the Earth.

The success of complex models has not eliminated the need for simple models. The latter models still provide valuable information about independent processes and climatic changes occurring on small spatial and temporal scales. Thus, they serve to develop basic theoretical understanding that enables complex models to simulate broader interactions between the atmosphere, oceans, biosphere, and other component processes. Along with models of intermediate complexity, such as those used to study long time-series corresponding to glacial processes, simple models are regarded as part of a hierarchy of models upon which complex models are based.

In the future, models will continue to generate highly-complex, detailed three-dimensional representations of climate dynamics. Nevertheless, challenges remain that prevent models from providing a perfect simulation of real climate. Scientific understanding of many of the key process that control climate sensitivity (such as clouds, vegetation, and ocean convection) is incomplete. Consequently, these processes cannot be represented in detail in climate models. Additionally, the predictive capabilities of climate models are linked to their performance in reproducing the historical record, which is largely limited to geological data and relatively recent global temperature observations. Processes could exist on a longer temporal scale that even the highly-complex models of today cannot take into consideration. For example, the presence of non-linear processes could potentially change the behavior of climate abruptly. Future progress of climate modeling will depend on the continued commitment to developing improved mathematical and computational techniques, more data, and better theoretical understanding of climate dynamics.

History of Climatology

CLIMATOLOGY IS THE branch of atmospheric science dedicated to the description and analysis of the Earth's climate and its biospheric interactions over extended periods of time. Climatology began as the observation and description of weather on subcontinental and continental levels. The Ancient Greeks believed that climates were nothing more than temperature gradients varying along latitude belts. Climatology was primarily observational speculation prior to the dawning of the scientific age, when devices for measuring and studying weather were invented, and the keeping of systematic weather records began.

EARLY ATTEMPTS TO UNDERSTAND THE CLIMATE

The scientific roots of climatology, a subdiscipline of meteorology until the late 20th century, were planted in the work of Edmund Halley's 1686 mapping of the trade winds and his assertion of a relationship between solar heating and atmospheric change. His work introduced the idea of weather and climate systems interacting with the physical features of the Earth. It was not until the early 20th century that the understanding of this interaction moved beyond observation to analysis and synthesis. Prior to the mid-20th century, climatology was divided into two subdisciplines: regional climatology, studying subcontinental and continental weather and climates; and physical climatology, gathering and analyzing the statistical data related to weather and climates. Climatology sought to describe and understand normal climates, but there was little understanding of the timescale or breadth of climate change, save for the ice age or of climate as a global system of interrelated climates forming a whole that is more than its parts.

Vilhelm Bjerknes's pre-1920s work on mid-altitude cyclones led him to create a model of atmospheric change based on hydrodynamics and thermodynamics. Bjerknes's work and Lewis Fry Richardson's 1920s equation-based weather predictions led to a rudimentary three-dimensional atmospheric model.

However, the complexity of the equations and magnitude of the calculations made the understanding of climate systems nearly impossible, until the availability of high-speed computers in the 1950s made numerical modeling of climate systems possible. This expansion led to the formation of the new subdisciplines of dynamic meteorology and dynamic climatology.

The second major impetus for change in climatology in the 20th century was World War II. World War II demonstrated the advantage to modern warfare of predictive meteorology when, for example, it was used to forecast the weather for June 6, 1944, the day of the invasion by the Allies of Nazi-occupied France. These conventional military applications, along with the need to understand weather patterns and climates as they related to the possibility of nuclear war and the expanding agricultural, industrial, communication, and transportation technologies, led to increased funding for training, research, and education in climatology.

CLIMATOLOGY PIONEERS

Several key figures emerged in the academic world as the regard for meteorology and climatology increased. Carl-Gustav Rossby created the Department of Meteorology at the University of Chicago in 1942, and there, with a team of researchers, developed the first physical climate models that viewed the entire planet as an integrated physical whole, or system. Reid Bryson, a World War II military meteorologist, left the geography department at the University of Wisconsin, Madison to form a meteorology department there, and then established, in 1962, a climate research center at Madison, after receiving National Science Foundation funding. Massachusetts Institute of Technology mathematician and meteorologist Edward N. Lorenz, also a World War II military meteorologist, began applying chaos theory to the atmosphere in the 1960s, and his theories were integrated into the increasingly-complex atmospheric-modeling relegated to computers. Despite these advances, the U.S. Weather Bureau continued to view climatology only as a tool for forecasting.

Concurrent with this growth of meteorology and climatology as academic disciples, was the development of geophysics, the physics of the Earth and its environment. When the International Union of Geodesy and Geophysics was founded in 1919, geophysics encompassed such disparate fields as geology, geodesy, meteorology, oceanography, seismology, and terrestrial magnetism. Though interdisciplinary in the breadth of the fields of study, geophysics was not interdisciplinary in the integration of the knowledge bases into a coherent whole.

The weapons of World War II, such as the atomic bomb, demonstrated the need for the collaboration of various scientific disciplines. This led to the creation (in 1946) of interdisciplinary projects, such as the U.S. Air Force's Cambridge Research Center Geophysics Research Directorate and the Air Force Cambridge Research Laboratories.

This interdisciplinary spirit was boosted 1957–58, when the International Geophysical Year encouraged the interdisciplinary collaboration on subjects such as climatology. The creation (in 1970) of the National Oceanic and Atmospheric Administration (NOAA), integrating oceanographic and meteorological studies was in recognition of the growing need for interdisciplinary science in the study of climate. The National Aeronautics and Space Administration (NASA) followed suit and orbited satellites designed to enhance these interdisciplinary studies by creating an Earth system science.

INTERDISCIPLINARY COLLABORATION

This new emphasis on scientific interdisciplinarianism was demonstrated with the 1977 founding of the journal, *Climatic Change*. This end of knowledge fragmentation and the increased collaboration among disparate fields helped fuel the growth of climatology as a scientific discipline. System interrelatedness was obvious by the mid-1970s, and the symbiosis of meteorology, mathematics, computer science, geophysics, chemistry, biology, and other relevant sciences evolved into an all-encompassing discipline under the academic rubric of Earth sciences.

This systems emphasis and interdisciplinary collaboration, augmented by advances in computer technology, expanded climatology from a restrictive, predominantly statistically-based descriptive applied climatology, to include a physical-mathematical modeling discipline with predictive global capability. The International Geosphere-Biosphere Program (IGBP), founded in 1986 and based at the Royal Swedish Academy of Sciences, sought to bring international interdisciplinary cooperation to the study of the global environment.

An important result of this system-based analysis was that the old concept of a normal climatic period gave way to the idea that the climate is dynamic and always changing. During the 1960s, J. Murray Mitchell Jr., a climatologist with various federal agencies and then with NOAA, asserted that human (androgenic) actions influence climate positively and negatively and warned that the negative human influence was apparent in what he determined to be statistically significant global warming. Though it was initially unclear to Mitchell if human atmospheric pollution, particularly carbon dioxide (CO_2), might lead to drastic global warming or cooling, it was clear to him that this pollution was radically affecting the global climate and that technological and sociological intervention where necessary to avert a disaster. By the mid-1970s, Mitchell and other scientists became convinced that the real danger was global warning, and not global warming.

The history of climatology was dominated by the global warming debate during the last 30 years of the 20th century. By the beginning of the 21st century, climatology was dominated by computer modeling, and by the assumption that the proper way to understand global warming, as well as regional climates and weather patterns, was by understanding the climate system of the whole planet. This change was reflected in the emergence of the new subdisciplines of climatology: climate change, bioclimatology, paleoclimatology, and applied climatology.

History of Meteorology

METEOROLOGY IS THE subdiscipline of atmospheric science that studies weather and climate using physics, chemistry, and other sciences. The term meteorology is derived from Aristotle's *Meteorologica* (350 B.C.E.). The first official regular weather reports were seen in China (1060 B.C.E.) with the first regular European weather observations in 500 B.C.E. The Ancient Greeks were the first to divide the world into temperature zones, and Aristotle was the first to articulate the hydrologic cycle, describing the circulation and conservation of the Earth's water using the evaporation and condensation cycle.

SCIENTIFIC MEASUREMENT

It was not until Rene Descartes's *Les Meteores* (1637 C.E.) that an attempt was made to establish the scientific basis of meteorology. Meteorology was nothing more than observational speculation prior to the scientific age, when devices for measuring and studying weather were invented, and the keeping of systematic weather records began. Galileo Galilei invented the water thermometer for measuring absolute temperatures in 1593, and may have constructed the first thermoscope for measuring temperature changes in 1607. Evangelista Torricelli invented (1643) the mercury barometer that detected atmospheric pressure changes, making possible the observation that drops in pressure substantially correlate with the advent of storms (in 1644). Blaise Pascal noted, in 1648, that atmospheric pressure decreased with increasing altitude, deducing a vacuum above the Earth's atmosphere, and, in 1667, Robert Hooke invented the anemometer for measuring wind speed.

Gabriel Daniel Fahrenheit created the mercury thermometer with his temperature scale in 1714, followed by Anders Celsius's alternative temperature scale in 1735, which was adopted in Napoleon's empire in the early 1800s. The daily observation of basic changes in air pressure, moisture, and the direction and speed of the wind was instituted by Laurent Lavoisie in 1765. Horace de Saussure's hair hygrometer (1780) for determining humidity provided the last major instrumentation, and one of the final measuring standards necessary to move meteorology from observation into research and theorization. Luke Howard's cloud classification system (1802) and Francis Beaufort's wind speed scale (1806) provided additional observational tools.

INTERPRETATION OF THE DATA

The scientific roots of climatology, a subdiscipline of meteorology until the late 20th century, were planted in the work of Edmund Halley's 1686 mapping of the trade winds and his assertion of a relationship between solar heating and atmospheric change. Benjamin Franklin (1706–90), sometimes credited as the first American meteorologist, observed that North American weather systems move west to east, discovered lightning was electricity (1752), charted the Gulf Stream, linked volcanic eruptions to weather changes, and associated deforestation with climate change. The German H.W. Brandes drew the first weather map in 1819.

Controversies based on the interpretation of the data began to increase as the number of government and academic-related weather observation and recording programs burgeoned in the United States in the first quarter of the 19th century. The most notable of these was the storm controversy (1834–59) involving William Redfield, James Espy, and Robert Hare, concerning the nature, cause, and methodology for studying storms.

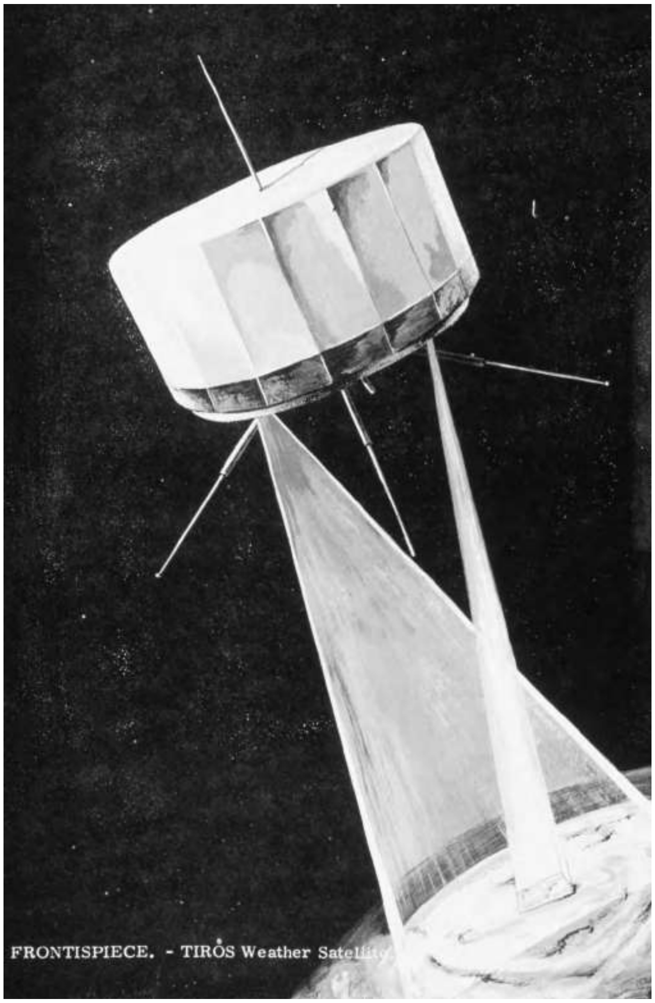
Though never resolved, the controversy gave impetus to increasing observational networks and the theoretical understanding and application of meteorology by the U.S. military, the Franklin Institute, the Smithsonian Institute, and the American Philosophical Society. Samuel F.B. Morse's telegraph and Morse code made the more rapid dissemination and analysis of this increasingly abundant information possible. The Army Signal Corps began using the telegraph in 1849, to disseminate daily weather observations through the U.S. Department of War, and in the same year, the Smithsonian began producing daily weather maps from telegraphic information.

In 1855, France created the first officially-sanctioned national weather service in response to the loss of French vessels at sea during a storm in 1854. The first daily forecast was created by Robert Fitzroy, and first appeared in the London *Times* in 1860, and in 1861 the first system for port storm warnings was instituted.

The modern weather map was introduced by the Paris Observatory in 1863, and was later enhanced by the use of innovative graphic devices, such as symbols and isobars, lines showing constant pressure. The U.S. Weather Bureau, created by the Army Signal Corps in 1870, was ceded to the Department of Agriculture in 1891, and Britain's Meteorological Office was formed in 1872.

William Ferrel's 1856 postulation that mid-latitude circulation cells created the prevailing westerly winds by serving as a deflecting force interacting with pressure gradients was confirmed in the late 19th century and named the Coriolis Effect (Force) in the early 20th century. Vilhelm Bjerknes's work on mid-altitude cyclones led him to create, by 1920, a model of atmospheric change based on hydrodynamics and thermodynamics. The concepts of air masses and weather fronts were forwarded in the 1920s.

Though Bjerknes work, along with Lewis Fry Richardson's 1920s equation-based weather predictions led to a rudimentary three dimensional atmospheric model. The complexity of the equations and magnitude of the calculations caused this area of meteorology to languish until the availability of high-speed computers in the 1950s. Edward N. Lorenz applied chaos theory to the atmosphere in the 1960s, and his theories were integrated into the increasingly complex atmospheric modeling relegated to computers. The advent of the 21st century brought an increased emphasis on computer modeling through such joint projects as the Global Atmospheric Research Programme (GARP), designed to model atmospheric phenomena on a global level.



Rendering drawn prior to launch of the TIROS I satellite system showing its range of vision on Earth's surface.

Though Teisserence deBort began using kites and balloons to gather temperature data in 1899, it was not until the 1940s that radiosones (balloons) began daily measurements of temperature, humidity, and pressure of the upper-air. World War II fighter pilots discovered the jet stream, and later, surplus military radars began to measure precipitation. Doppler radar began replacing conventional radar in the 1990s. The first weather satellite, TIROS I (Television Infrared Observation Satellite), was launched in 1960.

METEOROLOGY AND CLIMATE CHANGE

A hole in the ozone layer of the atmosphere was discovered in 1985, and the earlier detection of the warming of the Earth (1980) gave impetus to the idea that one of the causes was human (androgenic) induced climate change from man-made ozone depleting gases. The United Nations and the World Meteorological Organization (WMO) responded by creating (in 1988) the Intergovernmental Panel on Climate Change (IPCC) and tasking it with studying the hypothesized phenomenon. The IPCC determined that the Earth had warmed over the last 150-year period, and that that warming was due, in part, to human activity. In executive summary of the report, the panel concluded that most of the observed global warming experienced in the last 50 years was due to the increase in greenhouse gas concentrations. The IPCC and former U.S. Vice President Al Gore were jointly awarded the Nobel Peace on October 12, 2007, for their work on global warming.

The ever-increasing calculation power of computers made possible increasingly complex computer modeling of the atmosphere and many of the complex variables that impact weather and the climate. This made possible a greater understanding the causes and effects of such weather phenomenon as global warming and El Niño.

By 1997, a global treaty known as the Kyoto Protocol to the United Nations Framework Convention on Climate Change (UNFCCC) established legally-binding greenhouse gas emission restrictions on signatory countries by 2012, but did not include developing countries such as China and India. President George W. Bush of the United States did not sign the protocol. The enormous growth in the meteorology knowledge base in the 20th century led to its division into subdisciplines such as climatology, geophysical fluid dynamics, and atmospheric chemistry, as well as regional meteorologies.

Holocene Era

THE HOLOCENE, DERIVED from the Greek words *holos* and *kainos* meaning "entirely recent," covers the most recent unit of geologic time. Marked by a major shift in climatic conditions, it spans the last 11,550 calendar years before present to the present time. The prior epoch, the Pleistocene, was characterized by large swings in climate between cold (glacial) conditions and warm (interglacial) conditions. In contrast to the instability of the Pleistocene climate, the Holocene climate is far more stable and warm. This mild climate coincides with the Mesolithic period and the development of human technology, and is thought to play a key, supporting role in the advancement of human civilization.

Despite the generally mild climate, paleoclimate proxies (indicators of past climate) show that climate fluctuations lasting for hundreds to thousands of years did occur during the Holocene, albeit smaller amplitude changes than during the Pleistocene. Scientists use paleoclimate proxies such as ice cores, marine ocean sediment cores, ancient shorelines, fossil pollen, and tree rings, among others, to understand and estimate these changes in climate. These proxies have provided evidence for some of the significant Holocene climate fluctuations including the Younger Dryas, the Neoglacial, the Medieval Warm Period, and the Little Ice Age. Only a general timeline for these events is provided as the exact dates vary from one geographic region to the next.

The first significant climate change of the Holocene, the Younger Dryas, began during the transition from the Pleistocene to the Holocene when a final pulse of cold, glacial conditions interrupted the post-glacial warming. Major cooling in the North Atlantic region is evidenced by pollen records, which show that cold-tolerant plants reinvaded the landscape. The episode is named after *Dryas octopetala*, an arctic plant that spread to lower altitudes during this cold period. Greenland ice cores have also provided evidence of these colder temperatures.

By 6,000 to 7,000 years ago, climate had warmed to what is often referred to as the mid-Holocene thermal maximum. Vegetation zones moved to higher latitudes, and glaciers retreated in many regions of the world. This was followed by a second cooling episode, the Neoglacial, which lasted from approximately 2,500 years ago until 4,500 years ago. The generally cooler and drier Neoglacial climate led to widespread birth and re-growth of mountain glaciers. These glacial advances are physically evidenced by the remnants of debris originally transported down-valley by advancing glaciers and then deposited as the glaciers melted away.

The Medieval Warm period (also known as the Medieval Climatic Optimum) was a time of unusual warmth around 700 to 1,200 years ago. This warmer climate resulted in more harvesting and prosperity for human civilizations. In Greenland, the unusually warm climate attracted Nordic tribes in the high altitudes of the North Atlantic to migrate and settle the area, growing wheat in areas previously covered in deep snow. Pollen records show warm-tolerant plants flourished in these areas.

The Little Ice Age followed the prosperity of the Medieval Warm period. True to its title, the Little Ice Age was a cooling episode that lasted from approximately 200 to 600 years ago and was marked by moderate glaciation, crop failures, and famines. Substantial historical evidence, such as literature, maps, and art, is available to scientists as a record of this advance in alpine glaciers in many mountainous regions of the world.

The Holocene record shows a climate history with which scientists can compare recent changes in global climate. Evidence throughout the Holocene shows clearly that changes in climate have a direct influence on human civilization, and will continue its influence into the future. There is also substantial paleoclimatic evidence that the present greenhouse gas concentrations and rates of global warming are greater than those seen any time previously during the Holocene. This evidence suggests that these changes in climate are unique in the Earth's recent history

Scientists disagree about the exact nature of the Holocene climate changes and the mechanisms giving rise to them are not yet well understood. Researchers have proposed several mechanisms, of which three have been studied extensively. Solar variability (or changes in solar output) was theorized to be a mechanism; however, it is no longer widely accepted due to the large uncertainties in the solar-climate link. Another mechanism, changes in volcanism, has been shown to have a clear link to short-term climate changes, typically less than a few years. Less certain is if long periods of increased volcanism have a clear link with longer periods of climate change, or if short periods of climate change associated with volcanic events then give rise to longer periods. Another mechanism, ocean circulation, has been shown to give rise to lower frequency climate variability. Research in this area focuses on finding evidence concerning changes in ocean circulation that could have been the primary driver of climate change during the Holocene, or if it only served as an amplifier of the smaller changes in climate.

An additional area of active debate is whether these climate changes of the Holocene were global, hemispheric, or regional in nature. It is clear, however, that there were measurable fluctuations in Holocene climate over large regions, and that these changes in climate likely had a significant impact on the human civilizations in those regions.

Honduras

THE REPUBLIC OF Honduras lies in Central America, and has coastlines with the Caribbean Sea and the Pacific Ocean. Honduras has a land area of 43,278 sq. mi. (112,492 sq. km.), with a population of 7,326,496 (2006 est.), and a population density of 166 people per sq. mi. (64 people per sq. km.). About 15 percent of the land in the country is arable, with another 14 percent meadows and pasture used for the extensive raising of cattle, which contributes to the production of methane gas. In 1990, the carbon dioxide emission per capita for the country was 0.5 metric tons per person, rising to 0.94 metric tons per person by 2003. Some 88 percent of the carbon dioxide emissions come from liquid fuels, with 12 percent from the manufacture of cement. Honduras gets 63.1 percent of its electricity production from hydropower, with 36.9 percent from fossil fuels.

Internal flights in the country are relatively cheap, contributing to further greenhouse gas emissions, but one of the largest potential threats follows the confirmation, in September 1999, of large oil deposits along La Moskitia, one of the most important native environments in the country. This might also affect the Bay Islands, leading to a large oil industry, and further greenhouse gas pollution in Honduras and abroad.

Over 54 percent of Honduras is covered with forest, including much virgin cloud forest, and one of the most extensive tropical forests in the region. The rising water levels and water temperatures will have

U.S. aid workers rush food, shelter, water and medical aid to Hondurans made homeless by Hurricane Mitch in 1998.

the most obvious effects on the Bay Islands off the north coast of Honduras, with some coral bleaching noticed on the reefs there, especially after the El Niño event of 1997–98 and Hurricane Mitch on October 25, 1998. The coral reefs affected by bleaching include the most famous in Honduras, the Black Coral Wall and Pretty Bush, off the north coast of Utila, as well as those around the islands of Roatán and Guanaja. Furthermore, flooding of the Aguan River caused the Cayos Cochinos and Roatán to be inundated with soil and debris washed down during soil erosion. Flooding can also result in a greater prevalence of malaria and dengue fever.

The Honduran neo-liberal government of Rafael Leonardo Callejas ratified the Vienna Convention in 1993, and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. The government of Carlos Roberto Flores Facussé signed the Kyoto Protocol to the UN Framework Convention on Climate Change on February 25, 1999, it was ratified on July 19, 2000, and took effect on February 16, 2005.

Hot Air

INCREASING AIR TEMPERATURES, due to global warming, lead to an increased amount of hot air in the atmosphere. Hot air leads to unstable weather; this correlation could potentially link global warming to an increase in the strength, duration, and frequency of storms and other violent weather.

Hot air cools as it rises, as a result of its expansion due to the lower pressure found at higher altitudes. Importantly, the heat is not transferred to the surrounding air–the loss of heat is due to a decreased amount of energy in the air and the increased volume of the given parcel of air. If the rising air is at a different temperature than the air it rises into, "unstable" weather conditions will result, such as storms. The greater the discrepancy in temperature, the more violent the resulting weather will be.

If global warming continues, surface air will become warmer and warmer. As this warm air rises into the cooler atmosphere, the weather patterns could become less and less stable over the years.

Surface air temperatures have, in fact, been recorded to rise over time, across the globe. The rise has been calculated to be just less than 1 degree Fahrenheit (0.555 degrees C) per decade; this value seems small but it is not insignificant. The British Antarctic Survey (BAS), led by John Turner, reported in the year 2006 that the surface air temperature at the Antarctic Peninsula has risen at a rate three times greater than the rest of the Earth, in the past 30 years, which could be leading to the rising ocean levels.

Nevertheless, some experts warn that weather trends at the poles, such as Antarctica, should not be regarded in the same way as those trends closer to the equator. The temperatures at these extremes of the Earth have not been recorded as long as in regions closer to the equator. Additionally, the atmospheric and surface temperature inertia is largest at the equator due to the largest amount of surface area of the Earth, also affecting the rate of temperature changes.

Hungary

Hungary is located in central Europe and is a landlocked nation. Hungary has fertile soil and was an agricultural nation until 1948, when Communists came to power and began to industrialize the country. By the last years of Communist rule, nearly 40 percent of its citizens resided in places where air pollution was above accepted international standards. Coal-burning power plants and cars were responsible for most of the emissions. Inadequate sewage systems and industrial waste polluted the nation's rivers, including the Danube, and ground water. Alarmed by these problems, the Hungarian government passed new environmental regulations and received loans from the World Bank to implement controls. Another major shift in Hungarian history came in 1990 when a non-Communist government was elected and Hungary began the transformation to a free-market economy.

In the early years of changing from a centralized economy to a market economy, Hungary's pollutants decreased. Greenhouse gas emissions fell by 33.5 percent 1990–2000. The trend reversed itself 2000–04 as emissions rose by 2.5 percent. Hungary, a signatory to the Kyoto Protocol, joined the European Union (EU) in 2004. The country remained confident that it could meet the 6 percent reduction in emissions that the protocol required, although the economic advantages of EU membership made exceeding the goal likely.

However, real concerns about the effects of global warming on the nation's resources pointed to the need for more effective national strategies. The first four summers of the 21st century were hotter than normal and rainfall was lower than usual. The combination drained millions of gallons of water from Lake Balaton, central Europe's largest freshwater lake. The changes to the lake posed a direct threat to tourism, which was central to the region's economy. The Danube was also at its lowest levels in over a century, and Hungary's wheat crop was at two-thirds of its expected yield. Hungary signed the United Nations Convention to Combat Desertification agreement in 1999. By the time the agreement was formally announced in 2003, the problem had intensified, particularly in the Homokhatsag district in southern Hungary where ground water levels had fallen nearly 10 feet since the 1970s.

A 2006 Yale University study ranked Hungary in the second quintile according to its overall environmental health, but dependence on fossil fuels, high transport emissions, and a poor development of renewable energy sources were weak areas. The third item became especially significant when the European Union announced in 2007 that its member nations by 2020 should obtain 20 percent of their total energy from renewable energy sources, with 10 percent coming from biofuels. Hungary's Ministry of Economics and Transportation and the Ministry of Environmental Protection announced a 10-point action plan to slow global warming. The plan calls for the establishment of a National Energy Council, environmentally friendly tax changes, and a commitment to renewable energy and meeting the EU standard.

Hurricanes and Typhoons

HURRICANES AND TYPHOONS are tropical cyclones with maximum sustained winds of at least 74 mi. per hour (64 knots). Tropical cyclones that originate over the tropical Atlantic basin or the eastern/central North Pacific basin are called hurricanes, while those that originate in the tropical western North Pacific are called typhoons. Before the tropical cyclone reaches hurricane or typhoon status, there are stages of development the system will go through from birth to decay. Initially, when a poorly-organized mass of thunderstorms produces a weak circulation, the system is known as a tropical disturbance or tropical wave. When the winds increase to between 20 and 34 knots, the system is upgraded to a tropical depression, and when the winds increase to between 35 and

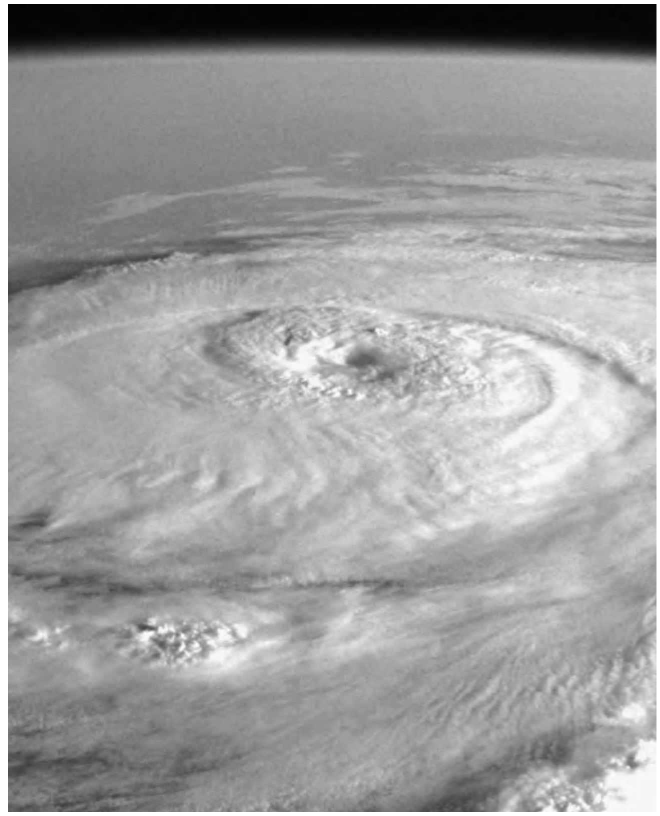
64 knots, the system is then called a tropical storm. At this point, the tropical cyclone is given a name.

For each tropical cyclone basin (Atlantic, eastern North Pacific, central North Pacific, western North Pacific, Australian region, Fiji Region, Papua New Guinea Region, Philippine Region, Northern Indian, Southwest Indian), there is a list of names. In the Atlantic, there is a six-year list of names. The list of names originated in 1953, and was first compiled and maintained by the National Hurricane Center. Currently, the lists are compiled and maintained by the World Meteorological Organization. Until 1979 (1978 in the eastern North Pacific), the list of names featured only female names. With the introduction of male names in 1979, male and female names are now alternated with each letter of the alphabet. The Atlantic basin has names for each letter of the alphabet from A to W, with the exceptions of Q and U.

In the event that each letter is used for a given year (as was the case in 2005), the Greek alphabet is then used (alpha, beta, gamma, and so on) for subsequent storms. If a particular storm is deadly or costly, the name is retired and replaced by a name beginning with the same letter. For example, there were five named storms in 2005 that were retired and replaced by the World Meteorological Organization (Dennis, Katrina, Rita, Stan, and Wilma were replaced with Don, Katia, Rina, Sean, and Whitney). The eastern Pacific basin has a similar six-year list of names, except that the list includes names for X, Y and Z (Q and U are still excluded). The western Pacific has five lists of names that are compiled and used sequentially by 14 contributing nations.

The Atlantic hurricane season begins on June 1st. and runs through November 30, with the peak frequency occurring during the months of August, September, and October. These months correspond to the time period where ocean temperatures are the highest. The eastern Pacific hurricane season is slightly longer, running from May 15. through November 30, with the peak frequency occurring during July, August, and September. Typhoons in the western Pacific can occur year round due to the vast supply of warm water, but typically occur from May to November.

Hurricanes and typhoons need certain conditions in order to intensify and grow. First and foremost, they need warm water to form. The threshold temperature that is generally considered necessary for tropi-



The impact of global warming on hurricane and typhoon formation are not fully understood.

cal cyclone formation is 79 degrees F (26 degrees C). The warm water from the ocean provides the energy that is transferred from the surface to the lowest layers of the troposphere. This causes the atmosphere to be unstable and allows for rising air. As the air rises, it cools, condenses, and releases latent heat, which causes the upper levels of the atmosphere to warm. Thus, an upper level high pressure is produced, which helps evacuate air to enhance the development of the surface low. The deeper the surface low becomes, the stronger the pressure gradient becomes, which creates stronger winds.

In addition to warm water, hurricanes and typhoons must form at non-equatorial locations, because they need Coriolis force (apparent force that causes an apparent deflection to the right of an object in the Northern Hemisphere because of the rotation of the Earth) to help the rotation, and in areas that help trigger surface convergence. One such area is the Intertropical Convergence Zone (ITCZ), which is an area where low pressure develops, however, few Atlantic systems develop there because of the proximity to the equator. The majority of Atlantic systems develop on the eastern side of tropical waves, which is an area that promotes convergence and rain showers. Another condition that must be satisfied for tropical cyclone development is the absence of vertical wind shear. Vertical wind shear is the change in wind speed or direction with height. When a hurricane or typhoon encounters areas with high vertical wind shear, the storm has a tendency to tilt, which inhibits the efficiency of the heat distribution in the atmosphere. Therefore, the upper level cannot form over the surface low that would cause the low to deepen. As a result, vertical wind shear causes the surface low to weaken.

The Saffir-Simpson scale is used to measure the intensity of hurricanes in the Atlantic and eastern Pacific. It uses estimated and measured maximum sustained winds in the eye wall to classify the intensity on a scale from one (weakest) to five (strongest). Only three category five hurricanes have struck the United States: Florida Keys (1935), Camille (1969), and Andrew (1992).

The impacts of global warming upon hurricane and typhoon formation are not fully understood. On one hand, an increase in global temperatures would increase ocean temperatures, which provide more energy for the tropical cyclone. On the other hand, it is not exactly known how warming would change vertical wind shear and the frequency of teleconnection patterns such as El Niño, which impact vertical wind shear. El Niño generally strengthens trade winds, particularly over the Atlantic basin, which inhibits Atlantic hurricane formation (as was the case in 2006). However, during El Niño years, there tends to be a slightly more active eastern Pacific season.

Hydrofluorocarbons

HYDROFLUOROCARBONS (HFCS) ARE a group of organic compounds that contain carbon, fluorine, and hydrogen. They are by-products of industrial manufacturing and were introduced as a replacements for chlorofluorocarbons and other ozone-depleting substances. However, though HFCs have zero ozone depletion potential (ODP), they have intrinsic and significant global warming potential (GWP), typically in the range of 1,000 to 3,000 times that of CO_2. Thus, they are among the six key greenhouse gases listed in the Kyoto Protocol for emission reduction. Other greenhouse gases listed by the protocol are CO_2, CH_4, N_2O, PFCs, SF6, and HFCs. Industry and government are collaborating on research and development, communication, and other activities to find new technologies, designs, and processes to manage these emissions.

The emissions management is occurring through non-regulatory means, voluntary measures, and industry-government collaborations. The air-conditioning and commercial refrigeration industry has particularly contributed to the success of the management process.

HFCs are generally colorless and odorless gases at environmental temperatures and are mostly chemically unreactive. They are non-flammable, having very low toxicity; they are recyclable, and highly energy efficient. There has been a significant growth in the market for HFCs because they have been identified as important alternative fluids for many end users. They find applications in refrigeration and air-conditioning, foam-blowing, general aerosols, solvent cleaning, firefighting, and metered-dose inhaling. They are preferred due to certain physical and chemical characteristics, especially their low toxicity and low flammability. The main sources of atmospheric HFCs are traceable to their sources of application. Two other major emitters are chemical plants making HCFC 22 (where HFC-23 is emitted as a by-product) and HFCs. There are several points in the lifecycle of HFC-using products at which emissions can occur. A computer model uses four emission factors to characterize the HFC emissions, namely fluid manufacturing, product manufacturing, product life, and disposal loss factors.

Examples of HFCs include trifluoromethane (HFC-23), difluoromethane (HFC-32), fluoromethane (HFC-

41), 2-chloro-1,1,1,2-tetrafluoroethane (HFC-124), 1,1,2,2,2-pentafluoroethane (HFC-125), 1,1,2,2-tetrafluoroethane (HFC-134), 1,1,1,2-tetrafluoroethane (HFC-134a,), 1,1-difluoroethane (HFC-152a), 1,1,1,2,3,3,3-heptafluoropropane (HFC-227ea). HFC-23 is created as a byproduct in the production of HCFC-22. Small amounts are also used in semiconductor manufacture and as fire-extinguishing agents. 1,2,2,2-tetrafluoroethane (HFC-134a) is now used in place of CFC-12, gaining importance as a replacement for CFCs in automotive air conditioners.

HFC-134a is also used as a refrigerant in most new refrigerators and in commercial chillers. Leakage from these sources, which occurs primarily during servicing of the units, rather than during normal operation, is much less than from automotive air-conditioners. Short-term uses of HFC-134a, on the other hand, are becoming an important source of emissions. 1,1-difluoroethane (HFC-152a) is used as a blowing agent, an ingredient in refrigerant blends, and in fluoropolymer manufacturing applications. Other HFCs with considerable radiative forcing potential include HFC-125, HFC-143a, HFC-227e, and HFC-236fa. In addition to replacing HCFC-22 in stationary air conditioning and refrigeration applications, HFCs are expected to gain new markets as foam-blowing agents.

The opportunities to reduce global warming emissions from HFC end-use markets could be considered from four perspectives, namely the minimization of emissions throughout the lifecycle of a product, usage of a zero/low GWP alternative fluid, usage of an alternative technology, and the minimization of indirect emissions of CO_2 from energy used by HFC users. These approaches should be considered from the viewpoints of practical feasibility, environmental effectiveness, and economic impact before the most cost-effective emissions-reduction strategy can be developed.

In some end-use markets, such as refrigeration, there may be significant opportunities for adoption of emissions-reduction techniques. In others, such as aerosols, emission reduction may not be a viable option. HFC emissions should not be considered in isolation, but in relation to emissions of other global warming gases. In some cases, the use of HFCs can reduce CO_2 emissions; therefore, an appraisal of total global warming impact must be made to properly understand the best fluids or technologies to apply.

Hydrological Cycle

THE HYDROLOGIC CYCLE (water cycle) is a global, Sun-driven process. On Earth, water travels in a cyclic process, transported from water bodies to the atmosphere, then to land, and subsequently, to water bodies in the hydrologic cycle. Water is evaporated by the Sun, incorporated into clouds as water vapor, falls to the land and water bodies as rain, and from land it goes back to the water bodies through several hydrologic processes, such as runoff and infiltration. The hydrologic cycle is a closed system for Earth, as the amount of water remains fixed throughout, but it may vary with its distribution geographically, temporally, and seasonally. Six major components of the hydrologic cycle are precipitation, infiltration, evaporation, transpiration, surface runoff, and groundwater flow. Evaporation and transpiration together are known as evapotranspiration. The volumes of different components of hydrologic cycle are: 110,000 $km.^3$ of precipitation onto land and 458,000 $km.^3$ of precipitation on the ocean surfaces, with 502,800 $km.^{3.}$ of evaporation from oceans and 65,200 $km.^3$ of evaporation from land, of which 42,600 $km.^3$ is of river runoff, and 2,200 $km.^3$ is of underground runoff.

Increasing atmospheric concentrations of greenhouse gases warmed the Earth's surface by nearly 1 degree F (0.6 degrees C) during the 20th century. It may continue in this century, leading to a higher sea-surface temperature. One instinctive consequence of a warmer ocean surface is a larger vapor pressure difference between the sea surface and the adjacent atmosphere. Therefore, there would be an increased evaporation rate and subsequent increase in the other components of the hydrologic cycle. Computer simulation models found that a global warming by 7.2 degrees F (4 degrees C) is expected to increase global precipitation by about 10 percent, and that rainfall intensity will greater than at present. Scientists, through models, found that the upper tropospheric water vapor amount will increase by 15 percent with each degree of atmospheric temperature rise. The global water vapor amount will increase by 7 percent with each degree of atmospheric temperature rise.

Conversely, to make matters worse, water vapor acts as a prominent greenhouse gas. Increased water vapor alters the climate feedback loop. With a rise in surface temperature the water vapor amount in the atmosphere increases. The additional water vapor absorbs additional radiated energy which would normally escape from Earth's surface to outer space, and it makes the Earth's surface even warmer. This somber picture is further complicated by important interactions between water vapor, clouds, atmospheric motion, and radiation from both the Sun and the Earth's surface.

HYDROLOGICAL CYCLE INTENSIFICATION

Several studies have demonstrated that the hydrologic cycle has already intensified, with a distinct (measurable) amount due to an increases in earth surface temperature. The followings is some of the evidence:

Daily minimum nighttime temperatures have increased at twice the rate of daytime temperatures since 1950. Consequently, increased cloudiness and humidity at night as well as increased evaporative cooling during the daytime are encountered. That suggests that atmospheric water vapor amount has increased.

Radiosonde measurements from 1973–93, coupled with satellite data, suggest that there is a substantial increase in the level of water vapor in the atmosphere and the amount of precipitation in all regions of the Americas, except northern and eastern Canada.

There is a near-term collapse of the ocean's thermohaline circulation. More precipitation is falling in northern Europe, some parts of Canada, and northern Russia, but less to swathes of sub-Saharan Africa, southern India, and southeast Asia. A Canadian research team found with 75 years (1925–99) of rainfall data analysis through 14 powerful computer models that the Northern Hemisphere's mid-latitude (a region of 40–70 degrees N) received increased precipitation over the years. The models also showed that, in contrast, the Northern Hemisphere's tropics and subtropics (a region between the equator and 30 degrees N) became drier, while the Southern Hemisphere's similar regions became wetter.

More hurricanes, typhoons, ocean depressions, and floods are being experienced globally. The Americas, China, Japan, Bangladesh, and India are experiencing more than average of these. Flood frequencies and intensities in India and many other countries have increased.

South America and Central America are experiencing more frequent and more severe landslides. This is because the precipitation amount from a single event has increased drastically. Due to increase in monthly mean (average) temperature, precipitation amounts in the United States and Australia have increased. This is consistent with climate model predictions.

Glacial retreat is another example of a changing water cycle and has been extensive since 1850. It is clearly visible in the North Pole, Greenland, and Antarctica. It is happening as the loss of water from melting and sublimation is greater than the supply of water to glaciers from precipitation.

Other human activities are also altering the hydrologic cycle. They include: agriculture, alteration of the chemical composition of the atmosphere, construction of dams, deforestation and afforestation, removal of groundwater from wells, water abstraction from rivers, and urbanization. These are also the cause of global warming. The increase in the amount of precipitation and reduction of the number of freezing days as a consequence of global warming are to some extent helping agriculture. However, the changes in the hydrologic cycle may have adverse consequences, including the ones described.

WATER SHORTAGES

Due to the reduction in snowpack, many perennial rivers in the world are experiencing shortages of flowing water in summer months, and groundwater recharging has weakened. Consequently, agriculture suffers. Increased quick melting of snowpacks (due to the rise in surface temperature) in the northwestern United States and India causes summer floods. Increases in rainfall intensity may cause more soil erosion and less soil infiltration. This would create detrimental effects on agriculture. Many hydrologic structures may suffer damage, and may not withstand the higher precipitation intensity, because they were not designed for atypical storm events or rainfall intensities. Increased numbers of hurricanes, storms, and other activities as a consequence of changes in the hydrologic cycle associated with global warming are causing severe hardship to numerous people living on shorelines. Agriculture in the northern United States and southern Canada depends upon soil moisture conserved by snowpack on agricultural land. With less snowfall because of increased surface temperature, there may be less snow deposited on agricultural land, and agriculture will suffer. In summary, global warming causes and would cause the following visible changes in the hydrologic cycle: changes in total precipitation, changes in precipitation frequency and intensity, changes in flood and drought frequencies, and changes in tropical storm frequencies. It would also further amplify global warming, due to increased water vapor in the Earth's atmosphere.

Ice Ages

ENORMOUS ICE SHEETS hav, at times, spread across the globe, bringing with them a cold climate. One definition holds that the advance of glaciers to middle latitudes marks an ice age. Another, and perhaps complementary, definition holds that the spread of glaciers to encompass roughly one-third of the planet is the signature of an ice age. Glaciers have advanced and retreated from Earth's surface and from the ocean several times. The most exuberant estimate tallies 17 ice ages. A more conservative estimate is that Earth has endured the tumult of six ice ages. Scholars have debated not only the number of ice ages, but also their causes. The causes fall into three categories: astronomical, atmospheric, and terrestrial. The recognition of ice ages is recent. Only in the 1830s did Swiss zoologist Louis Agassiz, building on the work of predecessors, propose that parts of Europe, the Americas, and Asia had been covered by ice. As ice advanced and retreated, Agassiz asserted, it ground up rocks in its path and sometimes carried boulders a great distance. Agassiz thought in terms of a single ice age, but climatologists have increased this number in the 20th century.

The first ice age occurred, not thousands of years ago, but rather 2.6 billion years ago. The sun, comparatively young, was not burning at full strength, though this fact does not explain why the ice age had not begun earlier. A more satisfactory explanation focuses on carbon dioxide. The amount of carbon dioxide in the atmosphere diminished, lowering the capacity of the atmosphere to trap heat and, thereby, warm the Earth. As the amount of carbon dioxide diminished, temperatures fell low enough for ice to spread over parts of the primeval continents. The first ice age, lasting 300 million years, ended 2.3 billion years ago.

THE END OF THE FIRST ICE AGE

The end of the first ice age ushered in a warm climate that endured 1.3 billion years. This period was the longest interglacial, a warm interlude between two ice ages, in Earth's history. When it ended, ice returned in a trio of advances and retreats: one billion years ago, 750 million years ago, and 600 million years ago. Of these three, the ice age 750 million years ago may have been the largest, with ice near the Equator. Glaciers may then have covered half the Earth. Climatologists group these three as the Upper Proterozoic Ice Age. One cause of it may have been an increase in the number of photosynthetic algae in the ocean. During photosynthesis, algae, as well as plants, absorb carbon dioxide and emit oxygen. Carbon dioxide is a greenhouse gas, but oxygen is not. In absorbing carbon dioxide, the algae reduced the capacity of the atmosphere to trap heat.

A second cause of the Upper Proterozoic Ice Age may have been rapid continental drift, bringing the continents into high latitudes, where they acquired glaciers and subsequently drifted into the tropics where the glaciers disappeared. This explanation accounts for the fact that the Upper Proterozoic Ice Age was not a single event, but rather the aggregate of three glaciations. Still another cause may have been an exaggerated tilt to Earth's axis. The current tilt is 23.5 degrees, but the tilt during the Upper Proterozoic Ice Age may have been as large as 54 degrees, an orientation that would have given the Southern Hemisphere less sunlight than the Northern Hemisphere year round, prompting the growth of glaciers in the Southern Hemisphere.

THE ORDOVICIAN ICE AGE

The third glaciation of the Upper Proterozoic Ice Age lasted until 580 million years ago. A warm interlude held back the ice for 130 million years, but the recrudesce of glaciers 450 million years ago ushered in the Ordovician Ice Age. The concentration of carbon dioxide was 25 percent lower than it is today, reducing the capacity of the atmosphere to trap heat. This reduction, if it caused the Ordovician Ice Age, underscores that greenhouse gases play a large role in determining the climate. South America, South Africa, India, and Australia were then part of the super-continent Gondwanaland, much of which was above 60 degrees South. At this latitude, evaporation from the ocean formed clouds, which, in turn, released their moisture in the form of snow. Over time, the snow compacted into ice, giving Gondwanaland large expanses of ice. Parts of the continent drifted over the South Pole, ensuring that ice and snow did not melt at the highest latitudes. Ice covered the remainder of Africa, which was not then part of Gondwanaland. By 440 million years ago, North Africa had replaced Gondwanaland at the South Pole. Glaciers spread as far as what is now the Sahara Desert.

Glaciers retreated 425 million years ago. The periodicity of a 130 million year interglacial nearly repeated itself with an interglacial of 125 million years. The Permo-Caroniferous Ice Age, beginning 300 million years ago, was a time of mountain-building on the continents. As is true today, high elevations were home to ice and snow. Glaciers formed first in the mountains of Tasmania and Australia, lands then part of Gondwanaland. Parts of Angaraland, a super-continent of China and Siberia, were above 75 degrees North and so were cold enough for the formation of glaciers. Only Laurasia, a super-continent of North America, Greenland, and Europe west of the Ural Mountains, being between 15 degrees South and 40 degrees North, was near enough to the equator to be unsuited to the formation of glaciers. By 280 million years ago, the glaciers had reached their greatest extent. Forests, spreading in the tropics around this time, may have cooled Earth by absorbing carbon dioxide. Locking up water in ice, the glaciers reduced sea levels between 492–820 ft. (150–250 m.). Glaciers crept from the South Pole to 30 degrees South. By then, the continents had joined to form the super-continent Pangea. The formation of Pangea caused volcanoes to erupt, spewing debris and ash into the atmosphere. These airborne particles blocked out sunlight, cooling the climate and hastening the formation of glaciers. Lands once covered by warm seas dried out and became cold.

THE PERMIAN AND CENOZOIC ICE AGES

By 270 million years ago the glaciers were in retreat and by 250 million years ago only a few mountain glaciers remained. The ocean, swelled by water from melting glaciers, returned to its pre-glacial level. Dramatic as this transition from ice age to warm climate was, it was shorter than the two previous interglacials. Around 230 million years ago, the return of glaciers heralded the Permian Ice Age. This glaciation coincided with a mass extinction of both terrestrial and marine organisms. Around 180 million years ago, Pangea began to break up into South America, South Africa, India, Australia, and Antarctica, all of which retained glaciers.

The glaciers were again in retreat by 130 million years ago. The interglacial that chased away the glaciers lasted until one million years ago, when the Cenozoic Ice Age inaugurated a new cycle of advance and retreat. This most recent ice age has had several glaciations. Glaciations of 100,000 years have alternated with warm periods of 10,000 years. The most recent glaciation occurred 100,000 years ago. Glaciers spread to their greatest extent 18,000 years ago before retreating. Ice 10,000 ft. (3,048 m.) thick covered Canada,

Glaciers have advanced and retreated from Earth's surface and from the ocean several times; estimates of Ice Age occurrences range from six to 17. Their causes—astronomical, atmospheric, or terrestrial—have been debated by scholars.

Greenland, and northern Europe. The glaciers locked up 5 percent of Earth's water as ice. Sea level diminished, revealing the continental shelves as land. With its continental shelves exposed, Florida was twice as wide as it is today. Temperatures fell to 10 degrees F (5.5 degrees C) below current temperatures.

Colder temperatures reduced the rate of evaporation from the oceans. Rainfall decreased accordingly. The Cenozoic Ice Age was both cold and dry. Land not covered by snow and ice became desert. The glaciers held so much water as ice that the North Sea, the Baltic Sea, and the Bering Strait, bereft of water, did not exist. With ice 2 mi. (3.2 km.) thick in parts of North America and Eurasia, its melting released millions of gallons of water into the oceans. In North America, water flowed south through the Mississippi River as the glaciers retreated north. Once the glaciers reached the Great Lakes, water flowed not south, but rather east through the Lawrence River and into the Atlantic Ocean. The cold water stopped the warm water of the Gulf Stream from heating the Atlantic coast. Bereft of the Gulf Stream, North America retained its glaciers until 10,000 years ago, when they shrank to their current size.

The Cenozoic Ice Age coincided with the origin of modern humans roughly 100,000 years ago. Modern humans arose in Africa, which was warm in contrast to the lands of the ice age. With minimal hair and abundant sweat glands, humans were adapted to warm climes. Nevertheless, they wandered into Europe about 40,000 year ago. There they encountered Neanderthals, a type of human that had lived in Europe for some 200,000 years. In contrast to modern humans, Neanderthals were adapted to the ice age. Their stout frame and short arms and legs minimized the body's surface area exposed to the cold and so conserved heat. In one of the great paradoxes in history, modern humans, adapted to a warm climate, thrived in Ice Age Europe, whereas Neanderthals adapted to the ice age went extinct.

The Cenozoic Ice Age also aided the migration of humans to new lands. The glaciers lowered sea level some 394 ft. (120 m.), revealing a land bridge between

Southeast Asia and Indonesia. To the north, a land bridge between Asia and North America allowed humans to colonize the New World. The end of the Cenozoic Ice Age coincided with the extinction of the saber-toothed cat, the wooly mammoth, the mastodon, the hippopotamus, and the horse in the Americas. Whether humans hunted them to extinction or whether they could not adapt to a warm climate remains open to question.

THE LITTLE ICE AGE

Around 1300 C.E., temperatures fell 2 degrees F (1 degree C), ushering in the Little Ice Age. The number of sunspots decreased during the Little Ice Age, evidence that the sun emitted less heat than it does in warm periods. The number of sunspots reached its nadir 1645–1715, the coldest years of the Little Ice Age. From the outset, Europeans suffered under harsh conditions. Beset by cold, wet weather, their crops rotted in the fields. Famine, acute in 1315 and 1317, consigned some to starve and others to chronic hunger. Malnourished, the people of Eurasia were vulnerable to disease. One of the worst pandemics, the Black Death, struck Europe during the Little Ice Age, killing between one-third and half the population. The Norse of Greenland fared no better during the Little Ice Age. Able to farm the land in warm weather, the Norse struggled to eke out an existence in the cold of the Little Ice Age, and finally failed. In the New World, George Washington's Continental Army nearly disintegrated in the frigid winter at Valley Forge.

By 1850, the Little Ice Age had ended. Shedding its heat at the current rate, the Sun warmed Earth. Well-suited to this new warm period, humanity began its rapid ascent to the current population of more than 6 billion. Some climatologists predict that the current warmth, like warm climates of the past, will not last. The current interglacial has nearly run its course. Soon, ice will again cover vast areas of the world. Others, however, predict that the climate will become warmer, not colder, because of the increase in the concentration of carbon dioxide in the atmosphere. The ice caps and the ice on Greenland will melt. Mountains will lose their snow and ice. Coastal cities may flood. At the moment, no consensus exists whether Earth will or will not descend into another ice age.

Ice Albedo Feedback

ALBEDO IS AN estimate of the reflectivity of a surface. The sun produces solar radiation in wavelengths that can be reflected off of many of the Earth's surfaces, some more so than others. The albedo of Earth is estimated as the ratio of the outgoing solar radiation (250–2500 nm.), and the incoming solar radiation. A surface that is perfectly reflective (all incoming light is reflected back again) would have an albedo of 100 percent reflection, or, as a ratio, 1.00. A surface that has no reflectivity would have an albedo of zero percent reflection, and a ratio of zero. On Earth, open water, such as the oceans, has an albedo of 0.05, whereas newly fallen snow has an albedo of 0.90. Ice and snow have an average albedo of 0.80. In the polar regions, this means that approximately 80 percent of the sun's rays are reflected back into the atmosphere and only 20 percent of the ray's transfer energy into melting the snow and ice. As the Earth warms, the amount of snow and ice cover decreases.

As snow and ice are very reflective, this works to keep the polar and high-altitude regions cooler. If, as in the polar regions, particularly the Arctic, approximately 80 percent of the solar radiation is reflected back to the atmosphere, the ice and snow do not melt completely and the permafrost that is located directly beneath the ice and snow is never warmed. If the permafrost remains frozen, the ice and snow on the ground are maintained and the air remains cool. This maintenance of the ice and snow keeps the albedo of the region fairly constant, reflecting most of the solar rays back to the atmosphere, and the ice and snow remain even longer. Scientists believe that this feedback loop that maintains the ice and snow has contributed to ice ages in the Earth's past.

The opposite scenario can also be imagined. If the air temperature at the Earth's surface increases, the ice and snow will melt more quickly. If there is less ice and snow cover at the poles and in the high altitude regions, the albedo will decrease (soil and vegetation are less reflective than ice and snow). If the albedo in a region decreases, more solar radiation will be absorbed by the Earth, which will further increase the surface temperature, melt more of the ice and snow, and perpetually warm the Earth. Scientists believe that global warming drives this ice-albedo feedback loop.

As global warming continues to increase the air temperature at the Earth's surface, continual decreases in the amount of ice and snow covering large areas and the polar regions and high altitudes are expected. If this occurs, the ice and snow may permanently disappear from areas that were previously under snow for the much, if not all of the year. If these areas are exposed, and, specifically, the permafrost is allowed to warm, melting of the permafrost layer will occur. If the permafrost layer were to melt, water drainage into the soil layers would increase. If this occurs, the peat layer beneath the permafrost that never decomposed due to a lack of water, will have vast amounts of water and warmer temperatures, suggesting fast rates of decomposition of the peat. Peat stores carbon, and when it is decomposed, the carbon is released as carbon dioxide (CO_2) to the atmosphere. Scientists believe that CO_2 release is contributing significantly to global warming. If the peat decomposed and released more CO_2 to the atmosphere, even higher temperatures at the Earth's surface would, in turn, melt more ice and snow, and concomitantly release even more CO_2 through further decomposition of the peat. The cycle would continue until no region would be permanently covered in ice or snow.

Without the high albedo to reflect the sun's rays, expansive melting of ice and snow may occur. The contribution of melting ice to seawater would have a multitude of effects on global climate. For instance, if only the western Antarctic ice sheet alone melted, there would be a 16–20 ft. (5–6 m.) increase in mean sea level. However, if the entire Antarctic ice sheet were to melt, over the next thousands of years there would be a 184-ft. (56-m.) increase in sea level, causing catastrophic scenarios. Beyond sea-level rise, experts are concerned that the influx of freshwater to the oceans with the melting of the Antarctic Ice Sheet will significantly alter the salinity and temperature of the oceans, causing unpredictable effects on the ecosystems in this region. With decreased salinity, the evaporation rate of the oceans will change and the living organisms that are dependent on a stable aquatic environment may not survive. Changes in the ice-albedo feedback loop will likely have these and countless unpredicted effects on the Earth.

Ice Component of Models

CLIMATE MODELS HAVE developed from mathematical formulas used in the 19th century to try to predict the weather. The lack of accurate and comprehensive data and the need to rely on manual calculation techniques made these approaches very difficult, and ultimately, they were abandoned as it became clear that the results of the equations did not match real-world conditions. During World War II, military expediencies demanded that more data be collected about the atmosphere, and this capacity remained in force after the war. The quantity of data available enabled researchers to check their calculations against real-world conditions. The advent of computers reduced the time needed to complete calculations.

The result is that climate models were refined and developed to a far more sophisticated degree than had previously been imagined possible. One implication of this is that modelers have been able to include a number of new variables in their models, or else to increase the complexity with which existing variables are treated. As a result, the atmosphere is divided into an increasingly large number of layers, and land cover is divided into different elevations, types, and albedos, for example. The insertion of ice into climate models is a further example of the refinement. Models that include ice components may be referred to as oceanic models, and they are a necessary part of comprehensive Coupled Atmosphere-Oceanic General Climate Models.

Ice may be considered both as land cover and as part of the sea. The composition of the ice, as well as its size and structure, will have an impact on its albedo, which represents the degree to which light is reflected from its surface. Ice is involved in the exchange of salt from water to ice, and also has an impact on the surrounding land cover. Ice will increase or decrease according to fairly predictable patterns. However, the calving process by which icebergs divide is less easy to predict. The momentum of ice is now more accurately calculated by using scaling arguments, while incremental remapping is now used to consider horizontal advection.

In addition to modeling the presence of ice, researchers must also consider the ways in which the different components of the models interact with each other. Atmosphere, ocean, land, and sea-ice components exist in a dynamic state of change, depending on their interactions with each other and with external sources of energy. The impact of rapid ice-loss now experienced, for example, is being studied with great urgency, as it has unforeseen impacts upon the rest of the climate system, as well as the possibility of earthquakes and other tectonic activity. The release of more water into the seas will have an impact upon the amount of land above sea level and will, therefore, have an affect on patterns of human settlement.

As global warming and climate change continue to intensify, the amount of ice on the Earth's surface will continue to decrease. Estimates suggest that, if current trends continue, Himalayan ice will have disappeared within three decades, while polar ice is breaking up and melting at an ever-increasing rate. This will probably obviate the need to integrate the presence of ice into climate models in the future.

Iceland

OFFICIALLY PART OF Europe, Iceland has been a republic since 1944. The capital city is Reykjavik and the population (2007 est.) is 311,400. The total area of the island is 39,768.5 sq. mi. (103,000 sq. km.). Glaciers cover approximately 11 percent of the landmass. Iceland is located in a geological hotspot and has several active volcanoes. During the last glaciation, Iceland was completely covered with ice. Colonists, primarily from Norway, first settled Iceland in the late 9th century. According to DNA studies, approximately one quarter of the original population was composed of women from the northern British Isles. Woodland cover, now around 1.3 percent of the total landmass, was then approximately 30 percent. The settlers brought a farming economy based on sheep and cattle. With a climate generally unsuitable for grain growing, the main agricultural crop has been the grass on which the livestock have depended for winter fodder. The failure of grass in past centuries frequently led to famines, which caused considerable loss of life. From the late 19th century onwards, fisheries dominated the economy.

The climate of Iceland is largely determined by its position in the middle of the North Atlantic, at a point where contrasting cold and mild ocean and air currents meet. This makes the climate highly variable on all time scales, from days to centuries. The island is favorably influenced climatically by its proximity to the Irminger Current, a branch of the Gulf Stream. However, the Arctic Sea ice, also called drift ice, which is brought to Iceland by the East Greenland Current, has a mainly negative effect. The ice, which may have given the country its name, acts as a heat sink and lowers temperatures on land and, in the past, could block harbors and thus prevent fishing and the access of trading ships. Information on the past incidence of the ice reaching the coasts is a useful climate proxy indicator.

It has been suggested that Iceland experienced a relatively mild climate during the early centuries of settlement, but evidence is largely circumstantial. Barley, for example, which needs relative warmth during the growing season, seems to have been cultivated. Serious erosion, caused by livestock grazing and woodland clearing, was undoubtedly as large a contributing factor to later economic difficulties as climate change may have been.

Iceland's climate has varied considerably during the approximately 1,100 years since human settlement began. From around 1200 C.E., historical evidence begins to shed light on climate change, although 1430–1560 there are very few contemporary sources. From 1600, there is sufficient evidence to be able to reconstruct climate and sea-ice indices. The general view has been that 1600–1900 was unfavorable climatically, but a scrutiny of the data shows much variability. In particular, there was a relatively mild period 1640–70. The 1780s are likely to have been the coldest decade of the 18th century, but this was compounded by volcanic activity from the Lakagígar eruption in 1783. The 1801s and 1830s were also comparatively cold. The last great famine occurred in Iceland in the 1880s, when cold years and much sea ice occurred.

The first meteorological observations on Iceland were made 1749–51, but a continuous series does not begin until 1820. From that time on, there is detailed information on climate change provided by a number of systematic observations and historical records. The modern era of observations began with the establishment of the Icelandic Meteorological Office (Veðurstofa Íslands) in 1920. By the 1920s, a marked warming trend was well under way. Sea ice was an infrequent visitor until the cold period 1965–71. Since the 1980s, there has been a warming trend in the temperature records for Iceland, with very little sea ice reaching the coasts.

Idaho

LOCATED IN THE Pacific Northwest, Idaho, the 13th largest state in the United States, is also one of the fastest-growing states. Famous for its potato crop, it is an important agricultural state, producing one-third of the potatoes grown in the United States. Manufacturing, particularly electronics manufacturing, and tourism are also major contributors to Idaho's economy, which, according to some sources, is the fastest growing economy in the nation. Perhaps because the state's energy consumption is relatively low (40th among the 50 states) and because it once produced more than 80 percent of its power through hydroelectric facilities, Idaho has been slow to confront climate change and its effects. In 2007, however, the state took a number of significant steps to become more environmentally responsible.

Such reluctance to act seems incongruous for a state that dates its environmental activism to 1897 when President Grover Cleveland established the Bitterroot Forest Preserve, encompassing much of the northern region. More than three decades later, the U.S. Forest Service declared more than three million acres of Idaho's forestland primitive areas. In the 1960s, Idaho Senator Frank Church sponsored the bill that created the National Wilderness System, which now contains most of the primitive areas set aside in the 1930s. Federal legislation was introduced in 2007 that could erode the protection of the wilderness areas and decrease carbon sequestration.

Some experts argue that climate change has already increased the number and extent of forest fires and reduced hydroelectric generation in Idaho. One regional climate model shows that Idaho may experience a 4–5 degree F increase in temperatures, bringing warmer, wetter winters and slightly hotter summers and may face a snow pack reduction of approximately 30 percent. For a state that depends on an abundant water supply for its hydropower plants, irrigation, and fisheries as well as regular use, such a scenario is ominous. Agricultural production in the state accounts for $2.8 billion each year. Well over half of this comes from crops, and nearly 70 percent of farms are irrigated. The predicted climate change could increase production of some crops, but potato production could fall by 18 percent. Water shortages could intensify damages.

Idaho's legislature approved the formation of a Carbon Sequestration Advisory Committee in 2002 to explore a new means of revenue for the state's farmers through sequestration sales to carbon dioxide producers as an effort to address greenhouse gas emissions. Idaho ranks 47th among the 50 states in its carbon dioxide emissions, but this low ranking fails to account for the 42 percent of the state's power that comes from power produced by coal-burning plants in nearby states. Once emissions from the transportation sector are added, almost 80 percent of energy consumed in Idaho is produced by fossil fuels. Despite these data, Idaho has been tardy in working within the state and in allying itself with regional and national groups to address greenhouse gas emissions. The state is not a member of the Western Regional Climate Action Initiative, a collaboration among six western states and two Canadian provinces to reduce emissions. It was only in summer 2007 that Idaho joined the Climate Registry, a multi-state effort to provide accurate data on greenhouse gas emissions to support reduction policies. Idaho has yet to develop a climate action plan, and a legislative attempt to require energy efficiency standards in construction of public buildings failed to move out of committee.

In 2006, the state legislature created the Legislative Council Interim Committee on Energy, Environment and Technology and charged the committee with developing an integrated state energy plan. A year later, the legislature renewed this committee. In 2007, further legislation cleared the way for wind farms on state endowment lands. The 2007 legislature also passed an act adopting the integrated Idaho Energy Plan developed by the Legislative Council's interim Committee on Energy, Environment, and Technology. This plan, the first state energy plan since 1980, encouraged greater reliance on renewable energy sources in place of dependence on fossil fuels and hydroelectric power.

Also, in 2007, Idaho Governor C.L. "Butch" Otter signed two executive orders that suggest a new commitment to action. The first established the Idaho 25 x 25 Renewable Energy Council, a group given the responsibility of developing coordinated programs to buttress the 25 x 25 Initiative for the state's agricultural and forestry sectors. The goal is for renewable sources to provide 25 percent of the state energy's requirements by 2025. The second executive order made the director of the Department of Environmental Quality the central point of contact for all greenhouse gas reduction programs and gave the director the authority to develop a greenhouse gas emission inventory and to recommend methods for reducing the state's emissions. The Department of Environmental Quality is the state's regulatory agency, responsible for enforcing state environmental regulations and administering federal environmental protection laws including the Clean Air Act, the Clean Water Act, and the Resource Conservation and Recovery Act.

Idaho is also home to the Idaho National Laboratory IINL), an 890 sq. mi. (2,305 sq. km.) U.S. government reservation, established in 1949 as the Nuclear Reactor Testing Center. In the more than five decades since its creation, the INL has extended its focus to encompass research and development in biotechnology, energy, and materials research, and conservation and renewable energy. In 2005, a separate unit, the Idaho Cleanup Project, was established to clean up previously contaminated sites and protect the Snake River Aquifer that provides drinking water for more than 300,000 Idahoans. The most recent extension of INL is the Center for Advanced Energy Studies, a $14-million facility that Idaho will be engaged not only in energy research, but also in a climate change technologies program.

Idaho State Climate Services

THE NATIONAL CLIMATIC Data Center, the National Weather Service, and the University of Idaho founded the Idaho State Climate Services in May 1978 to provide climate services that had formerly been supplied by a National Weather Service program. Professor Myron Molnau was instrumental in establishing the center. The State Climate Services program is housed in the Biological and Agricultural Engineering Department and is headed by the state climatologist for Idaho. The Idaho Agricultural Experiment Station, Idaho Cooperative Extension System of the University of Idaho, and Idaho Water Resources Research Institute support the center. The tasks of the State Climatologist and State Climate Services are to: act as liaison between Idaho weather information users and the National Climatic Data Center, keep a databank of climatological and hydrological data and information, and compile a regular bibliography of publications pertinent to Idaho and Pacific Northwest climate. The center receives additional cooperation from the National Climatic Data Center, the Western Regional Climate Center, and the National Weather Center.

In 2002, the Idaho State Climate Services received national certification from the American Association of State Climatologists. Following review by the American Association of State Climatologists, the Idaho State Climate Services qualified as an Association Recognized State Climate Office (ARSCO). The center has various databases, including Inside Idaho, a historical record of daily data from more than 250 weather stations in Idaho, some dating as far back as 1890. It includes data on precipitation, temperature, pan evaporation, wind run, snowfall, and snow on the ground. This database, like others managed by the Idaho State Climate Services, can be accessed online and downloaded. In addition to the actual data, the databases include all original forms and maps used by the State Climate Services. The long time span of the data provided by the service allows researchers to accurately assess the variability of weather conditions. Russell Qualls, a faculty member in the department of biological and agricultural engineering, is the Idaho state climatologist and serves as the director of the center. In recent years, the center has specialized in research on the effects of El Niño and La Nina on the Idaho economy.

Illinois

ILLINOIS HAS AN area of 57,914 sq. mi. (149,997 sq. km.), with inland water making up 756 sq. mi. (1,958 sq. km.) and Great Lakes coast water of 1,575 sq. mi. (4,079 sq. km.). Illinois's average elevation is 600 ft. (183 sq. m.) above sea level and made up of four geographic regions: the Central Lowland (with extensive flatlands covering most of the state), the Interior Low Plateaus, the Ozark Plateaus, and the Gulf Coastal Plain (in the southern part of state). Illinois has warm to hot summers and cool to cold winters. In the winter, polar air masses move south or southeast across the state from Canada, bringing cold and crisp weather. In the summer, warm air masses move up from the Gulf of Mexico, and the weather is often hot and muggy. Lake Michigan tempers the summer heat somewhat for Chicago and other cities along its shores, and also delays the date of the first fall frosts nearby.

With no natural barriers like mountains, Illinois experiences the full sweep of winds. Easterly and southeasterly winds are mild and wet, southerly winds are warm and showery, westerly winds are dry with moderate temperatures, and northwesterly and northerly winds are cool and dry. The winds are controlled by storm systems. Precipitation (rainfall and snowfall) generally increases from north to south, with a state average of 37 in. (94 cm.) per year. Annual snow average is 30 in. (76 cm.) in the north and 10 in. (25 cm.) in the south. Lake Michigan has minimal influence on prevailing winds, and storm systems move in the same direction.

Rich soil accounts for high crop production (corn and soybeans); the northern two-thirds of the state lie in the Corn Belt. Fruit crops, especially peaches, apples, and strawberries, are raised in the southern hill lands. Industrial and urban centers exist along the Mississippi River. Coal-burning and nuclear power plants generate electricity in Illinois. Based on energy consumption data from the Energy Information Administration's State Energy Consumption, Price, and Expenditure Estimates (SEDS) released June 1, 2007, Illinois's total carbon dioxide emissions from fossil fuel combustion in million metric tons carbon dioxide for 2004 were 235.97, made up of contributions from: commercial, 12.15; industrial, 38.53; residential, 24.71; transportation, 68.58; and electric power, 92.

In the past 15 years, the state experienced a severe drought in 1988, flooding in 1993 and 2002 (partly because of the flatness of the land), heat waves in 1995 and 1996, and a destructive windstorm in Bloomington in 1999. The drought emergency declared throughout much of Illinois in 2005 illustrates the potential problems associated with global warming. Farmers, communities, and wildlife all depend on healthy stream flows throughout the state. Six counties on the shore of Lake Michigan (in the largest lake system, containing one-fifth of Earth's open fresh water) and the city of Chicago rely on Lake Michigan as a source of drinking water. Global warming projections indicate higher rain and snow levels in winter and spring in Illinois, and estimated summer temperatures increasing 9–17 degrees F (5–9 degrees C) by the end of the century.

While climate models vary on the amount of temperature increase possible, potential risks include decreased water supplies, population displacement (both human and animal), and changes in food production, with agricultural production improving in cooler climates and decreasing in warmer climates. Changes in rain patterns to downpours, with the potential for flash flooding, raise the health risks of certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents. Warmer temperatures can also cause heat-related illnesses and lead to higher concentrations of ground-level ozone pollution, causing respiratory illnesses, especially in cities. Increased temperatures would in turn increase evaporation rates and cause drier soil conditions. Torrential rain would contribute to major flooding. Inconsistent precipitation levels are projected to put more pressure on already scarce water resources, causing the potential for decreased corn and soybean yields.

STEPS TO REDUCE GREENHOUSE GAS EMISSIONS

In July 2005, the Illinois Commerce commission passed a plan urging state power companies to obtain at least 2 percent of electricity from renewable energy sources by 2006, increasing the amount by 1 percent every year to 8 percent in 2012. Illinois's greenhouse gas reduction target is to meet 1990 levels of six greenhouse gases by 2020, with emissions falling below 1990 levels by 2050. Illinois established the Climate Change Advisory Group in October of 2006. Illinois joined the Climate Registry, a voluntary national initiative to track, verify and report greenhouse gas emissions, with acceptance of data from state agencies, corporations, and educational institutions in January 2008.

In 2005, the governor signed a law, effective July 2006, requiring local governments, school districts, universities, community colleges, and mass transit agencies to fuel their diesel vehicles with 2 percent biodiesel, a renewable fuel made from soybeans or agricultural waste. They will join the state facilities already using the two percent biodiesel per an executive order passed in 2002. As early as 1996, Illinois legislators were developing a strategy in response to global greenhouse gas emissions. Illinois wanted to be ahead of potential federal mandates. A taskforce developed greenhouse gas inventories and identified greenhouse gas emissions reduction programs. Some actions were deemed necessary regardless of global warming predictions, including strengthening water laws for quantity and quality, remapping floodplains, and continued research on the structural integrity of construction in vulnerable areas in Chicago, the Illinois River Basin, and the Great Lakes Basin.

Impacts of Global Warming

IMPACTS FROM THE phenomenon known as global warming include environmental, social, and economic effects. Environmental impacts include sea-level rise, melting of the polar ice caps, and an average increase in temperature. These impacts are documented in the reports of the Intergovernmental Panel for Climate Change (IPCC), which commissions reports by scientists worldwide on the issue of climate change. The IPCC Report of 2007 is the first one that reflects scientific consensus that global warming is underway, and that it is primarily human induced. For example, human activities, such as fossil fuel burning, land-use changes, agricultural activity, and the production and use of halocarbons are among the factors causing climate change. The economic report by Nicholas Stern in 2007 highlights that climate change has potentially disastrous consequences for humanity.

TEMPERATURE VARIABILITY

Perhaps best known, is that temperature variability, specifically temperature increase, will be one of the effects of climate change. While the range of projections relating to temperature rise varies, the IPCC scenarios, using a range of climate models, predict overall a rise in globally-averaged surface temperature of 2.5–10 degrees F (1.4 to 5.8 degrees C) 1990–2100. While at local and regional levels this figure will vary, at a global level it is roughly 2–10 times larger than the observed warming of the 20th century, and is unprecedented during at least the last 10,000 years, based on paleoclimatic data.

Changes in temperature and precipitation (rainfall) patterns have increased all around the world. In the United States, average temperatures have increased by roughly 1 degree F (0.6 degrees C) during the past century, and precipitation has increased by five to 10 percent. Alaska has sustained an average temperature increase of 4–7 degrees F (2–4 degrees C) in just the past 50 years. Temperature increase has also had a number of related effects, such as the increased melting of the summer Arctic sea ice. Since 1979, more than 20 percent of the polar ice cap has melted in response to increased surface and ocean temperatures. The oceans are warming. Global ocean temperature has risen by 0.18 degrees F (0.10 degrees C) from the surface to a depth of (2,297 ft.) 700 m. 1961–2003.

WARMING OF WATER MASSES

Key oceanic water masses are changing. Southern Ocean mode waters and Upper Circumpolar Deep Waters have warmed from the 1960s to about 2000. A similar, but weaker pattern of warming in the Gulf Stream and Kuroshio mode waters in the North Atlantic and North Pacific has been observed. Long-term cooling is observed in the North Atlantic subpolar gyre and in the central North Pacific.

SEA-LEVEL RISE

Another predicted effect of climate change is an increase in sea level. Sea-level rise is caused by thermal expansion of the oceans, melting of glaciers and ice caps, melting of the Greenland and Antarctic ice sheets, and changes in terrestrial storage. Changes in sea level will be felt through increases in intensity and frequency of storm surges and coastal flooding; increased salinity of rivers, bays, and coastal aquifers resulting from saline intrusion; increased coastal erosion; loss of important mangroves and other wetlands (the exact response will depend on the balance between sedimentation and sea-level change); and impact on marine ecosystems such as coral reefs.

Sea-level rise is accelerating worldwide. Globally, 100 million people live within about 3.3 ft. (1 m.) of present day sea level. Eight to 10 million people live within 3.3 ft. (1 m.) of high tide in each of the unprotected river deltas of Bangladesh, Egypt, and Vietnam. IPCC reports estimate that the global average sea level rose at an average rate of .07 in. (1.8 mm.) per year 1961–2003, and within that period, the rate of rise was faster 1993–2003, about 0.12 in. (3.1 mm.) per year. Overall, the IPCC concludes there is high confidence that the rate of observed sea level rise has risen from the 19th to the 20th century. The total 20th century rise is estimated to be 0.55 ft. (0.17 m.) In 2001, IPCC projections were for a sea-level rise of between 3.5–34.6 in. (9–88 cm.) 1990–2100 and a global average surface temperature rise of between 2.5–10.4 degrees F (1.4 and 5.8 degrees C.). In 2007, IPCC projections based on different scenarios predict seal level rise from 0.01 to up to 0.02 in. (.18–.59 mm.) by 2099.

Toward the end of the 21st century, projected sea-level rise will affect low-lying coastal areas with large populations. The cost of adaptation could amount to at least five to 10 percent of Gross Domestic Product. Mangroves and coral reefs are projected to degrade further, with additional consequences for fisheries and tourism. Snowmelt runoff as a result of seal level rise will have major consequences. For example, one change will be a change from spring peak flows to late winter peaks in snowmelt-dominated regions. Many species, both aquatic and riparian (riverine) have evolved to take opportunity of the spring flows as a result of snowmelt. For example, some fish time their reproduction strategies specifically to avoid the stress of springtime flows. Changes in springtime flow regimes, or high winter flows associated with rain or snow events, can scour streambeds and destroy eggs. Trees that provide riparian habitat along rivers may find it harder to reproduce as they depend on high spring flows. Many species, such as salmon, already under pressure from other environmental impacts, will be further impacted by climate change. For example, higher temperatures and a reduced stream flow in the Columbia River Basin may be increasing the mortality of juvenile coho salmon; in some cases increased temperatures may be creating thermal barriers for the migration of adult salmon.

Temperature increase has had a number of related effects, such as the increased melting of the summer Arctic sea ice.

There are a number of associated events that are a result of climate change and will also have impacts on sea-level rise. For example, the Kangerdlugssuaq Glacier in Greenland is moving much faster, melting at a rate of 8.7 mi. (14 km.) a year in comparison to just 3.2 mi. (5 km.) a year in 1988. This loss will also have serious implications for sea-level rise, with some scientists predicting that within the next 100 years, ice cover in this region will completely disappear over summer and that species living within it, such as polar bears, will be threatened. The complete melting of the Greenland Ice Sheet and the West Antarctic Ice Sheet would lead to a contribution to sea-level rise of up to 23 ft. (7 m.) and about 16 ft. (5 m.), respectively.

INCIDENCE AND SEVERITY OF STORMS

Increased incidence and frequency of storms is another predicted effect of climate change. For example, since 1996, the number of named tropical storms in the North Atlantic per year has increased by 40 percent, a figure considered extreme in the 1950s. Some research indicates that there is a link between higher sea-surface temperatures and storm frequency. Researchers have found that 1970–2004, warmer sea-surface temperature has been the major factor in the increase in category 4 and 5 hurricanes globally. Scientists have also shown that there is a strong correlation between sea temperature and annual hurricane power in three different hurricane basins in the North Atlantic, and two in the Pacific. Hurricane Katrina and the tsunami in Southeast Asia are both examples of the increased frequency and intensity of natural events that result from climate change.

ATMOSPHERIC COMPOSITION

Another effect of climate change is changes in atmospheric composition. It is possible to measure these changes, as the composition of air, prior to industrialization, is known from testing air bubbles frozen in ice cores from Antarctica. Since pre-industrial times, the concentration of CO_2 within the atmosphere has risen from about 270–280 parts per million by volume (ppm) to over 360 ppm today. Moreover, CH_4 has risen from about 700 parts per billion by volume (ppb) to over 1700 ppb, and N_2O has increased from about 270 ppb to over 310 ppb. Halocarbons, substances that are not naturally present in the atmosphere, are now present in large amounts.

This is important because changes within the atmosphere have disrupted the total energy budget of the planet. The balance between incoming, solar shortwave radiation, and the outgoing long-wave radiations has upset the normal radiative balance. This change is called radiative forcing. The Earth's response to this phenomenon is to try to restore the balance by warming the lower atmosphere. In so doing, the surface temperature of the planet increases.

ECOLOGICAL SYSTEMS

Ecological systems are changing, upset, and modified as a result of climate change. About 20–30 percent of plant and animal species assessed so far are likely to be at increased risk of extinction if increases in global average temperature exceed 2.7–4.5 degrees F (1.5–2.5 degrees C). Significant loss of biodiversity is projected to occur by 2020 in some ecologically rich sites, including the Great Barrier Reef and Queensland Wet Tropics. Other sites at risk include the Kakadu wetlands, southwest Australia, sub-Antarctic islands, and the alpine areas of both countries. In Latin America, by mid-century, increases in temperature and associated decreases in ground water are projected to lead to gradual replacement of tropical forest by savanna in eastern Amazonia. Semi-arid vegetation will tend to be replaced by arid-land vegetation. There is a risk of significant biodiversity loss through species extinction in many areas of tropical Latin America.

A typical example of the effect of climate change is the coral reef ecosystem. Coral bleaching, resulting from the breakdown of the symbiotic relationship between corals and unicellular algae (*zooxanthellae*), is often caused by the warming of sea temperatures. Reef coral are very sensitive to temperatures outside of their acceptable range; a rise of just 1 degree above long-term averages is enough to cause coral stress and bleaching. If these temperatures exceed average levels for a long period of time, the reef system will collapse. The mass bleaching events reported on the Great Barrier Reef and elsewhere around the world over the last five to 10 years have been triggered primarily by anomalously high water temperatures. Increased levels of CO_2 in the sea also affect the acidity of the ocean's surface water, and, hence, reduce the amount of dissolved carbon carbonate for reef-building corals.

The extent of ecological consequences will partly dependent on the extent of temperature change and water availability from precipitation and runoff in any given location, but ultimately, ecological changes will occur across the planet. For example, in North America and Australia, parts of these continents will become wetter and others drier, with variability in precipitation events causing unpredictability in runoff patterns and changes to ecological systems. Many species are dependent on, or live within, specific temperature ranges; thus, a change in temperature, for example, their extremity, duration, and seasonality will have a correlative affect on rates of growth and reproduction. For animals, such as turtles, cassowaries, or salmon, all of which reproduce at certain temperatures (and produce certain sexes within certain temperature ranges), variation in thermal regimes will have significant effects. Some species may be able to adapt and shift the geographic ranges of their distribution, but for many, the effects of temperature change will be catastrophic as the areas they live in become unsuitable and uninhabitable.

Increased air temperatures will also effect wetland, estuarine, and marine species. For example, a warming of water temperatures by 7 degrees F (4 degrees C) in present-day ecosystems would represent a northward latitudinal shift in thermal regimes of about 422 mi. (680 km.), which will have major ramifications for aquatic ecosystems. Moreover, enrichment of soils as by CO_2 will alter species composition in some wetlands.

Climate change will also alter the hydrological regimes of rivers and lakes through changes in water flows. Reductions in the frequency or intensity of high flows that normally inundate flood plains may dry out wetlands, and cause ecological changes from wetland to terrestrial-adapted species. Water tables will rise in areas that become wetter and vice versa, changing species composition in many areas. For example, a reduction in the frequency or magnitude of high flows that inundate the floodplain would tend to dry out floodplain wetlands, isolate them from the adjacent stream or river, and replace wetland plant species with more terrestrially adapted species.

SOCIETAL IMPACTS

Climate change will have major effects on humanity. For example, global climate change and sea-level rise can influence coastal fisheries in a number of ways. Approximately 70 percent of the U.S. fisheries' catch is derived from estuarine-dependent species, and their young are dependent on suitable habitat. Rising sea levels that lead to destruction of coastal wetlands can have direct negative consequences for coastal fisheries. More indirect effects could result from wetland loss that leads to shoreline erosion, which, by adding fine sediments to the water column, would reduce water clarity and, thus, interfere with feeding ability. Many shellfish species also use coastal wetlands as an important habitat and are vulnerable to wetland loss caused by sea-level rise.

There will be a diverse range of socioeconomic costs arising from weather damage and vulnerability to climate change. The *Stern Report* concludes that the economic cost of global warming without action, using conservative scientific estimates for change, will be the equivalent of losing at least 5 percent of global gross domestic product (GDP) per year. Nicholas Stern notes that if little action is taken and a wider range of predictions is considered, then the costs to the global economy will be up to 20 percent of the world's GDP or more.

Socioeconomic systems will be affected by the increase in floods, and droughts. Projections confirm that many countries will experience decreased yields to their crop productivity, especially in areas projected to receive lower rainfall. Climate change will significantly affect those living in the Pacific. In the 1990s, for example, the Pacific Island region sustained costs of up to $1 billion from climate-related incidents.

For many African regions, warmer and drier conditions have led to a reduced length of growing season, with detrimental effects on crops. At lower latitudes, especially in seasonally dry and tropical regions, crop productivity is projected to decrease for even small local temperature increases 1.8–3.6 degrees F (1–2 degrees C), which would increase risk of hunger. In some countries, yields from rain-fed agriculture could be reduced by up to 50 percent by 2020.

Water shortages will put increased pressure on forestry and agriculture. By mid-century, annual average river runoff and water availability are projected to increase by 10–40 percent at high latitudes and in some wet tropical areas, and decrease by 10–30 percent in some dry regions at mid-latitudes and in the dry tropics, some of which are already water-stressed areas. For example, in Africa By 2020, 75–250 million people are projected to experience an increase in water stress from climate change. If coupled with increased demand, this will adversely affect livelihoods and exacerbate water-related problems. In the course of the century, water supplies stored in glaciers and snow cover are projected to decline, reducing water availability in regions supplied by melt water from major mountain ranges, where more than one-sixth of the world population currently lives. Freshwater availability in central, south, east, and southeast Asia, particularly in large river basins, is projected to decrease because of climate changes that, along with population growth and increasing demand arising from higher standards of living, could adversely affect more than a billion people by the 2050s.

Much livestock will find it hard to adapt to the physiological effects associated with climate change, and there are projected increases in pest infestations associated with climate extremes. Projections also show that a warming of the world's temperature by a few degrees will result in a global increase in food prices.

Climate change will also have impacts on human health. For example, people will experience higher heat stress, and loss of life in floods and storms. Heat-related mortality will increase. There will also be a range of direct impacts on disease through increased range of vectors such as mosquitoes. Projected climate change-related exposures are likely to affect the health status of millions of people, particularly those with low adaptive capacity. These indluce increases in malnutrition and consequent disorders, with implications for child growth and development; increased deaths, disease, and injury due to heat waves, floods, storms, fires and droughts; the increased burden of diarrheal disease; the increased frequency of cardio-respiratory diseases due to higher concentrations of ground level ozone related to climate change; and the altered spatial distribution of some infectious disease vectors.

The impacts of climate change will fall disproportionately on developing countries that do not have the economic or social resilience to adapt quickly enough to the effects they will experience. For example, the effects of sea-level rise will affect many Pacific Island nations who will be displaced by coastal flooding and erosion. In Bangladesh, up to 90 percent of the country consists of low-lying land. The effects of climate change on Bangladesh and other countries will be major, displacing millions, and potentially causing a worldwide environmental refugee crisis. Researchers estimate that up to 50 million people worldwide will become environmental refugees by 2010, due to rising sea-level rise, intense and more frequent storms, inundation, and other climate change-induced effects. Ongoing coastal development and population growth in areas such as Cairns and Southeast Queensland (Australia) and Northland to Bay of Plenty (New Zealand) are projected to exacerbate risks from sea-level rise and increases in the severity and frequency of storms and coastal flooding by 2050.

The Working Group 1 Fourth Assessment Report, 2007 has concluded that, of the more than 29,000 observational data series seven, from 75 studies that show significant change in many physical and biological systems, more than 89 percent are consistent with the direction of change expected as a response to warming. Importantly, both past and future anthropogenic CO_2 emissions will continue to contribute to warming and sea-level rise for more than a millennium, due to the timescales required for removal of this gas from the atmosphere.

India

INDIA WILL BE greatly affected by global warming. The effect will be experienced in the reduction of snow cap size in the Himalayas, retreat of glaciers that feed the rivers, an increased flooding of the snow-fed rivers initially, followed by partial drying up of the rivers, and formation of new lakes and flooded lakes at upper altitudes.

Outside the polar region, the Himalayas contain the largest volume of ice. The size of this ice depends on South Asian monsoons, as well as the winter precipitation that the area receives resulting from the flow of moisture-laden winds that originate in the North Atlantic Ocean and pass through the Mediterranean Sea. About six centuries of historical records and analyses of ice dust and chloride concentrations in the Tibetan ice field have shown that there were modest monsoon failures in India in 1230, 1280, 1330, 1530, 1590, and 1640. The most catastrophic failure, with severe drought, occurred 1790–76. Researchers have ascertained that there is a positive correlation between snowfall and temperature. In recent years, the Himalayas and the Tibetan plateau have experienced warming periods, such as 1960–90, causing diminution of snowfall.

Glacial retreat has been observed in the Himalayas. The United Nations climate report predicts that by 2035, some Himalayan glaciers will disappear with the rising temperatures. Gangotri glacier, the source of the Ganges River, is retreating at a rate of 755 ft. (230 m.) per year. The glacial retreat and lower ice cap after 2035 will lower the volume of the snow-fed rivers of north India, such as the Indus, Ganges, and Brahmaputra rivers, and some of the tributaries originating from the Himalayan ice field. Flooding will endanger riverside cities, such as Varanasi, Kanpur, and Patna.

These million-plus cities already experience flooding during the high monsoon season and will be further endangered. Flooding will also wreak havoc on the farming areas of northern India and cause dislocation in the road and rail transports. Some of the multipurpose River Valley Project dams, such as those across the Kosi and Sutlej rivers, will overflow, causing extreme devastation of rice paddies, cornfields, and settlements.

When a tipping point is reached by 2035, the ice melting will either stop, or be minimized because of continued warming; therefore, the rivers will experience weakened streams during monsoon months and in summer. The perennial nature of these rivers then will be challenged, as they will look like those of south India, where the size of the rain-fed rivers is much diminished during the non-monsoon dry months. Variation in water flows will disrupt river irrigation, on which a large number of the farmers depend, particularly in the Bihar, Uttar Pradesh, Haryana, Punjab, and northwestern Rajasthan states.

As global temperature continues to rise from about 57 degrees F (14 degrees C) (base) in 2000 to an estimated 66 degrees F (19 degrees C) (maximum) in 2100, various effects will be felt on weather, water bodies, farming, desertification, precipitation, and diseases. Sea levels will rise to an estimated 3.9 in. (0.1 m.) (minimum) to 35 in. (0.9 m.) (maximum) by 2100. Parts of coastal cities of India, such as Mumbai, Chennai, and Kolkata, and coastal area farmlands will be inundated, especially during high tides. Parts, or entire coastal islands will also be submerged. Lohachara is the first island in the world to be submerged due to global warming. This Sunderbans Island is situated in the southern edge of the Ganges delta in the Bay of Bengal. Its 10,000 residents turned into the first global warming-generated refugees. The Lakhadweep group of 27 islands, scattered in the Arabian Sea off the coast of the south Indian state of Kerala, is home to about 61,000 people. These low-lying coral islands are in danger of submergence as well. If this happens, the Indian Union will lose one of its seven territories.

India is the world's fourth largest greenhouse gas emitter. Such man-made environmental pollution aggravates the process of global warming. With increased temperatures, there will be a constant rise in precipitation. Higher intensity of cyclones reaching levels 4 and 5 that originate mainly in the Bay of Bengal will plague the coastal states of West Bengal, Orissa, Andhra Pradesh, and Tamilnadu; the territory of Andaman and the Nicobar islands will also be affected.

Rising evaporation resulting from warmer conditions in the Indian Ocean and Arabian Sea will accentuate the desertification process around the West Indian Rajasthan Desert. Rising temperature will also enable farmers and plantation (tea and coffee in particular) operators to increase their domain upwards to higher altitudes. Therefore, there will be an increase in primary sector activity in certain mountainous parts of north-northeast and southwest India. Anopheles mosquitoes spreading malaria will also invade the same higher altitudes. Higher altitude areas and the resort towns like Darjeeling, Nainital; Massouri in the Himalayas; and Ooty (Udhagamandalam) and Kodaikanal in the Western Ghats Mountain Range will be invaded by anopheles mosquitoes spreading malaria, which will only breed in warm weather.

Indiana

INDIANA IS A Great Lake State, with a 41-mi. waterfront on Lake Erie. Parts of Indiana are agricultural, and the state is a leading producer of corn. Most of

Indiana is urban, but the iron, steel, and oil companies that swell the economy of the state tend to be located in smaller cities. Indiana ranks 15th in the United States in population. The combination of a large urban population and heavy industry means that much of the state faces major challenges to protecting the environment from global warming and climate change. Educating the public is the major environmental focus. Government actions include emission reduction programs designed to reduce smog, soot, dust, sulfur dioxide, nitrogen dioxide, carbon monoxide, and lead. Air quality monitors have been placed throughout Indiana. Improving waste management is also a priority, and Indiana is concentrating on cleaning up contaminated sites, leaking underground storage tanks, spills, landfills, and open dumps. Environmental activists are pressuring the government to initiate policies promoting sustainable energy and to withdraw support for new coal-fired power plants in the state.

The Indiana Department of Environmental Management (IDEM) and the Indiana Department of Natural Resources share the chief responsibility for dealing with issues arising from global warming and climate change. The Office of Air Quality, the Office of Land Quality, the Office of Water Quality, and the Office of Pollution Prevention and Technical Assistance are housed within IDEM. The Land Bureau, which is part of the Department of Natural Resources, is responsible for environmental issues concerning fish and wildlife, forestry, and state parks and preserves.

Indiana has instituted the Environmental Stewardship Program to encourage business leaders to become more environmentally aware. Benefits of the program include expedited and flexible business permits, reduced reporting and inspections, and, in some cases, reduced monitoring. The government also sponsors the Indiana Comprehensive Local Environment Action Network (CLEAN) to encourage local governments to become involved in protecting the environment. Benefits of the program include matching funds for recycling and pollution prevention.

Environmental priorities often clash with economic goals in Indiana. In 2007, the governor announced that construction would begin on a 40 billion cu. ft., $1.5 billion coal-gasification plant. Indiana Gasification, LLC owns the facility, which was the first in the United States to use eastern coal to generate natural gas of pipeline-quality. Environmentalists were opposed to the construction because of potential sulfur emissions, but it won popular support because of the potential for significantly reduced fuel prices.

Industries consume about half of the energy used in Indiana, and most of that energy comes from coal. Consequently, Indiana has one of the highest levels of coal consumption in the United States. Between 1990 and 2001, Indiana's population increased by 10 percent; at the same time, carbon dioxide (CO_2) levels rose 12 percent, to a total of 230.2 million metric tons. Indiana is fifth in the United States in CO_2 emissions. A lawsuit filed by eight states and the City of New York has accused major energy companies of perpetrating global warming and climate change as a result of toxic emissions.

Two of those companies operate in Indiana. The American/Electric Power Company, Inc./American Electric Power Service Corporation, which generates an estimated 226 million tons of CO_2 each year, tops the list. Cinergy Corporation, which produces an estimated 70 million tons of CO_2 emissions per year, is ranked fifth on the list.

CLIMATE CHANGE GOALS

Efforts to combat global warming and climate change resulted in Indiana becoming 23 percent more carbon dioxide efficient 1990–2001. However, in the summer of 2007, Environmental Integrity Projects released a list of the 50 American energy companies emitting the highest levels of CO_2 during the previous year. With 17 plants on the list, and four in the top 50, Indiana was ranked second only to Texas in having the most environmentally damaging energy plants. The group also identifed a number of power plants that release contaminants such as sulfur dioxide, nitrogen oxide, and mercury. Duke Energy Company received federal tax incentives to build a new clean-coal plant in Indiana, but CO_2 emmissions continue to pose problems after other contaminants are removed at such facilities. PSI Energy, Indianapolis Power and Light, and Northern Indiana Public Service Company (NIPSCO), which were ranked in the top 50, decreased CO_2 emissions 2005–07 by millions of metric tons. At the American Electric Power Plant in Rockport, however, CO_2 emissions rose by 17.4 million tons during that timeframe.

Indiana University

INDIANA UNIVERSITY (IU) is public university internationally known for the quality of its academic programs, which attracts students from all over the world. IU plays a key role in the economic and social well-being of Indiana residents, offering educational, cultural, and financial benefits to the state. The University consists of eight campuses: the original campus in Bloomington, which is a residential campus; an urban campus in Indianapolis, which also includes the IU Medical Center; and six regional campuses in Gary, South Bend, Fort Wayne, Kokomo, Richmond, and New Albany. IU offers a total of 963-degree programs for undergraduate and graduate students at its statewide campuses.

The School of Public and Environmental Affairs (SPEA) offers Bachelors, Masters and Ph.D. degrees in Environmental Science. Fields of expertise include global warming, global climate change, carbon sequestration, and conservation of forests, coral reefs, wildlife, and watersheds. The SPEA also houses several centers of excellence in research. Distinguished Professor, Ronald A. Hites is the director of the Environmental Science Research Center. The goals of the center are to promote excellence in environmental science research and to foster increased interdisciplinary collaboration among environmental science faculty on the Indiana University-Bloomington (IUB) campus. The center does not offer degree programs. Its activities include seminars, discussion groups, and proposal preparation workshops.

Dr. Hans Peter Schmid Professor and Director of Graduate Studies is also Director of the Institute for Research in Environmental Science (IRES). His research interests include biosphere-atmosphere interactions, exchange of CO_2, water vapor and energy between forests and the atmosphere, boundary layer meteorology, boundary layer development over complex surfaces, surface-atmosphere exchange over inhomogeneous surfaces (observation and modeling), spatial aggregation modeling of turbulent fluxes, modeling of subgridscale variability in terms of surface texture, source area/footprint modeling for turbulent flux, and experimental design and measurement of turbulent surface-atmosphere exchange processes.

IRES MISSION

The mission of the IRES is to promote and coordinate research collaboration among environmental scientists at Indiana University Bloomington (IUB). IRES' activities enhance and facilitate communication between scientists affiliated among other departments and schools at IUB. This collaboration also supports integrative graduate research projects with cross-disciplinary mentorship, provides administrative support for externally-funded research programs in environmental science, and enhances the visibility and competitiveness of environmental science at IUB for research funding agencies, professional organizations, and the recruitment of prospective graduate students and faculty.

Schmid, along with Dr. Sue Grimmond, oversee the Morgan Monroe State Forest Project. This project, assisted by funding from the Department of Energy, manages the AmeriFLUX/FLUXNET tower located in Morgan-Monroe State Forest north of Bloomington, Indiana. The tower is designed to measure CO_2, H_2O and heat fluxes over a deciduous forest along with collecting other meteorological data. Courses offered at Indiana University that focus on Global Warming and Climate Change include: Environmental Change, Weather and Climate, Environmental Change—Nature and Impact, Environmental Remote Sensing, Hydroclimatology, and Climate Change.

Indian Ocean

THE INDIAN OCEAN has seen some dramatic changes owing to the effects of global warming and climate change. The major effects of global warming have been the rise of waters temperature, and also the rise in the water level. Researchers have shown not only a general warming of the surface of the Indian Ocean, but also warming of about 3.6 degrees F (2 degrees C) over the last 40 years, in the region of 40 degrees S and 50 degrees S, down to a depth of 262 ft. (800 m.). A study by the National Aeronautics and Space Administration (NASA) showed that tradewinds that cover the southern part of the Indian Ocean have also weakened 1992–2000 so much that there has been up to a 70 percent reduction in up-welling and cool currents. Scientists are also worried about the survival of many of the marine turtles in the Indian Ocean, for which global warming and climate change represent yet another threat.

Most of the focus of world attention on global warming in the Indian Ocean remains focused on the potential loss of land through rising sea levels. This is because there is much low-lying land around the Indian Ocean. The Republic of the Maldives, an archipelago of 1,190 islands (202 of which are inhabited), is at risk of submersion if there is a significant rise in the level of the Indian Ocean. With the Maldives having an elevation of less than 8 ft. (2.5 m.), the government of the Maldives has been actively campaigning for countries around the world to reduce greenhouse gas emissions.

Although the Maldives is at greatest risk of being entirely submerged, many other islands in the Indian Ocean are also under threat. These include the Laccadive Islands, and some of the islands in the Andaman and the Nicobar groups (all parts of India), as well as islands of the British Indian Ocean Territory, especially in the Chagos Archipelago. Some of these islands, too, have the very real risk of total submersion with rising water levels. There is also a concern about islands in the Seychelles, Mauritius, and the French island of Réunion. Parts of mainland Asia are also at risk, especially Bangladesh, which is suffering increasingly from floods, and the land around the mouth of the Irrawaddy in Myanmar (Burma).

The problems in Bangladesh, one of the most densely-populated countries in the world, have been serious for many decades, and further floods threaten to cause even longer-term economic problems. Many geographers believe that global warming has led to more frequent floods and cyclones, regularly displacing many farmers who lived on the Ganges-Brahmaputra Delta. The Sunda Islands, off the west coast of Sumatra, have also seen a rise in flooding that has led to increased breeding of mosquitoes and the rise in the prevalence of insect-borne diseases such as malaria and dengue fever, problems also exacerbated by more flooding in Myanmar, which has become more regular since the 1980s. Prolonged flooding would seriously undermine the agricultural base of both Bangladesh and

The most dramatic effects of global warming on the Indian Ocean due to have been a rises in temperature and sea levels.

Myanmar, resulting in worsening coastal problems. As the coastline is battered by the Indian Ocean, it is expected that some of the farmers will move inland, threatening, in the case of Bangladesh, the Sundarbans, which is currently the largest mangrove forest in the world, home of the Royal Bengal tiger, and other fauna and flora.

The most dramatic instance of flooding in the Indian Ocean was caused by a tsunami that caused devastation to parts of northern Sumatra and also along the coasts of Sri Lanka and Thailand on December 26, 2004. It resulted in the deaths of some 230,000 people, of whom the majority (168,000 by some estimates) were from Indonesia. The worst affected areas were the Indonesian province of Aceh, and the town of Galle in Sri Lanka, with deaths in many other countries, including an estimated 289 people in Somalia. There was devastation to the coastline, and loss of marine life, including shrimp off the west coast of Sumatra and Thailand. Although trade had long linked the countries of the Indian Ocean, the 2004 tsunami emphasized to the people in the region, the environmental problems in the area, and the links between global warming and a greater prevalence of flooding. The tsunami caused casualties in 15 countries.

Researchers have turned to studying the ocean currents. Although the water of the Indian Ocean has received warm saline water from the Red Sea past the Gulf of Aden, the rising water temperature has caused a decline in the diversity of fish in that part of the Indian Ocean. Global warming has also been suggested as a possible cause of changes in the temperature of the Agulhas Current, affecting the population of sardine and tuna off the coasts of southern Africa.

Geelong Grammar School, Australia

Indonesia

THE REPUBLIC OF Indonesia covers an archipelago of 13,667 islands, and has a land area of 735,355 sq. mi. (1,904,569 sq. km.), with a population of 231,627,000 (2006 est.), and a population density of 347 people per sq. mi. (134 people per sq. km.), although this reflects a massively overpopulated Java, and many underpopulated islands. Jakarta, the capital and the largest city, has a population density of 33,049 per sq. mi. (12,738 per sq. km.).

Agriculture is the most important sector of the economy, with 10 percent of the land arable, 7 percent used for meadows and pasture, and 62 percent of the country covered by forests. Indonesia is a significant oil producer, and 81 percent of its electricity production comes from fossil fuels, mainly petroleum, with liquid fuels making up 55 percent of Indonesia's carbon dioxide emissions, and gaseous fuels making up 21 percent. The increased demand for electricity for air conditioning and personal use is reflected in a greater demand for electricity in the country than during the 1990s. However, although Indonesia contributes about one percent of the world's carbon dioxide emissions, because of its large population, the rate of per capita carbon dioxide emissions is low, at 0.8 metric tons per person in 1990, rising gradually to 1.4 metric tons by 1996, and fluctuating between those levels since then.

One of the reasons for these fluctuations is the extensive forest fires on the islands of Sumatra and

Borneo (Kalimantan), where large portions of the jungles were burned to help clear them, and caused pollution in the region. In 1998, up to 2 million acres (809,371 hectares) of land, one-eighth of which was primary forest, was damaged in fires, severely reducing the local habitat of the orangutan. Although Indonesia is relatively well served by public transportation, much of it is offered by older buses and pickup trucks, which. The increased private automobile ownership, brought about by increased affluence in the Indonesian middle class, has led to transportation producing 18 percent of carbon dioxide emissions. Another 18 percent comes from manufacturing construction, 17 percent from residential uses, and 21 percent from electricity and heat production.

Global warming is expected to increase flooding, as dramatically seen in the Boxing Day Tsunami, on December 26, 2004, which devastated the northwest coast of Sumatra, especially the town of Banda Aceh, resulting in the deaths of about 131,000 people, with an additional 37,000 listed as missing. Subsequently, there has been damage sustained to the west coast of Sumatra around Bengkulu, which was struck by a number of earthquakes in September 2007, resulting in the deaths of 13 people. Flooding has the risk of increasing the prevalence of insect-borne diseases, and in 1997 malaria was detected at 6,900 ft. (2103 m.) in the highlands of West Papua (Irian Jaya), the highest place that it has been found. Some rainforests have been cleared to make way for golf courses, an issue that became important in local politics in parts of Indonesia in the early 1990s.

To try to combat some of the problems presented by global warming, Indonesia has tried to increase its use of hydropower, but it still accounts for only 14 percent of electricity production. The Suharto government of Indonesia ratified the Vienna Convention in 1992, and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, which was ratified two years later. On July 13, 1998, the Indonesian government signed the Kyoto Protocol to the UN Framework Convention on Climate Change, ratified it on December 3, 2004, and it took effect on March 3, 2005.

Industrialization

INDUSTRIALIZATION, SOMETIMES CALLED development, has been a far-reaching, evolutionary process for more than 200 years. Industrialization is not only a process of extracting resources from the Earth and turning them into goods for consumption. It has significant implications for ways of thinking, social relationships, and the view of the Earth and its resources. Because of its dependence on fossil fuels to spur production and growth, industrialization has radically changed the global environment.

HISTORICAL ROOTS

The Industrial Revolution began around the turn of the 19th century. It marked a significant turn in human history, sparking a protracted effort to lower risk to human survival by increasing economic surplus, and mastering the environment. The Industrial Revolution's shorter-term impacts included a general increase in the living standard, improved overall nutrition and health, increased life spans, intensification of global trading, and increased gaps between the rich and poor within and across nations. The level of industrialization is a measure for a country's stage of development. Increased industrialization implies a higher quality of life and progress for a country's residents.

Industrialization initially emerged in Britain in the context of emerging capitalist social relations and rapidly spread to North America and Western Europe. Later, in the 20th century, communist and socialist economies adopted industrial processes and technology. Industrial development continues today in widely varying cultural circumstances, in nations such as China, India, and Indonesia, which are now major contributors of airborne pollutants.

Industrialization, historically seen as a linear process, is particularly suited to enriching mass societies because it allows for the efficient exploitation of vast amounts of natural resources and the use of fossil fuels to produce goods seen as necessary for improved overall social well-being. In essence, industrialization allows for the creation of an economic surplus that, in the relatively short term, lessens risk and increases the comfort for large segments of the population around the globe. Where industrialization is limited, living standards tend to be lower, with attendant poverty, poor health, and shortened lifespan.

WIDESPREAD BENEFITS

Typical analyses of industrialization study changes in local, regional, national, and global economies; social class relationships; government policy; industrial locations; and work processes and industrial organizations. While industrialization's impacts have been debated, the predominant view has been positive, equating industrialization with human progress. Until relatively recently, industrialization's environmental impacts have been ignored or relegated to the background. The mainly positive view of industrialization has prevailed, despite a long history of profit-maximizing firms that failed to account fully for the environmental costs of natural-resource extraction and production.

The positive view of industrialization is pervasive and understandable. For example, the overall wealth of developed countries is a powerful example for countries seeking to industrialize. The compelling myth that a seemingly unlimited supply of material goods is essential to individual freedom and happiness, a corollary to Adam Smith's insatiable wants and needs, bolsters this view. As industrialization spreads to more areas of an increasingly global sociocultural system, the growing demand for fuel and goods increases stress on the planet's ecosystems.

CHALLENGES TO INDUSTRIALIZATION

The traditional linear economics of industrialization posed a particularly thorny problem for the environment. Until relatively recently, industrial efficiency tended to revolve around ways to transform various materials into finished goods in the quickest, cheapest way, with limited regard for byproducts that may have had value if processed or reprocessed. Waste minimization was not a high priority because the costs of limiting pollution appeared to exceed the cost of releasing toxins into the air, soil, and water. In fact, for generations, economists tended to write off pollution costs as an externality, a price paid by someone else, not the industrial operation creating the pollution. Only in the past generation or so have plant operators, responding to laws and economic realities, focused on building loops to capture and reuse what once was considered waste.

The sheer abundance of natural resources in North America masked wider environmental effects of industrialization. Locally, it was easy for people to see denuded forests or fouled water or feel the sting of polluted air in their eyes or lungs. Yet, local leaders equated spewing smokestacks and polluted water with growth, jobs, and overall community economic well-being. Those who questioned industrial pollution, even if they had support from scientific data, faced criticism because they were said to oppose growth and development. In addition, scientific tools to assess impacts of industrial pollution were limited. Improved scientific techniques have increased knowledge about pollution and implications of industrialization on the global climate. This new knowledge has added power to traditional social critiques of industrialization.

Industrialization has not been accepted universally; critical analyses tend to focus on negative impacts of wealth concentration into fewer hands, worker exploitation, and, to some extent, local impacts of pollution. Analyses of industrial pollution have become more common since the environmental movement of the 1960s and 1970s. In addition, clearly recognizable historic, literary, and scientific threads link industrialization to environmental degradation. In the United States, for instance, Transcendentalists such as Ralph Waldo Emerson and Henry David Thoreau rebuked encroaching industrialization during the early 1800s. By the 1860s, nascent conservationists were beginning to develop scientific techniques to measure hydrological impacts of widespread deforestation driven by insatiable timber demands, of coalmines, railroads, and construction that underpinned the growing industrial economy. At the same time, these researchers speculated about the possibility of climate change related to the loss of forest cover across North American. Meanwhile, other researchers, especially in Europe, were beginning to research the impacts of what are now called greenhouse gases on the climate.

ROLE OF ENERGY

Energy consumption is key to understanding industrialization's impacts on climate. Pre-industrial economies were based on human and animal labor. In the mid-1800s, the industrial transition to larger operations, fired first by coal and later by oil and natural gas, unlocked carbon and other chemicals that had been sequestered under the Earth for eons. By the late 1700s, much of Europe had already been deforested, so the emergence of coal as a widely-used fuel was essential for continued survival of Western civilization, much less industrialization. Yet, coal opened opportunities for industrialization, making possible the production of steam-driven machines to replace human and animal labor. It also opened the way for stronger iron and steel for machinery and construction. In North America, the emergence of coal power occurred alongside forest clear-cutting, so the country was in the wood and steel age at the same time.

Industrial processes of the 19th and much of the 20th century wasted energy and polluted the atmosphere. Palls of smoke laden with carbon dioxide, nitrogen compounds, sulfur dioxide, and other pollutants hung over industrial cities and towns, blocking sunshine and creating dangerous smog. Acid rain damaged stone edifices, vegetation, and surface water supplies. Massive amounts of useful gas were flamed off into the atmosphere as coal was turned into coke to fuel the burgeoning metallurgical industry. Later, oil refineries burned off volatiles regarded as useless byproducts. Meanwhile, forests across the country were cut indiscriminately, eliminating ecosystems that could have cleaned the air. Farmers

Mining coal: At the turn of the 19th century, the Industrial Revolution began a significant turn in human history, sparking a protracted effort to lower risk to human survival by increasing economic surplus and mastering the environment.

burned forests to clear land for agriculture; wood left over from deforestation was burned on purpose or by forest fires. Gradually, however, people became more aware of the immediate health risks posed by industrial pollutants. Yet, discussions of climate change resulting from industrial fossil fuel emissions still have to vie for attention; it is difficult for people to discern the long-run impacts of climate change, and industrial progress is still valued in many circles.

Whatever its negatives, industrialization offers short-term, tangible benefits. Since the dawning of industrialization over two centuries ago, immediate benefits generally have been more important than environmental considerations that affect future generations. Continued industrialization has virtually guaranteed an economic surplus to decrease risks, increase general living standards, and stimulate long-term growth in demand. Supply and demand feed each other, not only in already-industrialized nations, but in the hopes and dreams of industrializing nations seeking to increase their material wealth. Pressure on the Earth's resources grows as atmospheric pollutants continue to increase.

Institute of Energy Economics (Argentina)

THE INSTITUTO DE Economía Energética asociado a la Fundación Bariloche (IDEE/FB), or the Institute of Energy Economics associated with the Fundación Bariloche (Bariloche Foundation) is an institute in Argentina that works to promote environmental awareness and education of environmental economics. It is independent, although strongly allied with the Bariloche Foundation.

The Bariloche Foundation is a nonprofit, private institution, allied with the United Nations Educational, Scientific and Cultural Organization (UNESCO) and other international organizations. Scientists and businesspersons at a conference in the city of San Carlos De Bariloche, Argentina founded it on March 28, 1963. The goal of the Bariloche Foundation is to facilitate and foster research, innovation, training, technical assistance, and the dissemination of information and knowledge. Its purpose is "to promote teaching and research in all branches of science, based on a solid, humanist culture and in accordance with the democratic principles contained in the Argentine Constitution." The Bariloche Foundation headquarters are located in San Carlos de Bariloche, with a business office in Buenos Aires, Argentina. The IDEE/FB is based in San Carlos de Bariloche.

The Bariloche Foundation has four major programs: Energy, Environment, Philosophy, and Quality of Life. The Energy program evolved in 1978 from the Bariloche Foundation's previous Department of Natural Resources and Energy, founded in 1967. This program employs agronomists, computer specialists, economists, diverse engineers, mathematicians, and statisticians, and is chiefly in charge of the IDEE/FB. The Environment program studies climate change, energy and the environment, natural resources accounting and other environmental issues, and rational energy use.

The Philosophy program fosters international collaboration and conflict analysis and resolution. Researchers study gender research, history of philosophical ideas, metaphilosophy, philosophy and history of science, philosophy of social sciences, practical and theoretical aspects of conflict analysis and resolution, and rationality. The Quality of Life program began as a project in 1989, and matured into a complete program five years later in 1994. This program monitors social equity and environmental sustainability in the San Carlos de Bariloche region as well as greater Argentina; and also the qualities of life experienced by residents of these regions as globalization continues.

The Bariloche Foundation's Energy program focuses on Argentina and Latin America, as well as in the global economic marketplace and international energy. Research, consulting, economic assistance, and other IDEE/FB services are focused on energy production and use, and how they relate to the economy, the environment, economical and environmental policy-making, and economic and environmental planning.

A major educational initiative of the IDEE/FB is the Latin American Postgraduate Course on Energy and Environment Economics and Policies. This course is a four-month long immersion course that has been conducted annually since 1969, and has trained more than 600 Latin American professionals. People who enroll in the course represent all sectors: energy companies publicly or privately funded, universities, and governmental or nongovernmental organizations from around Latin America, for example.

Additionally, the IDEE/FB offers the MEPEA, a Master's Program in Energy and Environment Economics and Policies. This program lasts for two years and meets every Friday and Saturday. It is assisted by the University of Comahue's Faculty of Economics and Administration, and is held in Argentina's city of Neuquen. The MEPEA has been in operation since 1999.

The major research foci of the IDEE/FB are: Energy Policies in the sense of institutional and managerial strategies, prices and tariffs, rational use of energy, regional integration, regulation, the sector's institutional structure, and technological progress; Energy and Environment in terms of emissions mitigation, and impact caused by each level of the energy chain, including sustainable development; Development of Methodology and Models for studies of energy in the fields of supply, demand, financing, and sources; Integrated Energy Studies for Different Geographical Areas; Economic, Technical, and Environmental Studies for various natural resources; and Sectorial Energy Studies for various energy-demanding sectors.

Intergovernmental Panel on Climate Change (IPCC)

THE FIRST WORLD Climate Conference organized by the World Meteorological Organization (WMO) expressed concern about significant extended regional and even global changes of climate due to human's activities on Earth. The conference appealed to nations of the world to foresee and prevent potential human-made changes in climate that might have adverse effects on human race. A joint UNEP/WMO/ICSU conference convened in Villach, Austria on the "Assessment of the Role of Carbon Dioxide and of Other Greenhouse Gases in Climate Variations and Associated Impacts." The conference concluded that a rise of global mean temperature could occur due to the increasing greenhouse gases and warming of the globe could result in sea level rises. This warming and probable rate and degree of warming are closely linked with other major environmental issues which will/could be profoundly affected by policies on emissions of greenhouse gases, just like the emissions of chlorofluoro- compounds under the Montreal Protocol and their effect on ozone depletion.

Recognizing the problem of potential global climate change, the WMO and the United Nations Environment Programme (UNEP) established the Intergovernmental Panel on Climate Change (IPCC) in November 1988 and was open to all members of the United Nations and WMO, with the aim of assessing in a comprehensive, objective, open, and transparent manner the scientific, technical, and socioeconomic information relevant to understanding the scientific basis of risk of human-induced climate change, its potential impacts, and options for adaptation and mitigation. Although the WMO and UNEP were the two main organizations involved in the creation of the IPCC, there were other intergovernmental organizations as well as nongovernmental organizations that were involved in establishing the IPCC. Also, the UN General Assembly, recognizing the need for international cooperation on climate change, joined the call through its resolution on "Protection of the Global Climate for Present and Future Generations of Mankind" during their 43rd session, held in 1988. The IPCC does not carry out any research on its own, nor does it monitor climate-related data or other relevant parameters. On the contrary, IPCC bases its assessment mainly on peer reviewed and published scientific/technical literature.

A small bureau of 15 was created to oversee the work of the panel and three working groups were also formed: Working Group I addresses topics including greenhouse gases and aerosols, processes and modeling, observed climate variations, and change. The experts of Working Group I have concluded that emissions from human activities are substantially increasing the atmospheric concentration of greenhouse gases and this will result in warming of the Earth's surface. Working Group II assesses the climate change impact on agriculture and forestry, natural terrestrial ecosystems, hydrology and water resources, human settlements, oceans and coastal zones, and seasonal snow cover, ice, and permafrost. Working Group III has further established subgroups to define mitigative and adaptive response options in energy, industry, agriculture, forestry, and other human activities, including coastal zone management. Each working group has two co-chairs, one from a developed country and another from a developing country, and a technical support unit. IPCC activities, including travel costs for experts from developing countries and countries with economies in transition, are financed through voluntary contributions from governments.

The IPCC has an official definition for climate change: climate change refers to a statistically significant variation in either the mean state of the climate, or in its variability, persisting for an extended period (typically decades or longer). Climate change may be due to natural internal processes or external forces, or due to persistent anthropogenic changes leading to change in the composition of the atmosphere or in land use.

The IPCC, in its two decades of existence, has produced many reports; four assessment reports have been produced at the behest of the UN General Assembly. On receipt of the *First IPCC Assessment Report 1990*, the UN General Assembly decided to establish an Intergovernmental Negotiating Committee (INC) in 1990 to initiate negotiations of an effective framework convention on climate change, to be completed prior to the UN Conference on Environment and Development (UNCED) in June 1992. Eventually, at the completion of negotiations, the United Nations Framework Convention on Climate Change was created in 1994.

The *Second IPCC Assessment Report 1995* prepared a comprehensive report on climate change and was recognized as the most authoritative assessment of climate change, its impacts, and response options. It indicated that the continued rise of greenhouse gases in the environment would have serious socioeconomic and environmental impacts, especially for developing countries. This second IPCC report, provided input to the negotiations for the Convention's Kyoto Protocol.

The *Third IPCC Assessment Report 2001*, also known as TAR, set out to meet new requirements. Some of the facts according to IPCC, Executive summary, January 2001 are: warming during the past 50 years can be attributed to humans, global surface temperature is expected to increase by degrees 2.5–10.4 F (1.4–5.8 degrees C) by 2100, and warming on this scale has not occurred during the previous 10,000 years.

The *Fourth IPCC Assessment Report 2007* was prepared with an aim to emphasize new findings, therefore, the structure and mandates of the Working Groups were kept unchanged. The report was presented to the United Nations General Assembly in 2007. Some of the observed impacts are detailed in the report: 11 of the previous 12 years ranked among the 12 hottest on record since 1850, Global sea-level rise had accelerated, mountain glaciers and snow cover have declined, and more intense and longer droughts have been observed over wider areas since the 1970s. The report also established direct links to human health and other issues and has raised international concern over climate change and need to act quickly to prevent the catastrophic impacts of climate change. The IPCC shared the 2007 Noble Peace Prize with Al

Gore for its efforts in bringing climate change to the forefront.

Internal Climate Variability

INTERNAL OR NATURAL climate variability refers to variations over time in one or more measures of climate, resulting from natural causes. The distinction between climate variability and weather variability is not a matter of different timescales; rather, it is based on the fundamental distinction between climate and weather: weather refers to meteorological conditions at a specific time and location, whereas climate refers to any statistical characterizations (such as a long-term mean) of weather conditions. Thus, for example, a single measurement of diurnal temperature range measures a weather variation, whereas an estimate of a multi-year mean diurnal temperature range is a climate variation. An alternative definition is that natural climate variability is any variation in climate not resulting from human influences, such as increasing atmospheric greenhouse gases.

Natural climate variations occur on all timescales up to the age of Earth (for billions of years), and can be classified as either forced or unforced. Forced variations are caused by factors external to the climate system, including: Earth's rotation (resulting in the daily cycle); Earth's orbit (resulting in the seasonal cycle); large volcanic eruptions, which can result in more small particles in the stratosphere, lowering temperatures for a few years; variations in the Sun's inherent energy output, which may have caused, for example, the Little Ice Age during medieval times; variations in Earth's orbital parameters, which result in redistributions of incoming solar radiation, and trigger glacial/interglacial cycles; slow motions of continents (plate tectonics); and slow changes in atmospheric composition, particularly greenhouse gas concentrations, resulting from changes in the balance between natural sources and sinks of these gases.

Unforced variations are internally generated redistributions of energy within the system that occur without changes in external factors. Important modes of unforced climate variability include: the Madden-Julian oscillation, or variations in winds, cloudiness, and other phenomena in the tropics, with a timescale of 40–50 days; the El Niño/Southern Oscillation, a dominant mode of year-to-year tropical climate variability, characterized by changes in sea-surface temperatures in the tropical Pacific; the North Atlantic Oscillation, also known as the Arctic Oscillation and the Northern Annular Mode, variations in sea-level pressure in the Arctic, occurring simultaneously with variations of opposite sign at mid-latitudes in the Atlantic, reflecting North-South motions of atmospheric mass; and the Pacific Decadal Oscillation, changes in north Pacific climate, with a timescale of 20–30 years.

FEEDBACKS

Both forced and unforced modes of natural climate variability are affected by feedbacks: responses of the climate system that either amplify or dampen the underlying variability. Glacial/interglacial cycles, for example, are exaggerated by ice-albedo feedback, in which land ice sheets (which result from cooling temperatures) reflect sunlight into space and thereby amplify cooling. Natural climate variability can be measured via traditional meteorological measurements, or different types of geological (proxy) measurements. Both approaches have limitations: the instrumental record (weather station measurements) is too short to characterize variability on many timescales of interest, while proxy measurements are typically too sparse to yield reliable estimates of variability over large regions (such as continents).

In principle, computer models of climate can be used to help understand natural variability, and simulations of intra-seasonal and intra-annual variability have improved in recent years. However, computational limitations prevent adequate simulation of millennial- and longer-timescale variability, and evaluation of simulations on these timescales is difficult. The character of natural climate variability has itself varied over time. In particular, records derived from ice cores show that the past approximately 10,000 years (the Holocene) have been unusually stable compared to the rest of the most recent 400,000 years; this is thought to have been a significant factor in the development of agricultural societies.

Natural climate variability on timescales of decades to a century complicates "detection of anthropogenic climate change," the search for signals of human influences in the observed climate record since the late 19th century. Because there is no a priori way to attribute an observed climate trend to either natural variability or human influences, a common approach has been to determine if an observed trend is too rapid to result from natural variability alone. While simple in principle, this approach is complicated by the difficulty of characterizing natural variability on the timescale of about a century.

International Council of Scientific Unions (ICSU)

THE INTERNATIONAL COUNCIL of Scientific Unions (ICSU), today known as the International Council for Science, was founded in 1931 as a nongovernmental organization, which would foster international scientific collaboration among all scientists, to work toward the greater good for humanity. The ICSU motto is "strengthening international science for the benefit of society."

The parent foundations of ICSU are the International Association of Academies (IAA), which lasted from 1899 until 1914; and the International Research Council (IRC), which lasted from 1919 until 1931. In the year 1998, the Council officially changed its name to the International Council for Science, keeping the acronym ICSU as a tie to its history.

The ICSU addresses global issues through international initiatives aimed to support scientists in undertaking a task that he or she could not do alone. Successful examples of these initiatives include International Geophysical Year (1957–58) and the International Biological Program, which took place between the years 1964–74.

In 1992, the United Nations Conference on Environment and Development (UNCED) took place in Rio de Janeiro, Brazil. The ICSU was invited to this Conference to act as the chief scientific adviser. Ten years later, the World Summit on Sustainable Development (WWSD) also invited the ICSU as chief scientific adviser, this time to Johannesburg, South Africa. In 2006, the ICSU celebrated its 75th anniversary, noting achievements in the fields of International Research Collaboration, Science and Policy, and the Universality of Science.

Internationally, the ICSU carries out its initiatives either by creating interdisciplinary bodies or supporting joint initiatives. Initiatives led by either of these groups can be organized into one of five categories: Assessment Bodies, Data and Information, Global Environmental Change Programs, Monitoring/Observations, or Thematic Organizations.

Globally, ICSU aims to "mobilize the knowledge and resources of the international science community". Along with this aim, the Council works to determine major issues of interest to this international science community, as well as of concern to science and the society at large. Another chief mission of the ICSU is to engender scientific collaboration among all scientists, regardless of race, gender, nationality, politics, or another potential division to communications.

A current issue that the ICSU is assisting in resolving is the difficulty and sometimes impossibility that international scientists from 'high-risk' countries have in obtaining visas to conduct research in the United States. This issue has been predominant since 2002; in 2006, Professor Goverdhan Mehta, then President of the ICSU, was initially denied such a visa. Professor Mehta is from India.

The ICSU is headquartered in Paris, France. The Council has additional regional offices in the areas of Africa, the Arab Region, Asia and the Pacific, and Latin America and the Caribbean. The African office was established with the vision of strengthening science through fostering sustainable socioeconomic growth in Africa. The other offices support international collaboration in their respective regions, as well as the sharing of knowledge and ideas.

The ICSU is governed by a General Assembly. Additionally, the Executive Board is composed of elected representatives who carry out resolutions of the General Assembly. The 14-member Executive Board is made up of six officers and eight ordinary members. The six Officers are the president, two vice presidents for Scientific Planning and Review and External Relations, the secretary-general, the treasurer, and the past president or the president-elect. These officers are distinct from the ordinary members because they manage the ICSU between Executive Board meetings. Additionally, the ICSU has numerous committees, acting on policies or ad hoc initiatives such as the Policy Committee on Developing Countries and the Planning Group on Natural and Human-Induced Environmental Hazards and Disasters, respectively.

International Energy Agency (IEA)

THE COUNCIL OF the Convention on the Organisation for Economic Co-operation and Development founded the International Energy Agency (IEA) on November 15, 1974. Initial member countries were: Austria, Belgium, Canada, Denmark, Germany, Ireland, Italy, Japan, Luxembourg, the Netherlands, Spain, Sweden, Switzerland, Turkey, the United Kingdom, and the United States. The initial documents allowed for further nations to join the IEA; as of 2007, 26 countries are members, from Europe, Asia, North America, and the South Pacific (Australia and New Zealand). Its French name is *Agence Internationale de l'Energie.*

There was an oil crisis 1973–74 in which the Organization of Arab Petroleum Exporting Countries (OAPEC) refused to ship oil to nations that had supported Israel during the Yom Kippur war. Affected countries included the United States, Japan, and Western European nations. In response to the dependency of these affected countries on Organization of the Petroleum Exporting Countries (OPEC) oil (OAPEC is made up of the Arab nations in OPEC along with Egypt and Syria, the two major countries fighting Israel during the Yom Kippur War), the International Energy Agency (IEA) was formed.

CURRENT GOALS

Today, the IEA has expanded its initial goal of reducing dependence on Arab oil to include what it calls the Three E's: economic development, energy security, and environmental protection. Its motto is "Energy Security, Growth and Sustainability through

Co-operation and Outreach." The IEA, headquartered in Paris, France, has five major offices: the Executive Office, Energy Technology and Research and Development, Long-term Cooperation and Policy Analysis, Office of Global Energy Dialogue, and Oil Markets and Emergency Preparedness. A staff of 150 comes from member countries, and is made up of scientists, statisticians, and management personnel.

In September 2007, the IEA Energy Efficiency and Environment Division was awarded the International Star of Energy Efficiency by the Alliance to Save Energy. The award recognized the IEA's efforts to research and foster energy efficiency, particularly its campaign to quickly phase-out incandescent light bulbs. 2007 was the 30th anniversary of the International Star of Energy Efficiency Award.

The IEA has several Standing Committees: the Committee on Energy Research and Technology (CERT), the Standing Group on Emergency Questions (SEQ), the Standing Group on Global Energy Dialogue (SGD), the Standing Group on Long-Term Cooperation (SLT), and the Standing Group on the Oil Market (SOM). The CERT focuses on technology for energy efficiency, from the research of such technology to its implementation. To carry out this purpose, the CERT has four major groups: the Fusion Power Coordinating Committee, the Working Party Energy End-Use Technologies, the Working Party on Fossil Fuels, and the Working Party on Renewable Energy Technologies.

The SEQ keeps member countries prepared for oil-shortage emergencies, and continuously reviews these countries', as well as the greater IEA's, emergency plans. As several major countries are not part of the IEA, the SGD works to continue communication with these countries, including China, India, and Russia. Meanwhile, the SLT maintains communication among IEA nations; in doing so, it refers to its Working Party on Energy Efficiency.

The SOM analyzes the international oil market and integrates short- and medium-term developments to keep the IEA member nations informed and prepared in the event of another oil emergency. Frequently, the IEA hosts workshops and other events to promote education and awareness in energy efficiency. Additionally, the agency often offers press releases to keep the public informed of its activities and concerns.

Experts at the IEA provide consulting to the leaders of the G8 countries (Canada, France, Germany, Italy, Japan, Russia, the United Kingdom, and the United States) at the G8 summits. For example, at the 2005 Summit in Gleneagles, the G8 developed a Gleneagles Plan of Action. This plan stressed the need for a dialogue between major energy and oil producing countries, as well as energy-consuming nations. The G8 requested the assistance of the IEA in fostering this dialogue. The six major areas covered by the Gleneagles Plan of Action are: alternative energy scenarios and strategies; carbon capture and storage; cleaner fossil fuels; energy efficiency in buildings, appliances, transport, and industry; enhanced international cooperation; and renewable energy.

International Geophysical Year (IGY)

THE INTERNATIONAL GEOPHYSICAL Year (IGY), in French, *Année Géophysique Internationale*, took place between July 1, 1957 and December 31, 1958. The International Council for Science (ICSU) began designing it in 1952. The ICSU addresses global issues through international initiatives aimed to support scientists. A successful example of these initiatives, besides the International Geophysical Year, is the International Biological Program, which took place 1964–74. The International Geophysical Year was inspired by National Academy of Sciences (NAS) member Lloyd Berkner and colleagues in 1950. It was modeled after previous International Polar Years, 1882–83 and 1932–33.

The IGY was to invite and allow all scientists to collaborate internationally in organized geophysical examinations. It would take place during peak solar activity, 1957–58. Initially, 46 nations pledged to send representatives; however, the IGY was such a success that within the year, 67 nations actually participated. Participating scientists in the IGY represented 11 chief fields of Earth sciences: aurora and airglow, cosmic rays, geomagneticsm, gravity, ionospheric physics, longitude and latitude determinations, meteorology, oceanography, rocketry, seismology, and solar activity.

The NAS assembled a U.S. National Committee (USNC) to blueprint the extent of American involvement in the IGY. The USNC was established in March 1953 and chaired by Joseph Kaplan, then a Professor of Physics at the University of California at Los Angeles. The vice chairman of the UNSC was Alan H. Shapley, a physicist at the National Bureau of Standards. The NAS appointed another National Bureau of Standards member, Hugh Odishaw, as executive secretary. He would later become the executive director. Initially, the American contingent was to be 16 core UNSC members overseeing five working groups and 16 technical panels; however, the team quickly reached more than 200 member scientists.

As part of the IGY, both the United States and the Soviet Union launched artificial satellites into outer space. The Soviet Union launched the first artificial satellite in October of 1957; it was called Sputnik I. The U.S. artificial satellite Explorer I launched in January 1958. In 1956, the British established the Halley Research Station on the Brunt Ice Shelf in Antarctica, for the IGY; the bay housing it was named Halley Bay, in honor of the English astronomer Edmond Halley (1656–1742). The work carried out in the Antarctic, while not initially as esteemed as Arctic or equatorial work, proved to be pivotal for modern estimates of total ice content on Earth. These estimates were determined from measurements of ice depths in the Antarctic.

International Geosphere-Biosphere Program (IGBP)

WITH THE DRIVING force of global climate change, a need emerged for a mechanism of international cooperation. In response to this need, the International Council of Scientific Unions (ICSU) appointed a committee for planning and implementation. In 1987, the International Geosphere-Biosphere Program (IGBP) was formed, and, in 1989, found headquarters at the Royal Swedish Academy of Sciences in Stockholm, Sweden. The scope of IGBP's mission is to study the dynamics of Earth's biological, chemical, and physical processes, and climate changes, along with the impact of human actions on Earth systems, and Earth systems on human society. By bringing together the wide range of academic and social disciplines on an international level, IGBP ensures a better understanding of the forces shaping the future. By integrating the knowledge base on all these processes and sharing the information, IGBP envisions a sustainable living Earth.

The initial planning took three years (1987–90) and required cooperation from many scientists (IGPB estimates approximately 500) before implementation of initial projects, 1989–92. The first projects addressed interactions of the water cycle with soil, vegetation, and atmosphere; predicting changes in terrestrial ecosystems from changing climate; determining effects of chemical transformations on the atmosphere and air quality; evaluating ocean circulation effects on atmosphere, sea floor, and continents; and collecting and studying climate change data throughout history. During the 1990s, projects were added to address the role of the coastal zone on Earth systems; evaluate how human and biophysical systems change land surfaces; use Global Analysis, Integration, and Modeling for predicting climate changes and directing research to clarify systems dynamics; create a network for the collation and dissemination of research and coordination of projects internationally; and establish access for exchanging data.

Institutions in Europe, North America, and Australia hosted much of the research. The first phase laying the groundwork and completing initial research ended in 1999. The IGBP evaluated past successes and determined a new set of questions to be answered. IGPB launched the second phase of research, 2004–13. Some projects were considered complete, such as the water cycle, terrestrial ecosystems, ocean circulation, land surfaces, Global Analysis, Integration and Modeling, and established access for exchanging data. The remaining projects were incorporated with new focuses and joined new projects in restructured research programs to include the major Earth System components (atmosphere, ocean and land), the points of interaction between the components, and the dynamics over time and space.

The study of Earth system science parallels the process of Earth systems, as a whole, for common goals. The commitment of IGBP to integrating the activities with the greater international community has fostered cooperation for developing scientific plans and created dialogue between participants to agree on a science question agenda. By involving hundreds of scientists from around the world, IGBP ensures the development of truly international research frameworks, and fosters the building of international and interdisciplinary networks, within national and regional research efforts.

Supporting the work of IGPB are the secretariat and the International Project Offices (IPOs), which maintain the network and manage the various aspects of communication, data exchange, and bringing together the various members of the scientific community. The secretariat manages records, meeting minutes, and membership, as well as public relations, and provides the scientific results of its research to international stakeholders and interested audiences. National Committees are situated around the world (in approximately 73 different countries) to assist with the activities of IGPB on a local or regional level. These committees assist in the coordination of studies in their area and provide a link between their area and the international community, as well as assisting with raising the necessary financial support for the research. The IGBP has received steady funding for project activities through contributions from approximately 35 countries of about $1.5 million per year since 2000.

International Institute for Sustainable Development (IISD)

THE INTERNATIONAL INSTITUTE for Sustainable Development (IISD), a Canadian-based nonprofit organization established in 1990, with nonprofit status in the United States, is a pioneer policy research institute focused on the development and implementation of policies on international trade and investment, climate change, and natural resource management that are beneficial to both the economy and environment on a global scale. The IISD believes that sustainability is a win-win approach that protects the natural world, while generating resources and economic growth. The IISD, which is funded by Canadian and foreign governments, agencies of the United Nations, foundations, individual donors, and the private sector, is committed to capacity-building in developing countries. The IISD cooperates with more than 200 organizations throughout the world and has managed programs in Africa, Asia, Canada, Central Europe, China, Eastern Europe, South America, the United States, and Western Europe.

EARLY PRACTICAL APPROACHES

In its early years, the IISD surprised members of the public and the press by supporting approaches that were more practical than those of other environmentalists, in large part through recognition of the interdependence of environmental and fiscal interests. The surprise grew exponentially, however, when the IISD criticized the payment of subsidies to move grain by rail, which encouraged cropping that was ill-advised, and attempted to control supply, stating that it was more advisable to simply subsidize farm income. The IISD has aggressively promoted its vision of sustainability to the global media. The IISD's Media Mail newsletter provides online subscribers immediate access to press statements. Press releases include not only statements issued by the IISD, but those in which the IISD is cited. According to the IISD, its website recorded 52 million visits from more than 100 different countries in 2004, resulting in more than 2 million documents downloaded.

GlobeScan, a Canadian business enterprise that provides global survey research and strategic guidance to corporations, governments, and nongovernmental organizations, voted the IISD as the most effective sustainable development organization in the world. The IISD's work and knowledge fall within a number of areas, including sustainable markets, security, natural resources, international trade, foreign investment for sustainable development, economics and sustainable development, and climate change and energy. For example, the IISD launched the Sustainable Commodity Initiative in 2002, by endorsing global efforts to improve the environmental and economic sustainability of commodities production, beginning with the coffee sector and the creation of the Sustainable Coffee Partnership. The IISD's extensive list of publications includes books, papers, and institutional history resources. Additionally, the IISD's readership base of 45,000 decision-makers and experts benefit from the institute's publications and objective research.

WIDE-REACHING PUBLICATIONS

IISD publications that reach wide audiences include *Environment and Trade: A Handbook*, a collaboration between the IISD and the United Nations Environment Programme, which meets the needs of readers who are generalists and policy-makers seeking a solid resource tool, and the *IISD Sustainable Development Timeline*, which features important milestones in sustainability, including, events, meetings, and publications using the release of Rachel Carson's *Silent Spring* in 1962 as a starting point. Publications include not only research findings, but program proceedings as well. In 2007, the IISD co-hosted a two-day workshop, "Early Lessons From the Implementation of Climate Change Adaptation Projects in Eastern and Southern Africa," with SouthSouthNorth, a coalition-based nonprofit organization committed to reducing structural poverty in Sub-Saharan Africa, Asia, and Latin America and to positioning poverty as a central issue in discussions about climate change. Representatives from nongovernmental organizations, government agencies, and funders attended the workshop.

International Research Institute for Climate Prediction

THE INTERNATIONAL RESEARCH Institute for Climate Prediction (IRI) is based at Columbia University in New York City, New York. The IRI partners with numerous local and global organizations, including the World Bank, the United Nations Food and Agriculture Organization (UNFAO), the World Meteorological Organization, the U.S. Department of Energy, the Geophysical Fluid Dynamics Laboratory, and the National Center for Atmospheric Research, to provide accurate seasonal forecasts of climate patterns to communities around the globe. The IRI has five programs: Agriculture, Climate and Environment, Economics and Livelihoods, Health, and Water. These programs address the concerns of the global regions of Africa, Asia and the Pacific, and Latin America.

The Agriculture program focuses on the study of climate and its impact on agriculture. A large part of the Earth's population is what the IRI calls "poor and food-insecure," relying on rainfall for watering of their crops. Thus, understanding weather patterns and accurate predictions of weather, such as rainfall, could be of great benefit to these communities. In response to this potential benefit, the IRI works with countries to develop methods for food security, natural resource sustainability, and poverty reduction.

The Climate and Environment program focuses on providing accurate weather forecasts in enough time to allow a country to prepare for adverse conditions such as drought. According to the IRI, tropical climates have the most predictable weather patterns, and yet the societies inhabiting these climates are often the most susceptible to hardship during difficult weather. The principle behind the Climate and Environment program is that when a community has access to accurate seasonal weather information, it can better plan for, and allocate resources for, adverse conditions, as well as for optimal weather conditions.

The IRI's Economics and Livelihoods program focuses on the economic impact of the climate. Because residents of rural areas are often reliant on good weather to travel and to obtain necessary goods and services, such as clean water, nutritious food, and healthcare, the Economics and Livelihoods program aims to provide accurate climate predictions so people can best take advantage of, and invest in, a good growing season.

The Health program at the IRI recognizes the impact of climate on the health status of individuals and populations. Beyond stress from heat or cold, other illnesses are correlated with certain climate conditions. The WHO classifies Malaria, for example, as a "climate sensitive communicable disease," along with cholera. Accurate climate prediction could warn healthcare providers prior to a surge in climate sensitive diseases, communicable and noncommunicable alike, and, thus, give them a chance to prepare proper treatments, potential preventative measures, and infrastructure to reduce the potential spread of such a disease.

Finally, the Water program investigates the effect of climate on availability of clean, fresh water to those who need it. Accurate seasonal climate predictions would assist countries and communities in developing plans for storage of water in times of plenty, and distribution of this stored water in times of drought or other adverse conditions. Additionally, the IRI Water program advises communities in proper urban planning to best manage the risk of a water shortage.

The institute maintains several seminar series to share information and knowledge, and to keep its members up to date with late-breaking research and technology. A board of 12 people from different countries manages it. A board chair leads them. An International Scientific and Technical Advisory Committee (ISTAC) provides the board with scientific advice. ISTAC members represent all aspects of science and society. For example, an ISTAC member may be from government, a nongovernmental organization, academia, the private sector, or climate organizations from local to international levels.

International Solar Energy Society (ISES)

THE INTERNATIONAL SOLAR Energy Society is an international nonprofit, nongovernmental organization with a focus on the development and diffusion of renewable energy technologies.

The society has 30,000 members globally from industry, research, and government; there are national sections in 54 countries. The following goals are stated in the society's mandate: to encourage the use and acceptance of renewable energy technologies; to realize a global community of industry, individuals, and institutions in support of renewable energy; to create international structures to facilitate cooperation and exchange; to create and distribute publications for various target groups to support the dissemination of renewable energy technologies; to bring together industry, science, and politics in workshops, conferences, and summits on renewable energy, and to advise governments and organizations in policy, implementation, and sustainability of renewable energy activities world-wide. The motto of the ISES is "think globally, act locally."

The ISES is headquartered in Freiburg, Germany. The international office is supplemented with national sections that network and coordinate energy professionals and sponsor activities in the member countries. The national sections spearhead local projects. Members are encouraged to engage at both the national and international level. In addition, regional offices have been opened to coordinate beyond the national level. Regional offices exist for Africa, the Asia Pacific region, Europe, and South America.

The society was founded as a nonprofit organization in 1954, as the Association for Applied Solar Energy. The first meetings of the society were held the next year in Tucson and Phoenix, Arizona. The society journal began in 1957. In 1963, the name of the society was changed to the Solar Energy Society.

In 1970, the society headquarters were moved from the American Southwest to Melbourne, Australia. The current name was adopted in 1971. The society took part as a consulting nongovernmental organization in the United Nations Conference on Environment and Development (UNCED), held in Rio de Janeiro, Brazil in 1991. In 1995, the international headquarters moved to Freiburg, Germany.

PUBLICATIONS FOR DEBATE AND DIALOGUE

The ISES has several publications, most notably its official journal *Solar Energy*, which includes articles on the science and technology of solar energy applications. The journal also publishes articles on indirect applications of solar energy, such as wind energy, and biomass.

The ISES also publishes *Renewable Energy Focus*, formally known as *Refocus*. This bimonthly publication aims to provide a "forum for debate and dialogue" between research, industry, and government on the topic of renewable energy. The society also hosts the biennial Solar World Congress, which fosters communication between industry, government, and the research community. The conference is a major event within the field.

The ISES supports a variety of projects. The Solar Academy training program focuses on the integration of solar technologies into building design, with a focus on renewable energy, conservation, and efficiency. The Solar Cities initiative aims to promote renewable energy use in long-term planning processes. The project highlights "solar communities"; cities or towns that make a commitment to emissions reduction targets, renewable energy sources, and energy efficiency.

The RESuM project, (Rural Energy Supply Models) is a tool-design project intended to help rural areas secure a sustainable energy supply. The solar food processing and conservation initiative is a newer project designed to increase knowledge of solar cooking and drying by creating a global network of interested solar food experts, farmers, producers, and decision-makers. The Solar Schools-Brighter Future program, launched as part of the 2000 Earth Day Celebrations, aims to bring solar applications into the classroom setting, both to save energy and to act as a teaching aide.

The ISES is dedicated to the use of the internet as a networking tool and as a means of knowledge dissemination. *Refocus* is also published as a weekly online newsletter, and the society has also designed a global network and database with online cooperative authoring, known as WIRE, or World-wide Information System for Renewable Energy. ISES is also a member of the International Renewable Energy Alliance.

International Union of Geodesy and Geophysics (IUGG)

THE INTERNATIONAL UNION of Geodesy and Geophysics (IUGG) was established in 1919 as a nongovernmental organization. Original members were Australia, Belgium, Canada, France, Japan, Portugal, the United Kingdom, and the United States. It is based at the University of Colorado in Boulder, Colorado, and is also known by its French name, *Union Géodésique et Géophysique Internationale*.

Geodesy and geophysics refer to the study of the sciences of the Earth and its position in space. Individual fields within these faculties include composition and tectonics of the Earth, dynamics of the Earth and its components, Earth shape, internal structure of the Earth, gravitational and magnetic fields, hydrological cycles of the Earth including ice and snow, magma generation, volcanism and rock formation, solar-terrestrial relations, and anything to do with the atmosphere, ionosphere, magnetosphere, and oceans. Additionally, study can be extended to the moon and the other planets in our solar system. These studies can be carried out using data collected on the Earth or via high-altitude data-collection instruments or artificial satellites.

The IUGG is "dedicated to advancing, promoting, and communicating knowledge of the Earth system, its space environment, and the dynamical processes causing change." When a natural disaster occurs, the IUGG partners with the United Nations Educational, Scientific, and Cultural Organization (UNESCO) to investigate. UNESCO is a United Nations agency that was established in 1945 to foster international communication in the fields of culture, education, and science.

Members to the IUGG are individual countries. When a country wishes to join the IUGG, a current member country must first nominate the country; the nominating country is thereafter called the adhering organization. The country must next nominate a national committee to serve the IUGG, including at least an officer. There are multiple associations within the IUGG; joining countries must nominate a correspondent to each association. Finally, the applying country must choose to be a regular or associate member. As of 2007, there were 65 member nations representing Africa, Asia, Central America, Europe, North America, Oceania, and South America.

The IUGG is currently a scientific union within the International Council for Science (ICSU), along with 24 other unions. The ICSU was founded in 1931, as the International Council of Scientific Unions (hence the acronym); it became the International Council for Science in 1998, keeping the acronym ICSU as a tie to its history.

Within the IUGG, there are eight associations. These associations are the International Association of Cryospheric Sciences (IACS), the International Association of Geodesy (IAG), the International Association of Geomagnetism and Aeronomy (IAGA), the International Association of Hydrological Sciences (IAHS), the International Association of Meteorology and Atmospheric Sciences (IAMAS), the International Association for the Physical Sciences of the Ocean (IAPSO), the International Association of Seismology and Physics of the Earth's Interior (IASPEI), and the International Association of Volcanology and Chemistry of the Earth's Interior (IAVCEI).

The IUGG is a self-proclaimed "purely scientific organization," with the objectives of "the promotion and coordination of physical, chemical and mathematical studies of the Earth and its environment in space." It is managed by an IUGG council and holds a general assembly with delegates from each adhering body. The first general assembly was held in Rome, Italy in 1922. Since then, it has been held around the globe approximately every two to four years; it was held in Boulder, Colorado, in 1995, and at Perugia, Italy, in 2007. The first recorded attendance rate is 333 people for the 1930 meeting in Stockholm, Sweden; the 2003 meeting in Sapporo, Japan hosted 4,151 people. All member countries are invited to propose to host the general assembly; applications must be submitted at least six months prior to the scheduled meeting date.

University of Illinois at Urbana-Champaign

Intertropical Convergence Zone

THE INTERTROPICAL CONVERGENCE Zone (ITCZ) is a narrow band where the trade winds of the two hemispheres collide. At or near the ITCZ, sea-surface temperature (SST) is at a maximum. As the winds travel over the tropical water, they pick up moisture; where they collide, they are driven upward. The air is also forced upward by convection resulting from heating by the ocean. As the air rises, it cools, the moisture condenses, and heavy rain results. The heat released drives the regional and global atmospheric circulation. It also makes the ITCZ an origin site for cyclones. Another effect of the upward movement of air is relatively calm surface winds. This causes the ITCZ to be an area of downwelling, and, thus, low nutrients and productivity. The ITCZ interacts with other climatological features, affecting weather and climate in the tropics and subtropics.

The ITCZ might be expected to fall directly on the equator, because, on average, this is where the Sun is strongest. In actuality, the ITCZ moves, but tends to fall preferentially in the northern hemisphere, over the eastern Pacific and the Atlantic oceans. The shift can be 10 degrees or more in latitude, or several hundred mi. (km.), and it has significant effects.

The cause appears to be related to the western boundaries of South America and Africa, particularly the northwest to southeast slopes of the boundaries at the equator. This weakens the northeasterly trade winds, thereby warming the water north of the equator and allowing southeasterlies to cross into the north prior to convergence.

The easterly trade winds are the prevalent winds in the tropical Pacific and Atlantic oceans. These winds push the warm surface water west, exposing cooler water, known as the Equatorial Cold Tongue. Stronger trade winds in the south favor upwelling below the equator. Low-level stratus clouds above the cold water and evaporative cooling aided by the winds reinforce the hemispheric temperature difference and move it westward. The Sun is closest to the Earth during northern winter, which may also favor prevalence of a northern ITCZ. The dominance of monsoons over trade winds in the Indian Ocean maintains equatorial symmetry there.

The ITCZ fluctuates over many timescales. Local winds are important seasonally, more distant winds can be significant interannually, and ocean circulation can affect sea-surface temperatures on decadal or greater scales. Normal annual migration is from 10 degrees north latitude in August to 3 degrees north in February. In March and April, a double ITCZ above and below the equator can form. Weak trade winds and subsequent decreased upwelling in El Niño years may move the ITCZ south of the equator in the Pacific.

The asymmetry of the ITCZ aids in establishing an annual, rather than a biannual, weather cycle in the tropical eastern and central Pacific Ocean, even though the sun crosses the equator twice yearly. Seasonal air temperatures there exhibit wide divergence because the seasonal weakening and strengthening of the southeasterlies reduce or enhance upwelling and evaporative cooling. Models indicate that this phenomenon could intensify in response to increased greenhouse gases. Interannual and decadal variation in the ITCZ can result in droughts in some years, and floods in others. Southward displacement is associated with increased the occurrence and intensity of El Niño, while El Niño is suppressed by northward displacement.

The southward shift brings dry conditions to South America and perhaps western Africa, and increased rain in eastern Africa. Warming in one hemisphere or cooling in the other moves the ITCZ in the direction of warming. Past deflection of the ITCZ likely resulted from orbital changes that affected how the sun strikes Earth. Prolonged shifts have been linked to changes in human society, because of their effects on precipitation. The Northern Hemisphere is currently experience greater warming than the Southern Hemisphere because of the greater ocean heat sink in the south. This raises the possibility of change in the El Niño/Southern Oscillation regime. Changes in the Atlantic Meridional Circulation could also reorganize heat distribution, thereby evoking a response in the ITCZ.

Iowa

IOWA HAS AN area of 56,272 sq. mi. (145,744 sq. km.), with inland water making up 402 sq. mi. (1,041 sq. km.), including 31 natural lakes most formed by glaciers and reservoirs. Iowa's average elevation is 1,100 ft. (335 m.) above sea level, with a range in elevation from 480 ft. (146 m.) at the Mississippi River, to 1,670 ft. (509 m.) in Osceola County. Iowa has 2 million acres of forested land. The topography is central lowland, part of the interior plains. Iowa's rivers drain into the Mississippi River system. Iowa has many small lakes, and dams on smaller rivers have created several reservoirs. Dams on the Mississippi River have created large reservoirs on the eastern state line formed by the Mississippi River.

Iowa's climate is fairly uniform throughout the state, with hot, muggy summers, and harsh winters. Des Moines's average January temperature is 20 degrees F (minus 6 degrees C) and the average July temperature is 76 degrees F (24 degrees C) (with warmer daytime temperatures in the high 80s to low 90s F, or 27–32 degrees C). The highest temperature recorded in the state was 118 degrees F (48 degrees C) on July 20, 1934, and minus 47 degrees F (minus 44 degrees C) is the lowest temperature recorded in the state on February 3, 1996. The annual precipitation is between 26–36 in. (66–91 cm.) around the state, with more precipitation in the eastern part of the state. With no natural barriers like mountains, Iowa experiences the full sweep of winds.

Iowa's major crop is corn (hybrid corn developed to resist disease and drought). Hot and muggy summers and a long growing season (170 days in the south and 140 days in the north) lead to a good corn harvest. Beef, pork, wheat, soybeans, and apples are also major agricultural contributions to the economy. Major industries include chemicals, machinery, and electrical equipment manufacturing. Iowa has large coal reserves and most of the coal mined is burned to make electricity.

Iowa experienced a sample of possible impact of climate change with the Great Flood of 1993. Heavy rain (Des Moines reported 29.67 in. of rain) and snow runoff raised the Missouri, Mississippi, Des Moines, Cedar, and Iowa rivers and many smaller streams, causing severe flooding in much of the state.

Climate models vary on temperature increase for Iowa, from 2–7 degrees F (1–4 degrees C) in autumn and winter, from 1–4 degrees F (0.5–2 degrees C) in summer, and from 1–5 degrees F (0.5–3 degrees C) in spring by the end of the 21st century. Potential risks include increase in frequency and intensity of summer and autumn rainfall, making flooding a possibility in many areas, made worse by difficult drainage and the increasing chance of topsoil erosion. Flooding and runoff could contaminate water supplies (with eroded soils and agricultural chemicals containing high concentrations of nitrates, pesticides, and soil nutrients). Changes within established ecosystems (wetlands, forest, cropland, and prairies) would affect wildlife, including breeding grounds of waterfowl and migratory birds. Human health risks include, but are not limited to, contracting certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents. Warmer temperatures would increase the incidence of heat-related illnesses and lead to higher concentrations of ground-level ozone pollution, causing respiratory illnesses (diminished lung function, asthma, and respiratory inflammation).

Agriculture, the major source of the Iowa economy, may not be affected at lower temperature increases. Only if summer temperatures rise to the higher predicted levels and drier conditions become prevalent will livestock be affected by failure to gain weight and limited pasture yield. Iowa has the potential for an additional source of income selling emission credits achieved by carbon sequestration.

Based on energy consumption data from the Energy Information Administration's State Energy Consumption, Price, and Expenditure Estimates (SEDS) released June 1, 2007, Iowa's total carbon dioxide (CO_2) emissions from fossil fuel combustion in million metric tons CO_2 for 2004 were 80.20, made up of contributions from: commercial, 3.54; industrial, 15.58; residential, 4.77; transportation, 20.37; and electric power, 35.93.

Iowa established the Climate Change Advisory Group in April 2007 to assess climate change impact and develop a strategy for reducing greenhouse gas emissions. The Department of Natural Resources Air Quality must include greenhouse gas emissions estimates in construction permitting and emissions inventory programs. Iowa's 2002 Comprehensive Energy Plan Update required state facilities to purchase at least 10 percent of their electricity from renewable energy by 2005 and to reduce their energy consumption to 20 percent below 2000 levels. Iowa joined the Climate Registry, a voluntary national initiative to track, verify, and report greenhouse gas emissions, with acceptance of data from state agencies, corporations, and educational institutions, beginning in January 2008.

FARMER PILOT PROGRAM

Iowa farmers are participating in a pilot program that pays them to store carbon in their soil by not tilling. The Chicago Climate Exchange program then sells carbon credits to utilities and other big carbon polluters to offset emissions. Conservation in Iowa began long before global warming became an issue. In 1972, Iowa established the first soil conservation cost-share program in the United States, and, in 1980, renewed the commitment to soil conservation with a 20-year schedule for soil-erosion prevention measures. In addition, research and education continue to decrease the use of chemicals in farming. The Iowa legislature also passed environmental protection bills to preserve ground water and air quality, with the task performed by the Department of Natural Resources.

Iowa State University

IOWA STATE UNIVERSITY of Science and Technology (ISU) is a public land-grant and space-grant university located in Ames, Iowa. Until 1959, it was known as Iowa State College of Agriculture and Mechanic Arts. ISU houses 8 different colleges, 54 different departments, and enrolls 20,440 undergraduate and 4,583 graduate students annually. The College of Liberal Arts combined with the College of Agriculture offers undergraduate and graduate degrees in Environmental, Geological and Atmospheric sciences.

The Department of Geological and Atmospheric Sciences has implemented an internet-based university course addressing issues of global environmental change. The course provides access to recent scientific literature and structured learning activities on a wide range of global environmental issues. An electronic dialog allows online discussion organized by topic. A web-based laboratory allows students to test hypotheses and conceptual models by accessing and running a research-quality model of soil-vegetation-atmosphere interactions. Each student has a personalized password-protected electronic portfolio for managing all interaction with the course and the laboratory. A global learning resource network has been established to facilitate multi-directional flow of information and ideas from many countries on global change issues.

The authors have compiled pertinent information in the form of summary information, images, and suggested readings. The topics are subdivided into three blocks. The first block, Climate and Agents of Global Change, sets the foundation for understanding global change through observations of global mean temperature and trends in carbon dioxide. The second block, Models and Measurements of Global Change, focuses on climate modeling, the limitations of models and what we can learn from them. Block three, The Biosphere and Human Component of Global Change, addresses the impact by humans through population, deforestation, and desertification. The course objectives are to demonstrate the interconnectedness of the earth's environmental system, and to explore the scientific evidence for changes in the global environment; instill in students the value of peer-reviewed literature on global-change issues; engage students, by means of the internet, in dialog among themselves, with outside experts, and with students from other countries on the scientific, economic, social, political, and ethical implications of these global changes.

For each of the assigned units, members of the group read and discuss online the material and references for that particular unit, and monitor the outline dialog. The group constructs a short document for the entire class that summarizes key points from the Summary Information and from the online dialog.

Iran

ONE OF THE largest countries in the Middle East, the Islamic Republic of Iran has a land area of 636,372 sq. mi. (1,648,195 sq. km.), with a population of 71,208,000 (2006 est.), and a population density of 109 people per sq. mi. (42 people per sq. km.). Tehran, the capital and the largest city, has a population density of 26,620 people per sq. mi. (10,260 per sq. km.). Ten percent of the country is arable land; 27 percent is used for meadows and pasture, much of it for low-intensity grazing of sheep and cattle; and 7 percent of the land is forested, although this is declining rapidly with heavy deforestation.

With an economy heavily reliant on oil, and with the price of petroleum low in the country, Iran had a per capita rate of carbon dioxide (CO_2) emissions of 3.9 metric tons in 1990, rising to 5.6 metric tons by 2003. As for electricity production in the country, 94.2 percent comes from fossil fuels, and only 5.8 percent from hydropower. Iran embarked on a nuclear power program in the 1970s.

This nuclear power program was disbanded in 1979, but has been started up again, ostensibly to try to remove Iran's dependence on oil. Of the country's CO_2 emissions, 55 percent come from liquid fuels, 34 percent from gaseous fuels, and 7 percent from gas flaring. The low price of gasoline, along with the size and increasing prosperity of the country, has led to widespread use of private automobiles. As a result, there is considerable air pollution in Iran, with nearly 70 percent of it coming from fumes from vehicle exhausts. Also, few cars have catalytic converters, which allow for the worst pollutants to be removed before the fumes come through the exhaust. In recent years, the price of gasoline has risen, and this has helped reduce the increase in automobile use, but transportation still accounts for 24 percent of CO_2 emissions, the same percentage as electricity. Residential uses account for 17 percent of emissions, and 21 percent of emissions come from manufacturing and construction.

DEVELOPMENT AND DEFORESTATION

There has also been massive urban and industrial development, as well as deforestation, with soil erosion and overgrazing noticeable around the Alborz Mountains. A widespread drought hit Iran in 1999–2001, and, in one study in 2001, it was found that 90 percent of the wetlands had dried up because of the drought, with the winter of 1999–2000 the driest on record, and the years 1999, 2000, and 2001 ranking as the fifth, third, and seventh driest since records began in 1900.

The Iranian government ratified the Vienna Convention in 1990 and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, which was ratified in 1996. They accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on August 22, 2005, and it took effect on November 20, 2005.

Iraq

THE REPUBLIC OF Iraq, located in the Middle East astride the Euphrates and Tigris rivers, has a land area of 169,234 sq. mi. (434,924 sq. km.), a population of 28,993,000 (2006 est.), and a population density of 171 people per sq. mi. (66 people per sq. km.). Baghdad, the capital and the largest city, has a population of 5,831,000.

The Iraqi economy is heavily reliant on oil, and 12 percent of the land is arable, with a further 9 percent used for meadows and pasture. To try to reduce the reliance on imports from overseas, the Iraqi government of Saddam Hussein embarked on a process of turning the land in the delta of the Tigris and the Euphrates into farmland, alienating many of the Marsh Arabs in the area, and leading to major environmental changes in that region. During the Gulf War, 1990–91, many oil wells in Kuwait were set on fire, leading to massive environmental pollution in the region, and having a considerable effect on carbon dioxide (CO_2) emissions.

Because of the low price of gasoline in the country and increasing affluence during the 1990s, in 1998, some 90 percent of the country's CO_2 emissions came from liquid fuels, with a further 7 percent from gaseous fuels. The rate of CO_2 emissions per capita remained low, with 2.6 metric tons per person in 1990, reaching 3.4 metric tons in 1994, and then falling to 2.7 metric tons by 2003, a rate similar to that of its eastern neighbor Syria, which has no significant petroleum facilities. In spite of the reliance on petroleum, there have been studies of the possible use of solar power and wind power in Iraq. The studies have shown that there is clear capacity for solar power to heat domestic water and to supply continuous hot water to all the major population centers in the country.

The Iraqi government did not ratify the Vienna Convention and sent an observer to the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, but did not sign the agreement. Iraq is one of the few major countries whose government has not expressed a position on the Kyoto Protocol to the UN Framework Convention on Climate Change.

Ireland

AN ECONOMIC BOOM that began in the 1990s and continued through 2001 transformed Ireland from one of the poorest countries in Europe to one of the wealthiest, but the boom came with an environmental cost. No part of Ireland is more than 70 mi. (113 km.) from the Atlantic Ocean, and this proximity to the ocean renders the country particularly vulnerable to coastline erosion. Greenhouse gas emissions from land and air transportation increased 140 percent 1990–2004, making Ireland the second worst offender (next to Luxembourg) in spewing pollutants among European Economic Area nations. Deforestation has added to Ireland's environmental offenses.

A study compiled by climatologists for the Environmental Protection Agency draws a direct correlation between Ireland's shrinking shoreline and greenhouse gas emissions. The researchers reported that Ireland's average temperature has been rising at the rate of 0.75 degrees F (0.42 degrees C) each decade since 1980, the fastest rate of change in more than a century. At the same time, Ireland has experienced its 10 hottest years on record, rainfall has increased in frequency and intensity along the Atlantic coastline, and the study predicts worsening conditions.

Ireland, as a signatory of the Kyoto Protocol, is bound to limit its emissions increase to 13 percent by 2010. The European Union (EU), in 2006, questioned Ireland's ability to meet the target, predicting that the country will likely increase its emissions by 29 percent. The Irish government has defended its policies, insisting that increases in the nation's use of renewable energy for electricity production and more stringent measures for its building industry will make results better than EU predictions. However, as the opposition party is quick to note, road building increases emissions, as does Ireland's low level of forest cover. Despite 20 years of encouraging afforestation, Ireland's rates are 30 percent below target.

Ireland can claim some successes. Emission rates were reduced in energy supply, industry, agriculture, and waste management during the same period when transportation emissions increased dramatically. In April 2007, the Ministry for the Environment, Heritage and Local Government announced the National Climate Change Strategy for 2007–12. The plan included such measures as a goal of 15 percent of electricity to be generated from renewable sources by 2010, and 33 percent by 2020, with biomass to contribute up to 30 percent of energy input at peat stations by 2015; new support for afforestation, changes in tax regulations to discourage the use of fuel-inefficient cars; and grants for renewable energy heating sources for homes. A more detailed Transport Action Plan was promised for late 2007. The government believes these srategies will allow Ireland to meet 80 percent of its Kyoto target, with the remaining 20 percent coming from Ireland's use of the Flexible Mechanisms that allow Kyoto Protocol Parties to support the development of clean technology in the developing world in return for emissions credits.

Sea level in the Dead Sea. Israel may have 40 percent less water by the end of the 21st century than it had in 2000.

Israel

A POLITICALLY TROUBLED country since its inception in 1948, Israel is nevertheless a progressive nation. Israel's early commitment to environmentalism is in line with its progressiveness. The Israel Environmental Protection Service was established in 1973, and the Ministry of the Environment, largely responsible for monitoring compliance with the nation's environmental laws, began operating in 1988. The country is also a signatory to many international environmental agreements, including Climate Change, Climate Change-Kyoto Protocol, Desertification, and Ozone Layer Protection. But air and water pollution remain a problem. Israel's power consumption has increased 7.5 percent per year since 1990, the highest rate in the developed world, and its contributions to global warming doubled during the same period.

Although the Climate Change Convention classified Israel as a developing country, its greenhouse gas emissions are on the levels of developed countries. The largest source of carbon dioxide (CO_2) emissions is the burning of fuels for energy production, a source that has grown steadily since 1996, Israel's self-selected baseline year for the Kyoto Protocol agreement. Electricity production and road transportation account for more than 80 percent of the nation's CO_2 emissions. Ironically, Israel was at the vanguard of solar innovation, using solar water heaters as early as the 1950s. However, little effort has been devoted to using solar energy commercially to generate electricity. A 2006 Yale University study ranks Israel well above the average for its geographical region in both overall environmental health and its Environmental Performance Index, but Israel is still a long way away from meeting targets in CO_2 emissions and in its use of renewable energy sources.

Local experts warn that Israel could have 40 percent less water by the end of the 21st century than it had at its start. High-intensity rainstorms may cause runoff of topsoil and water into the Mediterranean and the Dead Sea.

The latter has already experienced major ecological damage. A new report by the Israel Union for Environmental Defense studied the United Nations Intergovernmental Panel on Climate Change's report and concluded that Israel's annual rainfall could decrease by 20 percent to 30 percent and that rising sea levels caused by the melting of polar icecaps could result in flooding that could devastate the nation's ports, power plants, and residential communities.

A rise in sea levels can also increase salinity, which would endanger Israel's potable water supply. The country opened a new desalinization plant in 2007, which, according to projections, will supply one-third of its water requirements by 2020. But the plant will exact costs as well, since more greenhouse gases will be emitted by the energy required to run the facility.

Israel has approved three new projects that reputedly could reduce CO_2 emissions by as much as 150,000 metric tons per year. Israel's status as a developing nation and the Clean Development Mechanism allow the country to sell "the reduction percentage" to developed countries eager to meet their own targets. These projects could mean good news for Israel, the developed countries, and the entrepreneurs who developed the new technologies.

Italy

21ST CENTURY ITALY is a modern, industrialized nation with the seventh highest Gross Domestic Product in the world. Like other developed countries, Italy must struggle with high consumption of resources and the environmental effects of that consumption. The leading causes of greenhouse gas emissions in Italy are road transport and fossil-fuel burning energy production. Water pollution and desertification are environmental problems. Italy has been slow to confront these problems, but, beginning in 2006, has been able to see some positive outcomes as a result of new technologies and environmental policy changes.

Italy has the third highest rate of private car ownership in the world, and the low percentage of unleaded gasoline sold, a mere 18 percent, intensifies the emissions problem, as do the popular motor scooters. In the 1990s, Italy's industrial carbon dioxide (CO_2) emissions gave the country the world's tenth highest level of industrial CO_2 emissions. Between 1990, Italy's base year for greenhouse gas emission according to the Kyoto Protocol, and 2005, Italy's emissions rose annually. Methane emission is also a problem. Experts suggest that methane emissions have the potential to reach levels comparable to emissions from Italy's fossil fuel industry.

Italy's greenhouse gas emissions have risen 12 percent since 1990. Italy did achieve a 1.5 percent reduction in 2006, but emissions from electricity production rose 4 percent, and automobile emissions were stable. To reduce CO_2 emissions, Italy has considered expanded rail systems, car-free Sundays, and a move from trucking to water transport, among other experiments, but local politics and contradictory opinions about what is best for the environment and the country's citizens make changes difficult.

The connection between the emissions problem and desertification is strong. The country's National Environmental Strategy for Sustainable Development (NESSD) included the reduction of greenhouse gases as the first item in its plans to protect and sustain natural resources. Some reports warn that climate change and its effects, such as declines in precipitation levels, could result in the desertification of as much as 32 percent of Italy's land area. In southern Italy, land that has been cultivated for millennia is being abandoned. Even flourishing businesses, such as the wine and olive industries, are suffering. In 2007, when Italy had its hottest summer in 250 years, the nation recorded its earliest harvest of wine grapes in 30 years, and production was down by over 10 percent. Olive production has been forced northward by the changes. Water levels in the Po River, which feeds irrigation channels in four Italian regions, have fallen 20–25 percent in the last 30 years. Researchers caution that average temperatures could increase by up to 9 degrees F (5 degrees C) by the end of the century.

FOUR DECADES OF INITIATIVES

Italy's initiatives to protect the environment now have a history of more than four decades. The Clean Air Law, the first legislation to deal specifically with air pollution, was passed in 1966. Ten years later, the Water Pollution Control Law was enacted. The Ministry of the Environment was established in 1896, and the Environmental Protection Agency was added in 1994. In addition to the Kyoto Protocol and the Convention to Combat Desertification (CCD), Italy is a signatory to more than 20 international environmental agreements, including Air Pollution, Air Pollution-Nitrogen Oxides, Air Pollution-Persistent Organic Pollutants, Air Pollution-Sulfur 85, Air Pollution-Sulfur 94, Air Pollution-Volatile Organic Compounds, Climate Change, Ozone Layer Protection, and Ship Pollution. However, enforcement of existing laws and commitments to international agreements has been inconsistent. A 2006 Yale University study ranked Italy 21st among 133 nations on its Environment Performance Index, but Italy's score of 79.8 placed it below average among both its income and geographical groups.

The country's wind power generation capacity has been growing. Wind power supplied 1 percent of the nation's total power demand in 2006 and should exceed the target capacity by 2012. Italy also developed Europe's first train with solar-power assistance providing energy for air-conditioning, lighting, and safety systems, thus making the train more fuel-efficient. Italy's higher energy prices provide a strong stimulus for businesses to invest in energy efficiency research and development.

Jamaica

LOCATED IN THE Caribbean, the Republic of Jamaica has a land area of 4,244 sq. mi. (10,990 sq. km.), with a population of 2,714,000 (2006 est.). It has a population density of 626 people per sq. mi. (241 people per sq. km.), making it the 49th most densely populated country in the world, with more than a third of the population living in Kingston, the country's capital. Fourteen percent of the land is arable, with a further 24 percent used for meadows and pasture. Although 27 percent of the country is still forested, the deforestation rate, 5 percent per year, is the highest of any country in the world. This is threatening wildlife diversity and contributing to ecological problems, not just in Jamaica, but also in the region, as there has been a rise in the carbon dioxide (CO_2) emissions per capita in Jamaica. Emissions were 3.4 metric tons per person in 1990, rising to 4.1 metric tons per person by 1997, and falling only slightly since then. Jamaica is 86th in the world in terms of its per capita CO_2 emissions.

Affected regularly by hurricanes in the Caribbean, the rising sea levels are less of a problem for Jamaica than many other Caribbean islands, but the rising temperature levels in the seas have already caused some problems with the bleaching of some coral reefs. There is also a threat to the entire coral reef system and its related marine life along the north coast of Jamaica. To highlight the problem, the Negril Coral Reef Preservation Society operates to encourage responsible diving, which has added to the problems caused by global warming. The threat is also to the green, hawksbill, and loggerhead turtles that nest on beaches in Jamaica, and also the West Indian manatees that can still be found on the south coast. The threat to marine life and land animals means that Jamaica is in the top 10 countries in the world in number of endangered amphibians and plant species.

To try to combat the factors that influence global warming and climate change, the Jamaican government maintains a comprehensive public transport system. Despite being in the tropics, some parts of Jamaica receive little rainfall. The town of Lucea in western Jamaica suffers from periodic droughts. The Jamaica Environment Trust (J.E.T.) has encouraged the replanting of trees, with help from the forestry department. The Jamaican government of Percival Patterson took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and two years later Jamaica was represented at the Global Conference on the Sustainable Development of Small Island Developing States held in Barbados. On June 28, 1999, the Jamaican government accepted the Kyoto Protocol to the UN Framework Convention on Climate Change; it took effect on February 16, 2005.

Japan

AN ISLAND NATION with the world's 10th largest population, Japan is one of the most powerful economic centers of the globe. Only the United States is more technologically advanced than Japan, and among single nations, only the United States can claim a larger economy, based on Gross Domestic Product. Unfortunately, Japan has also joined the ranks of world leaders in its contributions to global warming. In 2004, the country ranked fourth, behind the United States, China, and Russia, in its carbon dioxide (CO_2) emissions. Despite continued efforts to lower emissions through conservation, legislation, and technology, Japan continues to produce nearly 5 percent of the world's CO_2.

Japan began passing laws to control harmful industrial emissions as early as 1968, when the Basic Law for Environmental Pollution Control was passed in response to factory-produced air and water pollution. As awareness of environmental hazards increased, the law was revised with more stringent requirements. The Ministry of the Environment was established in 1971 and is given the responsibility for monitoring compliance with environmental laws and coordinating policies. In 1993, the Basic Environmental Law was passed to manage environmental problems on a global scale. The Ministry of Health, Labor, and Welfare and the Ministry of Agriculture, Forestry, and Fisheries are also involved in enforcing environmental policies.

KYOTO PROTOCOL

Japan is a signatory to the Kyoto Protocol and is obligated by the agreement to reduce its emissions by 6 percent of the 1990 level, but reports indicate that the country is far from the target. Even as CO_2 emissions from small-to-medium-sized industries have decreased, emissions from electricity consumption have increased 45.8 percent over the base year. During recent years, the share of passenger cars as a proportion of total passenger transport has increased, and even though Japan has established vehicle emissions standards for nitrogen oxides, carbon monoxide, and hydrocarbons, greenhouse gas emissions from automobiles for personal use have increased. In the case of CO_2, the increase has been 52.6 percent since 1990. To meet the Kyoto target would require a 14 percent reduction based on 2005 figures, and 2006 emissions were even higher. Complicating the picture is the Kashiwazaki-Kariwa Nuclear Power Plant, site of the world's largest nuclear output, where operations were suspended after an earthquake shook the facility in July 2007. Experts estimate that this suspension alone may raise Japan's CO_2 emissions by as much as 2 percent.

Pressure for more action is increasing as the immediate effects of global warming are felt throughout the nation. The production of rice, Japan's most important crop domestically, is expected to increase in some regions of the country as temperatures warm. Researchers predict that the rise in temperatures will decrease wheat production throughout the country. Concerns about heavier weed growth, harmful insects, and changes in rainfall patterns that create drought in some areas and cause flash floods in others generate fear as well.

A harbor on the island of Kyushu beneath the Sakurajima volcano in Japan. Host to the conference that led to the Kyoto Protocol, Japan has signed and ratified more than a dozen other international environmental agreements.

Japan has actively responded to these challenges. It has become a world leader by developing and implementing pollution control technologies and energy efficiency innovations. The Revised Energy Savings Law, adopted in 1999, encourages both central and local government to implement environmentally friendly technologies such as solar energy, wind power, and multi-fuel vehicles. Japan, host to the conference that led to the Kyoto Protocol, has signed and ratified more than a dozen other international environmental agreements, including Biodiversity, Desertification, Endangered Species, Environmental Modification, Hazardous Wastes, Ozone Layer Protection, Ship Pollution, Tropical Timber 83, and Tropical Timber 94.

Japan's investment in solving environmental problems on a global level has also included substantial contributions to the Global Environment Facility (GEF), a principal international multilateral funding mechanism set up in 1991 to aid developing countries in developing programs and projects that protect the global environment and promote sustainability. Japan contributed $84 million 1991–93, followed by an additional $415 million 1994–98, and $412 million 1998–2002. In 2007, concerned that Asia's energy consumption had grown by 230 percent since 1977, and alarmed by predictions that it would double again by 2030, Japan pledged $100 million in grants to the Asian Development Bank. The money is intended to promote renewable energy resources in a region that now accounts for a quarter of the world's greenhouse gas emissions.

Ignoring prognosticators, Japan insists that the nation will meet its Kyoto target. Not only did Japan focus on the improvement of its national and private forests at home through afforestation and forest conservation, but also its training and technology was made available to developing countries in Asia and South America. Domestic afforestation is expected to account for 3.9 percent of the 6 percent total deduction. With carbon credits earned through promoting projects in developing countries and carbon credits earned through resultant savings accounting for 1.6 percent, only .5 percent from standard emissions reduction will be required to meet the target.

POST-KYOTO

Looking beyond Kyoto, Japan has been bold in its long-term planning. In 2006, the nation identified five environmental objectives: improve energy efficiency by at least 30 percent, reduce oil dependence to 40 percent or lower, reduce oil dependence in the transport sector to 80 percent, target the share of nuclear power in electricity generation to 30–40 percent, and increase the share of crude oil owned by Japanese companies to 40 percent. In May 2007, former Japanese Prime Minister Shinzo Abe proposed a new initiative for cutting the world's greenhouse gas emissions by 50 percent of current levels by 2050. Abe praised the Kyoto Protocol for identifying the initial steps toward global solutions, but he insisted that the time had come for a new strategy that used innovative technologies, responsible use of resources, and the collaborative efforts of developed and developing countries to protect the Earth and the common interests of all nations. He challenged nations that have not ratified the Kyoto Protocol, including the United States, China, and India, to commit themselves to newly defined goals.

Abe also reiterated Japan's commitment to meeting his country's original Kyoto target by the year specified in the agreement. Some critics have speculated that Japan's objectives will require a green tax, a move frequently considered in the past, but delayed by opposition from the steel and electric power industries, whose greenhouse gas emissions are among the largest in the nation. The decline of gas consumption after price spikes and the decrease in consumption of plastic shopping bags after fees were levied on usage of the bags suggest that a green tax could be an effective measure on a larger scale.

Jet Streams

THE JET STREAMS are fast-flowing eastward currents of air in the mid-latitudes of both hemispheres, with their cores at altitudes above 30,000 ft. (9,144 m.). Although they flow eastward, they are driven by the temperature contrast between the equator and the poles. Near the equator where surface temperatures are at a maximum, the air rises and, in the upper atmosphere, flows poleward. As the air moves away from the equator, the eastward winds increase in speed relative to the Earth's surface, becoming the jet streams in mid-latitudes. (This is a consequence of the conservation of angular momentum.)

The jet streams are most intense during the winter season when the temperature difference between the equator and pole is at a maximum. When too intense, they become unstable, start to meander, and create weather phenomena. The meanders, which are associated with the southward flow of cold air and the northward flow of warm air, in due course become turbulent, creating a variety of weather phenomena including cyclones, anti-cyclones, warm fronts and cold fronts. This variability is strongest in winter, when the jets are most intense, and is weakest in summer when weather tends to be associated with local, convective phenomena such as thunderstorms.

Regarding global warming, if it warms primarily high northern latitudes, it will weaken the northern Jet Stream so that summer (rather than winter) weather will become more common.

Johns Hopkins University

THE JOHNS HOPKINS University, founded in 1876, is a private institution of higher learning located in Baltimore, Maryland. Johns Hopkins offers its undergraduate and graduate programs at the main campus in Baltimore and maintains full-time campuses in greater Maryland; Washington, D.C.; Italy; and China. Johns Hopkins was the first university in the United States to emphasize research applying the German model developed by Alexander von Humboldt and Friedrich Schleiermacher. More than 4400 undergraduate students attend Johns Hopkins annually with majors offered in 10 divisions from Arts and Sciences to Applied Physics.

The Department of Geography and Environmental Engineering, a division of the Whiting school of Engineering, offers graduate and undergraduate programs focusing on topics from pollutants in our air and soil, global warming, the effects of suburban sprawl on water quality and wildlife, and political and legal aspects of environmental policy. The Department of Geography and Environmental Engineering is consistently ranked among the top U.S. universities. The Johns Hopkins University Bloomberg School of Public Health also offers programs in Environmental Health. Several degree programs, bachelors, masters, and Ph.D. programs are offered.

CLIMATE CHANGE POLICY

President William R. Brody recently announced the adoption of a climate change policy that will make Johns Hopkins a driving force in the development of solutions to the ingoing many climate crisis. The university will set an example through the reduction of greenhouse gas emissions derived from university operations, with the vision of carbon neutrality. The university will also offer leadership and assistance on actions to reduce the carbon footprint of the Baltimore-Washington region. The policy will also call on to JHU to focus its strengths in science, technology, public health and public policy to find new solutions to climate change on a global level.

The President's Task Force on Climate Change will be charged with developing a comprehensive climate strategic plan and creating an interdisciplinary working group of experts who will focus on innovative and novel approaches related to climate change. In addition, the task force will begin to partner with state and local governments within the greater Baltimore-Washington region on climate change efforts, such as more-energy-efficient facilities, alternative fuel use, addition of climate-related courses to the curriculum, collaborative efforts with the community and other schools, and other proposals.

The Climate Change and Human Health Integrated Assessment website provides information on research conducted between 1998 and 2000 about the potential impacts of climate change through integrated assessment. This website aims to appropriately characterize and communicate the scientific research to support policy development and analysis. The site is a program of the Johns Hopkins University and the Johns Hopkins Program of the Health Effects of Global Environmental Change. Courses offered at Johns Hopkins University focused on climate change and global warming include:

RESEARCH ISSUES AND METHODS

The Research Issues and Methods course explores the trends and prospects of climate change and other global environmental changes (GEC). It focuses on three categories of "primary" research, using climate change as the foundation: improved empirical understanding of climate-health relationships; issues in detecting and attributing health impacts; and scenario-based modeling of future health risks.

This course explores how global environmental issues such as global warming, urban sprawl, deforestation, mining, environmental refugees, biodiversity loss, and food security may cause increasing human harm. It provides an overview of the science and policy issues related to the changing environment, how environmental problems affect human health, and emphasizes potential solutions and sustainable development methods essential for resolving a myriad of environment-health problems.

The Program on Health Effects of Global Environmental Change is dedicated to the scientific discovery and application of new knowledge pertaining to the human health risks posed by global environmental degradation. Students in the MPH, MHS, and DrPH programs are encouraged to participate in the activities of the program.

Joint Institute for the Study of the Atmosphere and Ocean (JISAO)

THE JOINT INSTITUTE for the Study of the Atmosphere and Ocean (JISAO) was founded in 1977, for the purpose of fostering research collaboration between the National Oceanographic and Atmospheric Administration (NOAA) and the University of Washington. The administrative units most directly connected with JISAO are NOAA's Pacific Marine Environmental Laboratory (PMEL) and the University's Department of Atmospheric Science and College of Ocean and Fisheries Science (COFS).

JISAO is governed by 36 Senior Fellows, almost evenly divided between University faculty and NOAA/PMEL staff, who hold affiliate faculty appointments in the University. JISAO provides funding and administrative support for postdoctoral fellows and senior visitors on leave from their academic institutions.

FOUR CORE RESEARCH AREAS

The Institute has four core research areas: climate, global environmental chemistry, marine ecosystems and coastal oceanography. The study of global warming represents a big part of the Institute's activities. Within JISAO is the Center for Science in the Earth System (CSES). CSES carries out integrated research on the impacts of climate on the U.S. Pacific Northwest by taking into account climate dynamics, ecological dynamics, hydrologic dynamics, and institutional and policy analysis. The CSES is divided into three groups: the Climate Impacts Group, the Climate Dynamics Group, and the Office of the Washington State Climatologist.

The Climate Impacts Group (CIG) is an interdisciplinary team researching the impacts of natural climate variability and global climate change phenomena, such as global warming on the Pacific Northwest. The CIG conducts research to understand the consequences of climate fluctuations for the Pacific Northwest, and works with local planners and policy makers to make this information relevant for regional decision-making processes. The research of the group centers on four key sectors of the Pacific Northwest environment: water resources, aquatic ecosystems, forests, and coasts. In addition to scientific research, the group also works to make such research available to policymakers and the general public. Thus, the CIG aims to establish a productive dialogue between decision-makers and the research community, to encourage planning for climate impacts. The CIG also aims to improve the skills of other research teams in the United States and abroad to carry out regional integrated climate impacts assessment and outreach. The group tries to reach these ambitious aims by periodically hosting meetings and workshops to discuss the most recent developments in research and methodologies in climate impacts.

Examples of these workshops include annual climate and water forecast meetings (held near the beginning of the water year) and policy meetings on how to prepare for climate change. CIG researchers also give lectures and presentations at conferences, public meetings, and special events. The group also works closely with the local media to disseminate ideas on climate, climate science, and climate impact. The CIG has also got its own media. It launched a quarterly electronic newsletter and list-serve in January 2005 to supply regular updates on Pacific Northwest (PNW) climate, climate research, meetings, and other information related to planning for climate variability and change in the PNW. As CIG and JISAO are part of the University of Washington, researchers of CIG develop and teach courses at the graduate level at the

University concerning Pacific Northwest climate, climate impacts, and the use of climate information and the role of uncertainty in decision-making. The team holds weekly seminars during the academic year for faculty, staff, students at Washington University which are also open to the public.

The Climate Dynamics Research Group (CDG) studies the physical dynamics of climate variability and climate change over the Pacific, especially as it affects the United States and the Pacific Northwest area. The group focuses, in particular, on the dynamics of the El Niño/Southern Oscillation and the Pacific Decadal Oscillation and their atmospheric effects both in the region and in distant areas. The areas of expertise of CDG members include atmosphere, ocean, and coupled modeling; the diagnostics of the atmosphere and ocean; and the analytic description of the climate system. CDG members are involved in the formulation of national and international climate programs.

The office of the Washington State Climatologist collects and disseminates weather data for the state, thus providing an authoritative source for local policy-makers and agencies working on different aspects of climate change. These data are also available to the public.

Jordan

LOCATED IN THE Middle East, the Kingdom of Jordan has a land area of 45,495 sq. mi. (89,342 sq. km.), a population of 5,924,000 (2006 est.), and a population density of 166 people per sq. mi. (64 people per sq. km.). Only 4 percent of the land is agricultural, with a further 9 percent used as meadow or pasture, mainly for the grazing of sheep and goats. There is also a small forestry sector in Jordan. For electricity production, 99.4 percent comes from fossil fuels, with only 0.6 percent from hydropower.

The high level of fossil fuel for electricity has contributed to a relatively high level of carbon dioxide emissions, making up 36 percent of total carbon dioxide emissions. These have been relatively stable, at 3.1 metric tons per person in 1990, rising slowly to 3.2 metric tons in 2003.

Other energy industries contribute to another 5 percent of emissions, with manufacturing and construction making up 14 percent, and residential use another 12 percent. Automobiles are heavily used in Jordan, which does not have an effective system of public transport outside of Amman and Irbid (where the suburbs are well-serviced), 23 percent of the country's carbon dioxide emissions come from transportation. Liquid fuels make up 91 percent of emissions by source, and of the remainder, 4 percent come from gaseous fuels, and 5 percent from the manufacture of cement.

The Jordanian government ratified the Vienna Convention in 1989, and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, which they ratified in 1993. It accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on January 17, 2003, which went into effect on February 16, 2005.

Geelong Grammar School, Australia

Jurassic Era

THE JURASSIC PERIOD extended from about 199 million years ago to 145 million years ago. This geological time period constitutes the middle of the Mesozoic era, also known as the Age of Dinosaurs. The start of the period is marked by the major Triassic-Jurassic extinction event. This period was named by Alexandre Brogniart for the extensive marine limestone exposures of the Jura Mountains, in the region where Germany, France and Switzerland meet.

During the early Jurassic, the supercontinent Pangaea broke up into the northern supercontinent Laurasia and the southern supercontinent Gondwana. The Gulf of Mexico opened in the new rift between North America and what is now Mexico's Yucatan Peninsula. The Jurassic North Atlantic Ocean was relatively narrow, while the South Atlantic did not open until the following Cretaceous Period, when Gondwana itself rifted apart. The Tethys Sea closed, and the Neotethys basin appeared. Climates were warm, with no evidence of glaciation. As in the Triassic, there was apparently no land near either pole, and no extensive ice caps existed.

The Jurassic geological record in western Europe is clear, where extensive marine sequences indicate a time when much of the continent was submerged under shallow tropical seas. In contrast, the North American Jurassic record is the poorest of the Mesozoic, with few outcrops at the surface. Though the epicontinental Sundance Sea left marine deposits in parts of the northern plains of the United States and Canada during the late Jurassic, most exposed sediments from this period are continental, such as the alluvial deposits of the Morrison Formation. The first of several massive batholiths were emplaced in the northern Cordillera, beginning in the mid-Jurassic, marking the Nevadan orogeny. Important Jurassic exposures are also found in Australasia, India, Japan, Russia, South America, and the United Kingdom. During the Jurassic period the primary vertebrates living in the seas were fish and marine reptiles. The latter include ichthyosaurs, plesiosaurs, and marine crocodiles, of the families Teleosauridae and Metriorhynchidae. In the invertebrate world, several new groups appeared, including rudists and belemnites. The Jurassic period also had diverse encrusting and boring communities, and it saw a significant rise in the bioerosion of carbonate shells and hardgrounds. Especially common is the ichnogenus Gastrochaenolites. On land, large archosaurian reptiles remained dominant.

The Jurassic period was the golden age of the great sauropods, Camarasaurus, Diplodocus, Brachiosaurus, and many others that roamed the land late during this period. They were preyed upon by large theropods (Ceratosaurs, Megalosaurs, and Allosaurs). During the Late Jurassic, the first birds evolved from small coelurosaur dinosaurs. Ornithischian dinosaurs were less predominant than saurischian dinosaurs, although some, such as stegosaurs and small ornithopods, played important roles as small and medium-to-large herbivores.

In the air, pterosaurs were common, filling many ecological roles now taken by birds. The arid, continental conditions characteristic of the Triassic steadily eased during the Jurassic period, especially at higher latitudes; the warm, humid climate allowed lush jungles to cover much of the landscape. Conifers dominated the flora, as during the Triassic; they were the most diverse group and constituted the majority of large trees. Extant conifer families that flourished during the Jurassic included the Araucariaceae,

A marine fossil: the European Jurassic geological record indicates continental submersion in tropical seas.

Cephalotaxaceae, Pinaceae, Podocarpaceae, Taxaceae and Taxodiaceae. The extinct Mesozoic conifer family Cheirolepidiaceae, dominated low-latitude vegetation, as did the shrubby Bennettitales. Cycads were also common, as were Ginkgos and tree ferns in the forest. Smaller ferns were probably the dominant undergrowth. Caytoniaceous seed ferns were another group of important plants during this time and are thought to have been shrub to small-tree sized. Ginkgo-like plants were particularly common in the mid- to high northern latitudes. In the Southern Hemisphere, podocarps were especially successful, while Ginkgos and Czekanowskiales were rare.

There was no polar ice during the Jurassic period, so the sea levels were higher than they are now. The climate was warm. Early in the Jurassic, the continents were jammed together into a supercontinent known as Pangaea, making much of the inland area dry and desert-like. Toward the middle of the Jurassic period, when Pangaea began to break up, there were vast flooded areas, temperate and subtropical forests, and coral reefs. The extensive water moderated the strong seasonality so that by the end of the Jurassic there was less seasonality than we have now. Many giant sauropods lived during the late Jurassic period. Conifers dominated the landscape.

There was a minor mass extinction toward the end of the Jurassic period. During this extinction, most of the stegosaurid and enormous sauropod dinosaurs died out, as did many genera of ammonoids, marine reptiles, and bivalves.

Kansas

PREDOMINANTLY AN AGRICULTURAL state, one out of every five residents in Kansas is involved in farming or food production. Kansas leads the nation in the production of wheat and sunflowers. Like many of its midwestern neighbors, Kansas is experiencing a rural exodus, with large numbers of residents leaving farms to move to urban areas. This exodus has increased the pollution that concentrates in industrial regions. With a total population of almost 3 million people, the state has specific concerns about activities that lead to global warming and climate change. One of those concerns is the regional haze that blankets the large cities of Kansas. In response, Kansas has initiated a regional haze program designed to reduce toxic emissions.

Between 1990 and 2001, carbon dioxide (CO_2) emissions in Kansas rose by 4 percent, reaching a total of 71.9 million metric tons. Kansas currently ranks 26th in the United States in CO_2 emissions. Concern over the threat that CO_2 emissions pose to global warming and climate change has resulted in program initiatives that successfully increased CO_2 efficiency by 23 percent. However, the government is engaged in a balancing act, attempting to protect health and the environment while promoting economic growth. In 2007, Kansas joined some 30 other states in establishing the Climate Registry, which is designed to measure, track, and report greenhouse emissions in order to reduce national levels of pollution.

Environmentalists began putting pressure on the Kansas state government in 2006, when it was announced that the Sunflower Electric Power Corporation would build three new coal-fired power plants in western Kansas. The plan proceeded, despite the fact that eight states had filed lawsuits accusing such plants of accelerating global warming and climate change. Opponents of the project were also concerned about possible threats to the Wichita Mountain National Wildlife Refuge, located 260 mi. (673 km.) away in Oklahoma. The Environmental Protection Agency predicted that sulfur emissions released by the coal-fired power plants would surpass federal limitations and threaten health and the environment. Sunflower officials answered concerns about mercury emissions by insisting that they would be well below federal standards. Government officials were faced with the dilemma of balancing threats to health and the environment against the 2,000 jobs created by the construction project.

The Department of Health and Environment is the Kansas agency that exercises major responsibility for programs designed to reduce activities associated with global warming and climate change. The Environment

In 2006, the Kansas Department of Transportation won national recognition through the Kansas Prairie Ecosystem Restoration, Education, and Conservation Initiative, which strives to protect endangered tall, mixed, and short-grass prairies.

Division is specifically involved with oversight and implementation of laws and regulations that deal with air, radiation, public water resources, industrial discharges, solid waste landfills, hazardous waste, asbestos removal, and fuel storage tanks. This agency has the authority to levy fines and impose penalties to enforce compliance. Responsibilities include offering financial aid assistance programs designed to reduce global warming and climate change.

The Environment Division houses the Bureau of Environmental Field Services and the Bureau of Environmental Remediation. Other Kansas agencies involved in protecting the environment are the Department of Agriculture, which implements the Pesticide and Fertilizer Program, the Department of Wildlife and Parks, the Kansas Forest Service, and the State Conservation Commission.

In Kansas, programs that target global warming and climate change include efforts to promote public awareness. Kansas Don't Spoil It and Get Caught Recycling are statewide educational campaigns that encourage recycling of solid waste products. Aging wastewater and deficient public water supply systems pose particular environmental threats, and efforts are underway to rebuild or improve existing facilities. To this end, the state appropriated $94 million to 37 localities in 2006. The Kansas Department of Health and Environment has also been engaged in a massive effort to decontaminate 28 public water supply wells that serve approximately 150,000 residents. Through the Watershed Restoration and Protection Strategy, the state works with local governments and federal agencies to address problems with the state's watersheds. The Stream Probabilistic Monitoring Program generates physiochemical and biological data from randomly selected streams to estimate overall compliance with state environmental regulations.

Recognizing the importance of energy conservation in decreasing global warming and climate change, Kansas provides assistance to low-income residents to make their homes more energy-efficient through the Kansas Warm Homes project. Volunteers from churches and civic and community organizations distribute energy conservation kits that include plastic window coverings, weather stripping, rope caulking, switch plate insulators, a door sweep, and florescent light bulbs. Volunteers also assist those who are unable to install kits on their own. The Kansas Energy Office of the Kansas Corporation Commission and the Kansas Housing Resources Corporation of the Kansas Development Finance Authority provide funding for the project.

In 2006, the Kansas Department of Transportation won national recognition for its efforts to protect the state's environment through the Kansas Prairie Ecosystem Restoration, Education, and Conservation Initiative. The purpose of the program is to protect endangered tall, mixed, and short-grass prairies that play a major role in preserving the habitats of the state's wildlife.

Although Topeka is the state capital, Wichita is the largest city in the state, in both population and area. Pollution in Wichita comes chiefly from motor vehicles, trains, and industries. City officials established the Air Quality Section of Environment Services to monitor the air quality around the city, perform asbestos inspections at demolition sites, and investigate complaints about air quality and hazardous materials. Kansas City partners with the Mid-America Regional Council to deal with air quality, watershed management, solid waste management, and green infrastructures. Initiatives include raising public awareness, protecting natural habitats, and promoting sustainable growth. In summer 2007, the Kansas City region failed to meet federal regulations established by the Environmental Protection Agency. The city immediately proposed plans to establish new emission controls on power plants, industrial boilers, and idling long-haul trucks. A voluntary initiative was also launched to educate the public about environmental threats posed by driving, painting, and using gas-powered lawn and gardening equipment.

Kazakhstan

KAZAKHSTAN IS LOCATED in Central Asia at the center of the Eurasian continent. With 1.05 million sq. mi. (2.72 million sq. km.), the country is the ninth largest nation of the world, and the largest landlocked country of all. The population of Kazakhstan was 16.7 million in 1990, and the population density of 3.9 people per sq. mi. (6.3 people per sq. km.) is one of the sparsest in the world. 280,200 people live in the capital city of Astana. The city with the largest population is Almaty, with 1,185,900 inhabitants.

The climate is continental; precipitation varies from less than 5.9 in. (150 mm.) in the central desert areas to more than 59 in. (1,500 mm.) in mountainous regions. Average temperatures in January range from minus 0.4 degrees F (minus 18 degrees C) in the north to 27 degrees F (minus 3 degrees C) in the south. Spatially averaged seasonal and annual air temperatures increased about 2.3 degrees F (1.3 degrees C) 1984–97, manifested especially in spring. Four major landscapes are the forest-steppe, steppe, semi-desert, and desert. The river network has had only limited development. However, it is important for irrigation and power generation.

Temperature rises caused the recession of glaciers in the mountains and changed mass water balances from positive to negative, threatening water supply and with it the farming economy and peace of the region, since many rivers are transboundary. Even more dangerous, resulting glacial lakes dammed by unstable moraines drain in an uncontrolled way. One of the most powerful recent debris flows to affect the northern valleys of the Tian Shan occurred in July 1973 in the Malaya Almatinka Valley.

Kazakhstan has about 57,000 lakes and more than 4,000 artificial water reservoirs, some of them drying out, like the Balkash lake and the Aral Sea, with disastrous ecological impacts in the south of the country.

Oil and gas condensate production are the keystone of Kazakhstan economy and amounted to 51.2 million tons in 2003. Kazakhstan holds about 4 billion tons of proven recoverable oil reserves, many of them untapped, and 2,000 cu. km. of gas. Expansion is planned, to produce as much as 3 million barrels (477,000 cu. m.) per day by 2015, lifting Kazakhstan into the ranks of the world's top 10 oil-producing nations. This is why the country received high credits from international organizations. Accordingly sound is the economy, which first went under the typical dynamics of a transition country after the breakdown of the Soviet system. While its gross domestic product (GDP) in purchasing power parity (PPP) amounted to $4,089 per capita in 1990, in 1994 it slid 40 percent to $2,442.

Forests cover 3.75 percent of Kazakhstan's total territory and are not commercially used. The available agricultural land consists of 79,151 sq. mi. (205,000 sq. km.) of arable land and 235,908 sq. mi. (611,000 sq. km.) of land devoted to pastures and hay. Agriculture accounted for 13.6 percent of Kazakhstan's GDP in 2003. Kazakhstan is the sixth-largest grain producer in the world. Wheat, barley, cotton, rice, and livestock, especially sheep-breeding are the most important agricultural commodities. Agricultural land occupies more than 326,642 sq. mi. (846,000 sq. km.).

PROJECTIONS

All General Circulation Models (GCMs) predict an increase in climate aridity, suggesting temperature increases from 7–12 degrees F (4–7 degrees C) under doubling carbon dioxide (CO_2) rates 2050–75. Precipitation change is projected to between a 10 percent decrease to a 20 percent increase, and is expected to be redistributed. Decreased wheat yields and negative impacts on sheep-breeding productivity are expected due to grassland yield decrease and the direct impact of increases in duration of stable hot weather on sheep. Doubled CO_2 levels would reduce water resources by about 20–30 percent in Kazakhstan. In the mountain areas the snow line will rise by 0.3–0.4 mi. (500–700 m.); mudflow activity will increase, with a reduction of the sub-humid zone for grain crop cultivation of about 6–23 percent. UKMO predicts the complete disappearance of the sub-humid zone from Kazakhstan territory.

EMISSIONS

Kazakhstan ranks as the 30th largest greenhouse gas emitter in the world, with per capita emissions of 8.14471 CO_2 equivalents per 1,000 people. It has been demonstrated that the energy share in 2005 was 78 percent, in second place was agriculture (8.4 percent), and the third source of emissions was industrial processes (6.7 percent). The wastes share amounts to 6.9 percent. The percentage share of the contribution of three basic gases with direct greenhouse effects in 2005 was the following: CO_2, 77.4 percent; methane, 17.7 percent; and nitrous oxide, 4.9 percent.

Further sequestering of CO_2 is planned to be achieved by increasing forests to 4.6 percent of land area by 2010 and to 5.1 percent by 2020, which would increase sequestration of about 6,000 Gg. Reducing arable areas on less productive land with simultaneous intensification in others, could sequester up to 674 Gg. Kazakhstan has a huge potential for energy saving in the power sector, especially by energy saving, and increasing energy efficiency, and the share of this sector already substantially decreased.

Adaptation strategies are long-term, market-based and oriented to external development. International assistance is required. Kazakhstan signed the United Nations framework Convention on Climate Change in June 1992 and ratified it in May 1995. In 1997, the government of Kazakhstan supported the World Bank Carbon Initiative on establishment of international carbon credits market and adopted a law on Energy Saving. In March 1999, Kazakhstan signed the Kyoto Protocol as a non-Party to Annex 1 of the UNFCCC and a non-Party to the Kyoto Protocol.

Keeling, Charles David (1928–2005)

CHARLES DAVID KEELING was a pioneer of climate science and atmospheric monitoring. Through his work at the Scripps Institution of Oceanography, Keeling constructed the most extensive record of atmospheric levels of carbon dioxide (CO_2) ever produced. Keeling's careful charting of rising concentrations of CO_2 in the Earth's atmosphere served to confirm scientific theories about the impacts of industrialization on the global environment and provided the empirical cornerstone for subsequent analyses of climate change.

Born in Scranton, Pennsylvania on April 20, 1928, Charles David Keeling studied chemistry at the University of Illinois (graduating in 1948), before obtaining his Ph.D. (also in chemistry) from Northwestern University in 1954. His move into atmospheric studies was confirmed in 1956, when the Scripps Institution of Oceanography recruited him to work on a new research program exploring the complex links between CO_2, global warming, and ocean systems. Keeling's initial work at Scripps was guided by the oceanographer Roger Revelle, who at the time was the director of the Institution of Oceanography. As an early advocate of the theory of an enhanced greenhouse effect, Revelle's work proved that the heightened levels of CO_2 produced by industrial society would not be absorbed, to any significant extent, by the oceans. This observation brought in to question the conventional wisdom of the early post-war period that anthropogenic CO_2 would be absorbed by ocean systems, plant-life, and other carbon cycle sinks, thus maintaining the global atmospheric balance of CO_2. It was, however, the assiduous work of Charles David Keeling that would confirm this crucial scientific theory.

Following his arrival at Scripps, Keeling worked to establish the necessary monitoring sites and equipment that would facilitate the accurate measurement of global atmospheric ratios of CO_2. With the support of the Environmental Sciences Services Administration of the U.S. government, Keeling was able to collect research data from two remote, pristine air locations: the Mauna Loa Observatory, Hawaii, and a monitoring station established at the South Pole. The use of pristine air-monitoring locations was crucial to Keeling's work. The fact that the Mauna Loa and South Pole monitoring stations were located at great distances from major local anthropogenic and biotic sources of CO_2 meant that they could provide accurate measurements of global changes in atmospheric CO_2 concentrations (although the Hawaii station was subject to occasional spikes in CO_2 created by local volcanic activity and vegetation).

In addition to securing the sites necessary to monitor global fluctuations in atmospheric CO_2, Keeling was also involved in developing the techniques and instruments that were needed to actually measure CO_2 in the atmosphere. The method deployed by Keeling for measuring air-borne CO_2 involves passing air through an aluminum tube using a diaphragm pump, and then forcing the air through a filter, to remove water vapor, after which an infrared analyzer tests the air sample. The assiduous monitoring of atmospheric CO_2 at Mauna Loa and the South Pole by Charles David Keeling and his colleagues 1958–2005 provided fascinating hourly, daily, and seasonal records of CO_2 fluctuations. It was, however, only when the biannual concentrations of atmospheric CO_2 were plotted over a longer time that the dramatic implications of Keeling's work become apparent. The so-called Keeling Curve that emerges from such a time-sequenced data plot reveals the inexorable rise of CO_2 in the atmosphere from 1958 to the present day. In discussing the ominous simplicity of the Keeling Curve, Michael McCarthy recently described it as one of the key images in human history.

Beyond his contribution to assessments of the changing fractions of CO_2 present in the atmosphere, Charles David Keeling took a holistic interest in the operation of the carbon cycle and the broader problems associated with air pollution. In relation to the carbon cycle, Keeling was at the forefront of attempts to accurately model the flow of carbon and show its changing seasonal patterns. His interest in the carbon cycle also led him to conduct detailed studies of the processes that determine the rate of, and levels of CO_2 that can be absorbed in seawater, while also hypothesizing about the role of plants in the removal of excess CO_2 from the atmosphere. In an address to a symposium on atmospheric pollution in 1969, Keeling reflected on the likely implications of global warming for human populations, while also highlighting the ongoing dangers associated with traffic pollution and urban smog. His combined interest in CO_2, atmospheric geochemistry, and the carbon cycle are expressed throughout his numerous publications.

Charles David Keeling's role as a pioneer of science and an advocate of environmental care and protection resulted in him receiving a number of awards and honorary positions. During his career, Professor Keeling was Guggenheim Fellow at the Meteorological Institute, University of Stockholm and scientific director of the World Meteorological Organization's Central CO_2 Calibration Laboratory. In 2002, he received the U.S. National Medal of Science, and in April 2005, he was awarded the Tyler Prize for Environmental Achievement. Charles David Keeling died on June 20, 2005 in Hamilton, Montana.

Kentucky

THE COMMONWEALTH OF Kentucky is known chiefly for producing horses, tobacco, whiskey, and bluegrass music. The state's coalfields, wetlands, waters, and forests are valuable resources, but they present unique environmental concerns that affect global warming and climate change. Forests and agricultural lands are regularly converted for industrial use, destroying habitats that are essential in protecting the state's ecosystems. Fuel-fired power plants pose a major threat to health and the environment. Kentucky borders seven states: Tennessee, Virginia, West Virginia, Missouri, Illinois, Indiana, and Ohio. Because of this, Kentucky's environment has a significant impact on a large area beyond its own borders.

STEPS TO REDUCE GLOBAL WARMING

The key element in Kentucky's environmental initiatives is educating the public and businesses, teaching residents about the ways in which specific behaviors make Kentucky more vulnerable to global warming and climate change. In 1992, Kentucky began tracking and reporting on 100 indicators involved in protecting the environment. The reports have been instrumental in passing environmentally-friendly laws, forcing state agencies to set environmental policy priorities, and holding the government accountable when they fail to protect Kentucky's environment.

The chief responsibility for reducing activities that increase global warming and climate change in Kentucky is assigned to the Department for Environmental Protection (DEP), which houses the Division for Air Quality, the Division of Environmental Services, the Division of Waste Management, and the Division of Water. The Environmental Services Division supports the DEP in ensuring compliance with state and federal guidelines in underground storage tanks, groundwater, superfund sites, toxic emission control, rivers, lakes, and streams. Additional responsibilities for Kentucky's environment are divided among the Department of Agriculture, the Governor's Office of Agricultural Policy, the Office for Consumer and Environmental Protection, the Environmental Education Council, the Environmental and Public Protection Cabinet, the Environmental Quality Commission, the Department for Natural Resources, the Natural Resources and Environmental Protection Cabinet, and the State Nature Preserves Commission.

Kentucky is ranked 26th in the United States in terms of population. The capital of the commonwealth is Frankfurt, but population and industry are centered in the Louisville-Jefferson County and

Lexington-Fayette County areas. The population of Kentucky increased by 10 percent 1990–2001. During that same period, carbon dioxide (CO_2) emissions rose by 30 percent, reaching a total of 152.2 million metric tons. Kentucky is ranked 13th in the United States in CO_2 emissions. Initiatives targeting this problem have resulted in a 6 percent rise in carbon dioxide efficiency.

In 2007, in the largest settlement resulting from violations of the federal Clean Air Act's acid rain program, East Kentucky Power Cooperative was required to pay at least $11.4 million in penalties for emissions violations generated by coal-fired power plants. These emissions included more than 15,000 tons of sulfur dioxide and 4,000 tons of nitrogen oxide emitted 2000–05. East Kentucky was also ordered to reduce toxic emissions by 400 tons annually, and to offset 20,000 tons of emissions that had been generated at two Dale Generating Stations units that were operating without acid rain permits. The company was ordered to install control technology to reduce nitrogen oxide (NOx) emissions at both units.

Eight states and New York City have filed suit against corporations with documented records of contributing significant amounts of pollutants that lead to global warming and climate change. American Electric Power Company, Inc./American Electric Power Service Corporation, which controls Kentucky Power, is number one on that list because it generates an estimated 226 million tons of CO_2 emissions each year. The Tennessee Valley Authority and Cinergy, which own and operate Kentucky fuel-fired power plants that respectively produce an estimated 110 million tons and 70 million tons of CO_2 emissions annually, are third and fifth on the list of companies involved in the lawsuit.

Pollution in the agricultural sector is addressed through the Kentucky Environmental Quality Incentives Program, which offers financial help and technical assistance to farmers who engage in conservation practices. Under the direction of the Natural Resources Conservation Service of the U.S. Department of Agriculture, EQIP provides funding for reducing soil erosion, improving water quality, animal waste management, wildlife management, and targeting watersheds and regions of particular environmental sensitivity.

Conscious of the impact of transportation and industries on global warming and climate change, the Louisville Metro Government, the University of Louisville, and Jefferson County Public Schools have formed the Partnership for a Green City to coordinate environmental efforts. The organization is focused on changing behaviors that threaten the environment, encouraging environmentally friendly transitions, and promoting environmental sustainability within communities.

The Kentucky Environmental Council publishes *Land, Legacy, and Learning: A Master Plan for Environmental Education in Kentucky* to raise public awareness of the effects of global warming and climate change on Kentucky. Since the first edition was released in 1999, Kentucky has required all teacher preparation programs to include environmental education and has provided specialized training for advanced environmental training. Specific recommendations in the publication are aimed at pressuring the state to provide basic environmental information to all residents of Kentucky. Specific activities inspired by the publication include the launching of a five-year project in 2004 designed to promote improved water quality through individual behavior.

The Commonwealth of Kentucky encourages controlling pollutants that accelerate global warming and climate through the KY Excel Program, a voluntary leadership program. The goal of this program is to promote cooperation among individuals, state and local government, and the business community by recognizing significant efforts made toward environmental progress in Kentucky. Members are required to conduct at least one environment-related project each year in the fields of conservation, education, energy efficiency, financial support, mentoring and technical assistance, performance improvement, public health, restoration, and waste reduction. Specific projects have dealt with promoting plans to get motor vehicles off the road through carpooling, walking, and biking; encouraging the use of vehicles that use alternative fuels; taking showers instead of tub baths; cleaning up dump sites; and collecting and recycling wastes.

In an effort to reduce toxic emissions from fuel-fired power plants, Kentucky announced in 2006 that it had applied for a cutting-edge billion-dollar FutureGen Project to build the first coal-fueled power plant with near-zero emission capability. The plan calls for the plant to generate electricity by capturing and storing electricity in geological formations. Hydrogen and byproducts produced by the plant are to be used by other industries in the state. The FutureGen Alliance, which oversees the project, will use the plant as a global research facility on clean coal technology and advanced energy development.

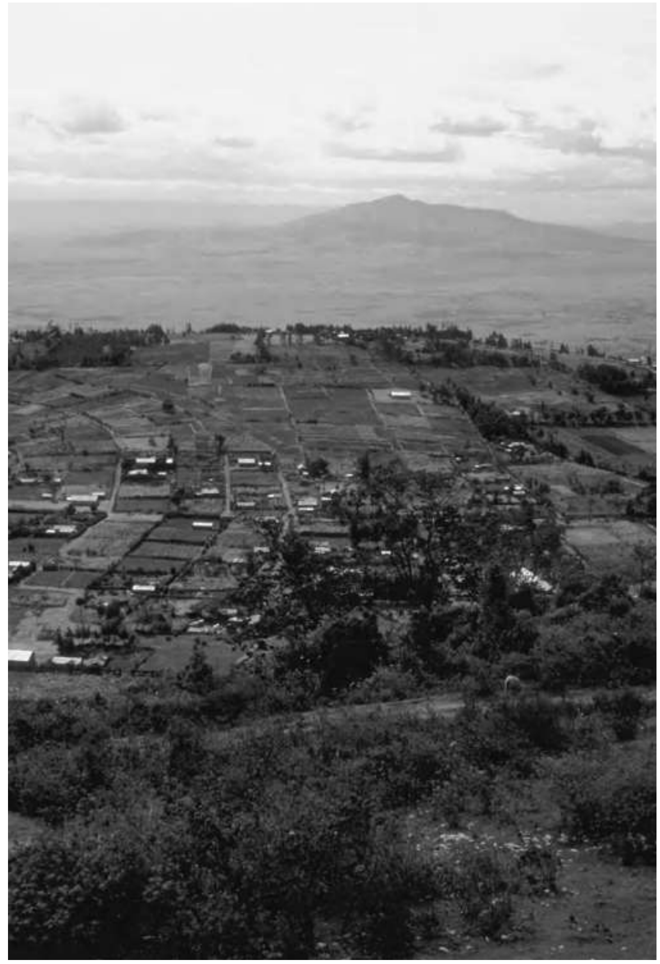
Kenya

THE REPUBLIC OF Kenya remains the center for east African trade and finance and is a world-renown destination for tourism. It is also beset by multiple, interrelated environmental concerns, including climate change, a rapidly growing human population, and a significant decline in flora and non-human fauna.

Straddling the Equator, Kenya is comprised of 225,000 sq. mi. (582,650 sq. km.) of diverse landscapes. These include wide, sandy beaches and coral reefs along the Indian Ocean coast in the southeast; the eastern African plateau and its semi-arid plains; the Rift Valley, with freshwater and saltwater lakes surrounded by fertile uplands; northern deserts flanked by Sudan, Ethiopia, and Somalia; southern grasslands that blend into neighboring Tanzania; and, in the west, a portion of Lake Victoria, as well as densely farmed highlands that run partly along the border with Uganda. Mt. Kenya's glacier-capped peaks top out at 17, 057 ft. (5,199 m.) above sea level, making it the second tallest mountain in Africa after Tanzania's Mt. Kilimanjaro.

Over the past century, both Mt. Kenya and Mt. Kilimanjaro have experienced marked recessions in the thickness of their glaciers, as well as the output of melt water absorbed by other landscapes and their inhabitants.



While nearly 75 percent of Kenya's labor force is engaged in agriculture, more than 80 percent of the land is arid or semi-arid.

According to the Intergovernmental Panel on Climate Change, sub-Saharan Africa is most vulnerable to projected changes due to global warming because widespread poverty and reliance on small-scale, rain-fed agriculture limit adaptation capabilities. Kenya has a population of 35 million, over half of whom live below the international poverty line. Although tourism and manufacturing contribute significantly to the Gross Domestic Product, the Kenyan economy relies heavily on export-oriented agriculture, with chief cash crop exports including water-intensive and climate-sensitive cut flowers, tea, and coffee. Nearly 75 percent of Kenya's labor force engages in agriculture and livestock production. More than 80 percent of Kenyan land is classified as arid or semi-arid, and 30 percent of its population and more than half of its livestock reside there. Only 5–8 percent of Kenya's land is considered suitable for horticulture. Other Kenyan exports include cement, petroleum products, and fish. The expanding industrial sector of Nairobi is home to a number of multinational corporations. Emissions standards are variably enforced.

Periods of drought and flooding have been typical across millennia in East Africa. Still, scientists note that human-induced climate change has led to erratic rainfall and land transformations that, since Kenya's independence in 1963, have been record-setting in terms of the severity of their impacts. Since 1963, Kenya's population has doubled twice, and the concomitant pressures on land, flora, and fauna are exacerbated by drought and flooding. Thus, climate change, along with population growth and a reduction in farmland and grazing land, is closely connected to armed conflicts. Efforts by 2004 Nobel Laureate Wangari Maathai and the Greenbelt Movement emphasize the link between environmental issues and peaceful governance.

From Kenya's agricultural base to national parks and reserves, there are likely to be substantial shifts in species diversity and community composition. The first sub-Saharan African country to do so, Kenya hosted the 2006 United Nations ministerial conference on climate change, comprised of the 12th Conference of the 189 Parties to the UN Framework Convention on Climate Change, and the 2nd Meeting of the 166 Parties to the Convention's Kyoto Protocol.

Kiribati

THE REPUBLIC OF Kiribati consists of 33 atolls in three island groups: the Gilbert, Phoenix, and Line groups, located between 1 degree north longitude and 173 degrees east latitude. The land area of 313 sq. mi. (810.5 sq. km.) is scattered over 1.4 million sq. mi. (3.5 million sq. km.) of Exclusive Economic Zone (EEZ), extending 2,485 mi. (4,000 km.) from west to east and about 1,243 mi. (2,000 km.) from north to south. The natural resource endowment is poor. Only Banaba is volcanic; the other 32 islands are low-lying coral atolls with soils of very poor quality and not useful for agricultural production. Soils are highly alkaline, calcareous, and shallow, with low water-holding capacity, little organic material, and few available nutrients. Drinking water is received from slightly brackish freshwater lenses, which collect rainwater and are part of the porous surface. With a growth rate 1995–2000 of 1.8 percent per year, an estimated 97,000 people lived in Kiribati in 2007.

Kiribati is facing increased urbanization, with densities of up to 2,581 people per sq. mi. (1,600 people per sq. km.) in Betio, Tarawa. Urbanization is problematic when considering a lack of infrastructure, especially regarding fresh water supply, sewage, and sewer options. Sea-level rise and the increased occurrence of high tidal waves has forced people to move away from lagoon and ocean-side coastal proximity, which is difficult on urban South Tarawa, where population pressures force people to live in closer proximity. As one of the consequences, people have built stone walls for protection. Coastal erosion has increased because of stone walls manipulating wave movements. This is similar to the effect of the construction of causeways. Sand extraction, which is needed for buildings and facilities, accelerates these effects.

With increased urbanization, families are also faced with changes in land tenure, which can cause cultural tension when considering that coastal erosion and sea level rise have led to different allocations, mainly land loss. The Kiribati government has repeatedly called on the international community to address the issue of climate change as, together with other low-atoll environments in the Pacific, Kiribati is threatened by sea-level rise. Kiribati, as well as Tuvalu, depends on international political empathy. There is fear that, in the future, the people of Kiribati could become environmental refugees. Existing migration schemes for Kiribati are small, with strongest links to Australia and New Zealand that allow only a limited number of people to temporarily migrate on a Pacific Access Category.

Korea, North

THE DEMOCRATIC PEOPLE'S Republic of Korea (DPRK) is located in the northern part of the Korean peninsula, which lies between 33 and 43 degrees N, and extends southward in to the northeastern Asian continent. North Korea is a transitional zone between the continental landmass of Asia and the island arc rimming the western Pacific Ocean. About 80 percent of North Korea is mountainous or hilly. Elevations are generally low, because the mountain ranges have been subject to long-term erosion, with relatively stable tectonic movement. A number of high altitude—2,625–3,281 ft. (800–1,000 m.)—plateaus are found in the northeastern and eastern part of North Korea. Mountain ranges drop abruptly toward the East Sea with little coastal plain. Some extensive lowlands are found mainly at the mouths of rivers flowing into the Yellow Sea.

Its peninsular configuration and mid-latitudinal location lead continental influence on the East-Asian monsoon climate of North Korea. North Korea's climate is regarded as a continental climate from a temperature standpoint, and a monsoon climate from a precipitation standpoint. The climate of North Korea is characterized by four distinct seasons. Summer is sultry because of the hot and humid airflow from the North Pacific high pressure, while winter is bitterly cold due to the influx of cold, dry northwesterly winds from Siberian high pressure. The average annual temperature is between 46–54 degrees F (8–12 degrees C), with great regional and seasonal variations in temperature. The lowest annual average temperature and the greatest annual temperature range are found in the northeastern interior mountainous regions. Annual average precipitation is 41.5 in. (1,054 mm.). A noticeable seasonal variation in precipitation is, however, found because of the monsoon climate. About 60 percent of annual precipitation is concentrated from June to August. Winter is dry; less than 10 percent of annual precipitation occurs in winter. Heavy snowfalls are common in the northern, mountainous regions.

Few studies have been done on climate change in North Korea, because access to weather data and other climatic information is limited. A gradual increase in mean temperature is, however, reported over the last century and this warming trend is significant. Recent global warming is responsible for a substantial increase in the frequency and intensity of natural disasters, such as severe droughts in spring and regional heavy rainfalls in summer since the late 1980s. Human mortality from the growing numbers of natural disasters is substantial. In July 2006, Typhoon Bilis brought 19.6 in. (500 mm.) of rainfall in one day. Subsequent widespread devastation caused by floods and landslides caused thousands of deaths, and damage to both the natural and human environments. In North Korea, recent climate change and the ensuing reduction in total agricultural production have induced widespread starvation and prevalent epidemic diseases. Climate change models predict that global warming will increase temperatures in North Korea by 3.6–7.2 degrees F (2–4 degrees C), and precipitation 20–30 percent by 2050. Seasonal concentration of precipitation will be even more intensified; there will be a greater increase in winter precipitation, and severe spring and early summer drought.

Korea, South

THE REPUBLIC OF Korea is located in the southern part of the Korean peninsula and associated islands that lie between 33 and 43 degrees N and extend southward into the northeastern Asian continent. Its peninsular configuration as an appendage of the Asian continent and mid-latitudinal location lead the continental influence on the East Asian monsoon climate of South Korea. South Korea has four distinct seasons. In summer, a hot, moist climate dominates South Korea, which is located in the western flank of the North Pacific high pressure system, while cold, dry northwesterly winds from the Siberian high pressure system take over the winter climate. In the transition periods of spring and fall, clear, pleasant weather occurs more frequently and the land-sea breeze becomes dominant with weakened monsoon wind.

The average annual temperature and the annual temperature range are 54 degrees F (12.3 degrees C) and 78.6 degrees F (25.9 degrees C), respectively. The lowest annual average temperature is found in the northeastern interior mountainous regions, while the highest occurs in Cheju Island, located in the South Sea. The temperature range is also much greater in the northeastern interior mountainous regions than in the south and along the coasts. These temperature patterns show influence of latitude, altitude, and the continent on temperature distribution. Summer is hot, with very little regional difference in temperature, while winter is very cold, but has great regional variation in temperature. The mean temperature of warmest month and coldest month is 76.8 degrees F (24.9 degrees C) and 30 degrees F (minus 1 degree C), respectively.

South Korea is a region of abundant precipitation, with an annual average precipitation of 51.5 in. (1,310 mm.). A noticeable seasonal variation in precipitation is, however, found because of the monsoon climate. In summer, heavy rainfalls are accompanied by a Changma front, a quasi-stationary front extending from Japan through Korea into southeastern China, and tropical cyclones are substantial and represent approximately 70 percent of annual precipitation. Heavy regional showers, often exceeding 12 in. (300 mm.) of rainfall in a day, or sometimes more than 32.5 in. (800 mm.), also characterize summer rainfall. As in much of Asia, winter in Korea is dry. Less than 10 percent of annual precipitation occurs in winter. Heavy snowfall is found on islands and in the eastern coastal regions. The spatial distribution of annual mean precipitation generally increases southward, but its spatial pattern is complicated because of complexity of topography.

Over the last century, a gradual increase (2.8 degrees F, or 1.6 degrees C, over 100 years) in mean temperature has continued, but a warming trend has become even more significant since the 1980s. The mean winter temperature has drastically increased, while no distinct increase in mean summer temperature is found. Both diurnal and annual temperature ranges, however, have been significantly reduced due to the noticeable increase in minimum temperatures. Since the late 20th century, considerable decrease in the frequency of frost days in spring and autumn has extended growing season length. The frequency and duration of heat waves and warm nights have notably increased. Although a gradual increase of annual precipitation is found, there is some controversy about the temporal trend of annual precipitation because of its considerable variation. Along with a gradual increase in annual precipitation, a significant decrease of annual rain days results in the increased rainfall intensity once rain occurs. The frequency of severe drought has also increased, especially in the southern part of South Korea.

Global warming is poised to substantially change both natural and human environments in northeast Asia. The environmental impacts of global climate change in South Korea include changes in average temperature, changes in precipitation and in the frequency and severity of storms, changes in the distribution of ecosystems, and changes in the socioeconomic environment. The frequency of weather disasters has decreased during the last 10 years, but their intensity and duration has significantly increased, as have human mortalities and economic damages. The South Korean climate is gradually turning from a warm temperate climate into a subtropical climate. Recent warming trends enable many broad-leaved evergreen tree species to grow near their northern range limit. Changes in the maritime environment are also noticeable. Due to the change in ocean circulation near the Korean peninsula, a large number of new warm water fish and other marine organisms have been identified, and their northern limit has extended northwards. Changing patterns of temperature and rainfall have caused a shift in the distribution of disease-carrying mosquitoes. The occurrence of epidemics, such as malaria and hantavirus pulmonary syndrome, has increased. In particular, malaria reappeared in the mid-1990s, after its disappearance for two decades.

Kuroshio Current

THE KUROSHIO CURRENT is the second largest ocean current in the world, and flows in the western Pacific from the east coast of Taiwan island, northwards to Japan, and then beyond Hokkaido past the Kuril Islands, where it merges with the North Pacific Current. In many ways, it is similar to the Gulf Stream in the Atlantic Ocean, which also carries warm tropical waters toward the polar region. The Japanese call it the Kuroshio Current, with some early English geographers translating this to the Black Stream, the name coming from the deep blue of the water; a few writers referring to it as the Japan Current. A branch of the Kuroshio Current, known as the Tsushima Current, passes through the Tsushima Straits between Japan and Korea, into the Sea of Japan.

The warm waters of the Kuroshio Current are largely responsible for the abundance of coral reefs off the east coast of Japan, bringing coral reef larvae from other coral reefs in the South China Sea and off the coast of the Philippines. As a result, the coral reefs off Japan are the northernmost coral reefs in the world; the waters off the coast of Japan are as warm as 68 degrees F (20 degrees C) off the Ryukyu Islands, and even reach 60 degrees F (16 degrees C) in winter off the southern coast of Honshu Island. It has been the center of the Japanese fishing industry since prehistoric times. Since the 1940s, there has been a significant decline in the fish in the Kuroshio Current; this can be attributed to over-fishing, or to global warming and climate change since the 1960s. In 1988, studies of the coral reefs showed heavy coral bleaching, which resulted in the deaths of many of the reefs. The pressure of population, with some waste dumped in the sea, has been a major contributory factor, as well as the rise in temperature of the Kuroshio Current.

This rise in temperature is the major actor in coral bleaching off the Osasawara Islands, which have 460 hectares of coral reefs, especially around Muko, Chichi, and Haha Islands. These losses cannot be simply attributed to overpopulation. The local fishing industry has been unable to sustain itself by fishing in Japan's territorial waters, leading to increasing numbers of Japanese fishing and whaling ships operating throughout the Pacific. Between 1993 and 1998, the fishing catch off Okinawa dropped by 21 percent. Off the Ryukyu Islands, although the number of fish has increased, the species diversity has dramatically fallen. The worst losses in coral reefs have occurred near Okinawa, where overpopulation has led to pollution. An aerial survey by the Environment Agency of Japan 1990–92 revealed that some 90.8 percent of the coral communities near Okinawa had less than 5 percent cover. In summer 1998, some 97 municipalities reported bleaching of coral reefs in their communities, especially of the Acropora species, which appears the worst affected.

Kuwait

KUWAIT LIES ON the Arabian Gulf; its geography is made up of mostly flat desert on the mainland, and nine islands off the coast, some marshy and uninhabited. The climate of Kuwait can be extreme, with temperatures ranging from very cold to very hot, although the average annual temperature is 91 degrees F (33 degrees C). The highest temperature ever recorded was 126 degrees F (52 degrees C) in July 1978. The long, dry summer extends May through October, with August the hottest month, having an average temperature of 112 degrees F (44 degrees C). The winters are mild, with January the coolest month, with an average temperature of 45 degrees F (7 degrees C). Rain storms may occur, and the wind may cause dust storms.

Despite the harshness of the environment, Kuwait supports more than 2 million people. With valuable oil fields estimated at 10 percent of world oil reserves, or 99 billion barrels, the major industries revolve around oil (including refining, marketing, and distribution). Kuwait's poor, dry soil means less than 1 percent can be used for farmland. Kuwait is one of at least 11 countries consuming more than 100 percent of their renewable water resources, though the water is reportedly free of water-borne pathogens. Limited fresh water means desalination plants are needed to supply fresh water. These plants require energy to heat the salt water to boiling and energy to provide cooling to condense the steam into fresh water droplets.

In March 2005, Kuwait ratified the Kyoto Protocol (an international and legally binding agreement to reduce greenhouse gas emissions worldwide, which took effect on February 16, 2005). It took effect in Kuwait's entry in June 2005. As a participant in the United Nations Framework Convention on Climate Change, Kuwait is responsible for providing national communication, including assessment of potential impacts of climate change. To meet this challenge, the Environment Public Authority (EPA), with an administrator appointed by the Council of Ministers, oversees environmental testing and education for voluntary programs. In addition, the EPA acts in a resource capacity. It advises federal and governmental policy makers on developing regulations and has authority to enforce the regulations provided within Kuwait's environmental laws through monitoring and compliance enforcement.

As an oil producer, Kuwait contributes to global emissions. Kuwait experienced the effects of human-induced climate change following the Gulf War; Iraqis set oil wells on fire while retreating. The fires burned an average of 5 million barrels of oil, and 70 million cubic meters of gas per day, producing emissions of carbon dioxide (500,000 tons per day) and sulfur dioxide (40,000 tons per day). In addition to emissions, the regional climate impact from smoke caused the surrounding areas to cool (between 10 and 20 degrees) and damage to the land allowed the wind to blow away eroded soil. Future impacts from climate change may include: changes in the coastline, a decline in the water supply that is already poor, and an increase in temperatures causing higher incidence of heat stress. It may also impair air quality, primarily through increases in ground-level ozone pollution in heavily populated urban areas.

Kyoto Mechanisms

UNDER THE KYOTO Protocol to the United Nations Framework Convention on Climate Change (UNFCCC), industrialized countries committed to reduce their greenhouse gas emissions by an average of minus 5.2 percent relative to their 1990 level emissions by 2008–12. To assist countries in attaining these reduction targets, the protocol created three flexible mechanisms. These mechanisms allow countries with reduction commitments to achieve their targets by acquiring credits from emissions reduced or avoided in other countries, where it may be more cost-effective to do so. The three mechanisms of the Kyoto Protocol are: Emissions Trading, Joint Implementation, and the Clean Development Mechanism. In this way, a country or a private or public entity within a country that reduces or avoids emissions more than it is required, may sell its emission reductions as credits to another country or entity that has not reduced its own emissions. Because greenhouse gases, in contrast to local pollutants, are uniformly distributed in the atmosphere within a week, it does not matter where the source of emissions is located. However, the cost of reducing or avoiding emissions may vary greatly.

Only countries with emission reduction targets under the protocol have "quantified emission limitation and reduction commitments," known as QELRCs, calculated and quantified as an "assigned amount." The total amount of emissions that each country with QELRCs can release 2008–12 (the first commitment period) must not exceed its assigned amount. Because emissions fluctuate from year to year, depending on the weather and economic cycles, an average over several years was chosen to check compliance with the reduction commitments. These are restrictions on a country's level of emissions, based on voluntarily adopted targets that collectively amount to a slightly more than 5 percent reduction relative to emissions in 1990. If a party exceeds its reduction target by cutting back on its emissions more than the amount specified in its QELRCs, it might sell its excess units or, under some circumstances, carry them over to the next commitment period. The QELRCs cover emissions of six greenhouse gases including: carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), Hydrofluorcarbons (HFCs), Perfluorocarbons (PCFs), and Sulfur hexafluoride (SF_6).]

A total of 39 countries have QELRCs, and they are listed in Annex B of the protocol with their respective targets. They are referred to as Annex I parties because they are also listed in Annex I of the UNFCCC, including: Australia, Austria, Belgium, Bulgaria, Canada, Croatia, Czech Republic, Denmark, Estonia, European Community, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Italy, Japan, Latvia, Liechtenstein, Lithuania, Luxembourg, Monaco, Netherlands, New Zealand, Norway, Poland, Portugal, Romania, Russian Federation, Slovakia, Slovenia, Spain, Sweden, Switzerland, Ukraine, United Kingdom, and United States. The European Community as a group is also a party, and the countries that compose it have internally redistributed their assigned amounts to collectively achieve their targets. The United States and Australia have not ratified the protocol, even though they agreed to specific reduction targets like the other Annex I parties did in 1997 when the protocol was adopted. Therefore, they are parties to the UNFCCC, but are not parties to the Kyoto Protocol and cannot participate in its mechanisms.

Because global warming is a result of accumulated emissions in the atmosphere, and non-industrialized countries have historically contributed little to the problem, developing countries do not have reduction commitments under the protocol. This is inscribed as one of the fundamental principles of the UNFCCC, which acknowledges that countries should act "in accordance with their common but differentiated responsibilities and respective capabilities and their social and economic conditions." It was therefore agreed that industrialized countries, which have greater responsibility and capability, should take the lead in reducing emissions.

ACCOUNTING UNDER FLEXIBLE MECHANISMS

The Kyoto Protocol does not bestow any "right, title or entitlement" to emit, and requires that domestic action constitute a "significant element" of Annex I parties' efforts to achieve their reduction targets, with the use of mechanisms only "supplemental to domestic action." To ensure that emission reductions bought and sold through the flexible mechanisms are measurable and real, the protocol establishes specific rules and accounting procedures for each of the flexible mechanisms. Emission reductions under any of the three flexible mechanisms generate a specific kind of unit that may be added to or subtracted from a party's assigned amount. Each unit is equal to one metric ton of emissions. All units are fungible, but have different names so they can be traced in the International Transaction Log, kept by the UNFCCC secretariat.

Under Emissions Trading, Annex I parties may trade assigned amount units (AAUs) issued on the basis of their assigned amount, or Removal Units (RMUs) issued on the basis of land use, land-use change, and forestry (LULUCF) activities (also known as carbon sinks), with other Annex I parties. They may also trade units acquired under the other flexible mechanisms. Because trading in emissions may be highly profitable, and given that enforcement of compliance under an international environmental regime could be weak, countries agreed to maintain in their inventories a certain level of credits, called the commitment period reserve. Emissions-trading is set out in Article 17 of the Kyoto Protocol.

Joint Implementation (JI) refers to credits acquired from projects that reduce or avoid emissions or enhance removals by sinks undertaken mainly in countries with economies in transition (EITs), namely central and eastern European countries that were part of the former Soviet Union. These countries are also Annex I countries, and have reduction commitments under the protocol. Credits traded under JI are recorded as Emission Reduction Units (ERUs). Because both parties involved in the transaction have reduction commitments and are therefore required to report on their overall level of emissions, the rules applied are less complicated than for Clean Development Mechanism (CDM) projects, where the host country has no reduction commitments. The basic principles of JI are defined in Article 6 of the Kyoto Protocol.

The CDM is similar to Joint Implementation in that both involve undertaking specific project activities. However, the CDM allows countries with reduction commitments to invest in a developing country in projects that reduce or avoid emissions, or enhance removals by sinks, and to use the resulting credits to meet its commitments. The CDM, therefore, is the only mechanism with a worldwide reach, and its purpose is twofold: to contribute to sustainable development in developing countries, and to make it easier for countries with reduction commitments to achieve their targets. The CDM is supposed to orient the future development of the less industrialized countries down a more sustainable path, and to prepare developing countries to contribute to mitigation without undertaking binding commitments.

The credits acquired under the CDM are called Certified Emissions Reductions (CERs). If resulting from afforestation and reforestation projects (the only two sink activities allowed), they are either temporary or long-term CERs (tCERs or lCERS). A levy of 2 percent of the number of CERs issued for every project is to go to an adaptation fund for vulnerable countries. Projects undertaken in the Least Developed Countries (LDCs), as well as small-scale projects, are exempt from this levy. Because the market offer is potentially unlimited, and developing countries have no reduction commitments, both seller and buyer have an incentive to inflate the emission reductions achieved. Therefore, to ensure transparency and accountability, the mechanism is subject to control by the CDM Executive Board, which, in turn, responds to the governing body of the Kyoto Protocol, the Conference of the Parties serving as the Meeting of the Parties (COP/MOP).

To participate in the mechanisms, Annex 1 parties must meet certain eligibility requirements. These include: ratifying the protocol; calculating their assigned amount; having a national system for estimating emissions and removals of greenhouse gases within their territory; putting in place a national registry to record and track the creation and movement of tradable units; and reporting annually on emissions and removals to the UNFCCC secretariat. The Facilitative Branch of the Compliance Committee oversees conformity with these requirements. Most of the rules and modalities that govern the mechanisms were established in a package of decisions known as the Marrakesh Accords, which resulted after many difficult political issues were agreed on in Marrakesh in 2001. They were adopted, along with the Kyoto Protocol, at the first session of the COP/MOP in Montreal in December 2005.

Kyoto Protocol

WHEN THE GOVERNMENTS adopted the Kyoto Protocol to the United Nations Framework Convention on Climate Change (UNFCC), it was quite obvious that its commitments would not be sufficient to seriously tackle climate change. At Conference of the Parties (COP) 1 (Berlin, March/April 1995), in a decision known as the Berlin Mandate, parties therefore launched a new round of talks to decide on stronger and more detailed commitments for industrialized countries. After two and a half years of intense negotiations, the Kyoto Protocol was adopted at COP 3 in Kyoto, Japan, on December 11, 1997. The Kyoto Protocol was open for signatures on that day and took effect on February 16, 2005. As of June 2007, 172 countries have ratified the protocol and the treaty expires in 2012. But some of the major countries such as the United States and Australia have not ratified the Kyoto Protocol. Big, developing countries such as India and China are part of the protocol, but are not required to cut back any emissions under this treaty (based on the rationale that developing countries should be given a chance for development). This has made the treaty controversial and, so far, the targets have not been fixed. This is based on the principle of common, but differentiated responsibilities, as most of the emissions to be reduced (or blamed for today's climate change) were produced historically (during the industrialization era when most the developing countries did not produce emissions) or originate in developed countries. Per capita emissions in developing nations are still relatively low compared to the developed nations, and the share of global emissions originating in developing countries will grow to meet their developmental and growth needs.

The United States argued that the developing countries should also be bound by limiting their emissions, but the Protocol did not impose any restrictions on them. Developing countries, on the other hand, felt that their development was hampered because the colonial powers prevented their development by exploiting their natural resources and selling their finished products to the developing countries hence preventing development of industry there. Now that they are free to carry on their development, no limits should be imposed on their emission levels, because of their heavy dependence on fossil fuel. Another point of difference between the developed and developing nation was whether to consider the absolute value of emissions or the per capita value—there is a great difference between the two sides, and hence, the controversy still persists.

HISTORICAL MILESTONE

The Kyoto Protocol is a historical milestone, as it is the first international agreement to set targets to reduce greenhouse gas emissions to tackle climate change. The Protocol sketches out the basic features of its mechanisms and compliance system, but did not flesh out the all-important rules of how they would operate. The 1997 Kyoto Protocol shares the UNFCCC's objectives, principles, and institutions, but significantly strengthens the UNFCCC by setting targets to limit green house gases. Under the protocol the signatory countries are divided into two categories: Annex I and Non-Annex parties. Annex I Parties are committed to individual, legally-binding targets to limit or reduce their greenhouse gas emissions. The targets cover emissions of the six main greenhouse gases, namely: Carbon dioxide (CO_2); Methane (CH_4); Nitrous oxide (N_2O); Hydrofluorocarbons (HFCs); Perfluorocarbons (PFCs); and Sulphur hexafluoride (SF_6). It was agreed that developed countries would jointly reduce their net emissions (emissions from sources minus removals by sinks) of these six greenhouse gases by 5.2 percent in the period 2008–12 in relation to emission levels in 1990. The Protocol does not list separate targets for each individual gas but instead a combined target for all the gases, expressed in CO_2 equivalence. On the other hand Non-Annex countries do not have obligations to reduce or limit the greenhouse gas emissions but can voluntarily do so.

The maximum amount of emissions (measured as the equivalent in CO_2) that a Party may emit over the commitment period, in order to comply with its emissions target, is known as a Party's assigned amount. To achieve their targets, Annex I Parties must put in place domestic policies and measures. The Protocol provides an indicative list of policies and measures that might help mitigate climate change and promote sustainable development. Parties may offset their emissions by increasing the amount of greenhouse gases removed from the atmosphere by carbon sinks in the land use, land-use change and forestry (LULUCF) sector. However, only certain activities in this sector are eligible. These are afforestation, reforestation and deforestation (defined as eligible by the Kyoto Protocol) and forest management, cropland management, grazing-land management and revegetation. The main objective behind these reductions (as pointed out in UNFCC) is to stabilize the concentration of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate change.

THE THREE MECHANISMS

The Protocol also establishes three innovative mechanisms known as Joint Implementation, the Clean Development Mechanism and Emissions Trading.

The Kyoto Protocol marks the first time an international agreement has set targets to reduce greenhouse gas emissions.

These are designed to help Annex I Parties cut the cost of meeting their emissions targets by taking advantage of lower cost opportunities to reduce emissions, or increase greenhouse gas removals in other countries than at home. Under the Joint Implementation mechanism, developed countries can make investments in Eastern and Central European countries in return for emission reduction credits (when there are emission reductions in the host countries, the investing country receives credits). Thus, if a country is not able to cut down emissions in its own country it can invest in some Eastern and Central European country on project(s) that deal with greenhouse gas emissions and get credit for the same. Emission trading allows the emission targets to be tradable. This is more like a "cap and trade" system where a cap is set on the maximum emissions allowed and then the country that emits more can buy the credits from the country that emits less than the cap. In other words, if a country emits less than its assigned amount it can sell the remainder to another country that has exceeded its allowed or assigned amount of greenhouse gas emissions. The Clean Development Mechanism allows countries and companies from developed countries to invest in sustainable development (or cleaner technologies/development) projects in the developing world, in return for emissions credits. In addition to these three original mechanisms, another mechanism called Activities Implemented Jointly was launched in 1995, as a precursor to Joint Implementation and Clean Development Mechanism and allows countries to participate voluntarily in schemes during a pilot phase, in which no crediting is allowed.

All the parties who have ratified the Protocol have to develop national systems for calculating emissions and cost-effective programs to improve the quality of the national inventories, and to cooperate in technology, science, and the development of education and training programs (for cleaner technologies). Developed countries in Annex II (the countries that have committed financial contributions for meeting Kyoto Protocol commitments) are expected to provide additional funds to meet the agreed fixed incremental costs for developing countries to meet their specific obligations.

Under sustainable development, free utilization of Kyoto mechanisms is essential. Still, Kyoto Protocol Article 17 stipulates that international emissions trading must be "supplemental" to "domestic actions" to meet the quantified commitment of each country. Introducing the Kyoto mechanisms and not yet allowing their utilization unless supplementary, is itself a contradiction. This was the focus of post-COP3 negotiations where European Union (EU) was advocating "supplementary" and introduced the concept of "bubble." This essentially meant that EU's assigned amount is reallocated among its member countries, hence EU would have a lower reduction cost than would be the case if a definitive amount were assigned to each country individually. Depending on how many Eastern and Central European countries join the EU the cost drops quite significantly. According to some literature the cost margin can be quite large, for example even when EU is to implement emission reductions twice its total target of 8 percent reductions, EU has a marginal reduction cost of 20 €/CO_2 ton (about $70 per C ton, this is in

2004) as compared to Japan's $300–400 per C ton and the United States' 100–200 per Carbon ton. At the same time, EU also raised the question of liability in emissions permits, for the purpose of preventing noncompliance caused by overselling emissions permits to other countries. This would translate into the fact that a certain volume of assigned amount must not be sold to other countries, and the remaining part of the assigned amount must be reserved, hence restricting emission permit exports. This would present no harm to the EU but have an impact on countries such as Japan.

THREE CONCERNS ON DIRECTION

The Kyoto Protocol has also become a debate between North and South. According to some scholars (mainly from the South) there are a few concerns related to the direction global climate regime is taking, which can be categorized into three sections:

- Although the principle of equity was central to the discussions of global climate change and even till the adoption of UNFCC, it has not been part of most the discussions since, and particularly since the Kyoto agreement.
- The focus of the regime is heavily on minimizing the burden of implementation of Kyoto reductions on polluting countries (industries) rather than being on the vulnerabilities of the communities and countries at greater risk and disadvantage due to climate change.
- Somehow the limelight is now on the global carbon trade and how to manage it, rather than on reduction of greenhouse gases (the main objective of Kyoto Protocol).

It is interesting to note that although the United States was a leader in drafting the Montreal Protocol and to implement it, such is not the case with the Kyoto Protocol. The reason for this may be that for the key countries, including the United States, the payoff structure is fundamentally different for the two agreements. For most of the key countries, unilateral compliance with the Montreal Protocol requirements was justified and boosted industry, in the sense that better technology needed to be developed to deal with changing things such as refrigerators, and American industry took the lead. On the other hand, the Kyoto Protocol might mean some cut-backs in emissions with an inverse impact on industries (but can boost industry if innovative greener technology is utilized). The Stern Review (a United Kingdom government-sponsored report on the economic impacts of climate change) concluded that one percent of global gross domestic product (GDP) is required to be invested to mitigate the effects of climate change, and that failure to do so could risk a recession worth up to 20 percent of the global GDP. Although some companies in the United States have begun working towards reducing greenhouse gas emissions, as a nation, the United States is still not part of the Kyoto Protocol. It is reasonable to predict that, when it comes to climate change, the United States will only move to ratify an international agreement reducing greenhouse gases if the perceived domestic costs of reduction decrease, or the benefits increase, or both. Without the United States participating, the success of any agreement will most likely be limited, because such a large amount of the world's greenhouse gas emissions are coming from the United States.

Kyrgyzstan

KYRGYZSTAN IS LOCATED in Central Asia, west of China, with which it shares its dominant geological feature: the Tien Shan mountain range. The former Soviet state has a varied climate, ranging from subtropical to polar, but most of the country is arid, high mountain terrain. Over 45 percent of Kyrgystan sits at elevations that make it uninhabitable to humans. Of the remaining 54 percent, only 19 percent of the land is considered comfortable for human habitation. Government researchers have found that, over the past 100 years, average temperatures in Kyrgyzstan rose by 2.8 degrees F (1.6 degrees C) (much higher than the global average of 1 degree F, or 0.6 degrees C). Precipitation rose only 6 percent during the same period. Scientists project temperature rises of between 3–8 degrees F (1.8–4.4 degrees C) by 2100, and projected precipitation increases of 6–54 percent, depending on the modeling program used.

In 2002, researchers announced that Issyk-Kul, the world's ninth-largest lake and second-largest saline lake, was showing a marked rise in water levels and temperature. This was shocking to many experts, who had seen the lake shrinking 1926–98, and expected that trend to continue. However, in 1998–2002, the lake level rose 10 in. (26 cm.).

This was deemed an extraordinary rise for a body of water that covers 2,317 sq. mi. (6,000 sq. km.). Temperature readings from across the lake showed increases of 6.6–7.5 degrees F (3.7–4.2 degrees C). Further study has shown that most of the rising water level is attributable to increased mountain precipitation and increased snowfall in the high mountains. The country's glacier fields are shrinking, but glacial melt is not believed to have played a significant role in Issyk-Kul's rise.

The government expects that, in the north and northeastern parts of the country, the desert belt will move up about 1,312 ft. (400 m.), the steppe belt about 820 ft. (250 m.), forest meadows 492 ft. (150 m.), and the subalpine belt 328 ft. (100 m.); other parts of the country will see less dramatic shifts of about 656 ft. (200 m.) for deserts and steppes, and 492 ft. (150 m.) for forest-meadows.

Kyrgyzstan's government is not concerned about energy use in the country, and is only moderately concerned about water availability. It believes most native flora and fauna will adapt to shifting climate zones, and forests will benefit from a greater range. It is slightly more concerned about the impact on human health, particularly an increase in vector-borne disease like malaria and dengue fever, which might flourish under warmer average temperatures. It believes this can be countered by improved standards of living and health care investments.

As a developing nation, Kyrgyzstan is not obligated to cut emissions under the Kyoto Protocol, but has stated a commitment to implement plans to reduce carbon emissions by encouraging sustainable agricultural practices, building energy-efficient housing, implementing environmental controls in industry, and investing in renewable energy sources.

Land Component of Models

CLIMATE MODELS simulate the interactions between the atmosphere, and the ocean and land surface beneath it. The land properties that matter most to the atmosphere include land elevation; the the presence of mountains, for example, can strongly affect the flow of air, causing it to rise and fall, thus creating zones of high and low rainfall.

The albedo of the land, which determines how much of the incident sunlight is reflected, depends critically on the nature of the ground cover, whether it is snow, ice, sand, or vegetation. The moisture content of the soil has a strong effect on the hydrological cycle, for example, the amount of evaporation into the atmosphere, and the amount of run-off into rivers and lakes. The roughness of the land surface affects the flow of air, which can become very turbulent near the surface.

Since climate models have reached a new generation of sophistication, the type and scope of variables employed in models have also changed. Perhaps the most startling change in model specifications has been the replacement of single variables to represent the three principal components of land, ice, and atmosphere, with numerous variables to account for these parts.

In terms of the land component, the single variable used in early models, which did not distinguish between land and sea, has been replaced by a suite of variables that model not just land and sea, but as many as three layers of land, including overlays of snow or ice, and a vegetation layer. The elevation of the land has also been incorporated into models, together with its impact on the albedo of the land—that is, the degree to which solar energy is reflected back away from the surface. Recent work has focused on the interaction between component parts. For example, the pressure and temperature of the land and the air or sea adjoining it will have significant impacts on the horizontal and vertical fluxes of masses of air, water vapor, or water. The interaction between land and sea ice also has implications for the flow of salt to and from different components, and this is important because salinity leads to different forms of behavior, with respect to interactions. Seasonality has also been modeled, as its impact on temperature has important effects over many parts of the land, particularly for Eurasia.

In technical terms, improvements to the land component derive from more sophisticated handling of fractional processes and turbulence. The actions and behavior of non-solids in turbulence remains one of the most complex areas of mundane physics.

Nevertheless, advanced computational power has gone a long way to help understand this behavior and predict how it is going to take place in a variety of environments. A second area of improvement concerns the handling of run-off of various types of precipitation. These issues have been tackled by a joint project known as the Common Land Model (CLM), which aims to pool the knowledge and understanding of research communities in various locations.

The land component of climate models most readily shows the impact of humans. Rapid urbanization, deforestation, and changes in land cover all have significant effects on the other components of the model, and also directly impact the atmosphere and its circulation. Cities, for example, are noticeably hotter than the surrounding areas, and this introduces new forms of circulation into the system. These changes also occur much more rapidly than changes in the sea or atmosphere. The increasing heterogeneity of the land, which the changes generally bring about, increase the complexity of models and the difficulties involved in attempting to simulate climate systems.

Land Use

THE CHARACTER OF the environment has been largely dictated by the uses to which humans have put the land. Nomadic man walked lightly on the land, roaming from place to place, taking only what was needed for survival, leaving the land largely as it was. As humans settled into more sedentary, agrarian pursuits, they began to physically transform the land to meet their needs. Transformations of the land were generally localized and environmental impacts minimal. The ascent of mercantilism saw the growth of villages and towns in which goods and services were produced and traded in a more highly-developed, social economy in which production methods began to have wider environmental impacts. The 19th century saw an unprecedented intensification of land use, industrial-scale agriculture, and manufacturing that has transformed the land and regional environments almost beyond recognition. More importantly, the introduction of carbon-based fuels—wood and coal to power early industrialization, and petrochemical fuels of the 20th century—began to have transformative effects on the global climate.

Regional and global climates transform, and are transformed by, a complex dance of culture and economic development with nature. Over the past 20 years, humans have become increasingly aware of the extent to which land development is directly or indirectly responsible for the emission of numerous greenhouse gases—primarily carbon dioxide and methane—that act as forcing agents for global warming. These influences derive not only from the combustion-related emission of greenhouse gases and their accumulation in the atmosphere, but also from the local warming of the atmosphere by the urban heat island effect.

Since the 1990s, increasingly sophisticated computer models have demonstrated the tight coupling of changes in land use to subsequent changes in atmospheric and ocean temperatures. As virgin and agricultural land is transformed, attendant greenhouse gas emissions contribute to climate change at the global scale. Locally, the land's albedo may decrease, resulting in the absorption of more of the Sun's radiant energy. In densely developed urban environments, this leads to a heat island effect, which directly modifies local and regional climates. The 2007 Fourth Assessment Reports from the Intergovernmental Panel on Climate Change have recognized land-use and land use change as significant, if not primary, contributors to global climate change.

After World War II, the United States—and to a lesser extent the rest of the developed world—experienced a rapid growth in per capita income and the development of mass-market economies. Driven also

In the 19th century, land use intensified with industrial-scale agriculture and manufacturing, transforming the land and regional environments. The introduction of carbon-based fuels began to transform the global climate as well.

by government policy (such as suburban mortgage subsidies, restriction of urban investment, urban flight, and the triumph of the automobile over transit in the United States) residential and commercial land-use development rapidly expanded outside existing urban boundaries to transform enormous swathes of undeveloped or agricultural land. The resulting low-density sprawl continues to drive—and, in turn, is driven by—the development of highway transportation infrastructure that encourages the seemingly endless growth of vehicle miles traveled and the attendant emission of carbon dioxide and other non-point source air pollutants.

As developing nations strive to join the global economy, their land-use choices also contribute significantly to global warming and climate change. Not only can these developing, largely agrarian, economies ill-afford the latest in power generation and pollution-control technologies (to limit greenhouse gas emissions), but the very survival of their populations often depends on the transformation—some say destruction—of natural landscapes that play a key role in climate protection. The large-scale deforestation of the Amazon Basin by Brazilian peasants and international corporations seeking to compete in global agricultural markets is gradually eliminating a globally-essential carbon dioxide sink. The chaos of unplanned urbanization and economic development are major contributors to the production and release of global warming gases.

Second-order land-use changes are motivated by first-order transformations. As populations respond to changing land uses—to urban development, suburban sprawl, and their attendant climatic effects—more land is ultimately transformed. Sprawl begets sprawl and amplifies local and global climate forcing. Intelligent reuses of previously developed land and those parcels left vacant as a result of leapfrog urban development (brownfield and infill development sites) can mitigate the resulting climate impact by limiting the development of new (highway) transportation infrastructure with its resulting climate impacts. In the long term, the increasing application of smart growth, traditional neighborhood development, and new urbanist principles may contribute to denser and more sustainable land use by encouraging mixed-use development.

University of Texas at Arlington

Laos

LOCATED IN SOUTHEAST Asia, and formerly part of the French Indochina, Laos has a land area of 91,429 sq. mi. (236,800 sq. km.), a population of 5,859,000 (2006 est.), and a population density of 66 people per sq. mi. (25 people per sq. km.). With only 3 percent of the country arable, and another 3 percent used for meadows and pasture, 55 percent of the country remains forested, although this is declining slowly with a large timber industry in parts of Laos.

Regarding the electricity production in Laos, 98 percent comes from hydropower, with the remaining 2 percent from fossil fuels. Laos is located on the Mekong River, and plans were first discussed in 1962, and drawn up in 1969, to build the Nam Ngum Dam to provide for the power needs of Vientiane, the country's capital. Although it already exports electricity generated from hydropower, the Laotian and Thai governments plan to build the controversial Pa Mong Dam. As a result of this heavy use of hydropower, Laos maintains one of the lowest per capita rates of carbon dioxide emission in the world, at 0.1 metric tons in 1990, rising to 0.22 metric tons by 2003.

The main effect of global warming and climate change on Laos is expected to be increased flooding of low-lying parts of the country, with a possible increase in the prevalence of insect-borne diseases such as malaria and dengue fever. Higher temperatures might also result in difficulty growing some crops in the country, resulting in lower yields. The government of the Lao Democratic People's Republic took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and they accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on February 6, 2003, which took effect on February 16, 2005.

Latvia

THE REPUBLIC OF Latvia, located in the Baltic, and until 1991 a constituent part of the Soviet Union, has a land area of 24,937 sq. mi. (64,589 sq. km.), a population of 2,277,000 (2006 est.), and a population density of 93 people per sq. mi. (36 people per sq. km.). Twenty-seven percent of the country is arable, with a further 13 percent used for meadows and pasture, much of that for raising cattle or dairy farming, contributing to the high per capita methane emission level.

Latvia generates 67 percent of its electricity from hydropower, with the remaining 33 percent from fossil fuels. As a result of this heavy use of hydroelectricity, Latvia produced 4.8 metric tons per capita of carbon dioxide (CO_2) in 1992, falling to 2.9 metric tons per person by 2003. This was far below its northern neighbor Estonia (16.1 in 1992, 13.6 in 2003) and lower than its southern neighbor Lithuania (5.8 in 1992, 3.7 in 2003). Forty-two percent of the carbon emissions in the country come from electricity and heat production (Latvia having bitterly cold winters), 27 percent from transportation, and 16 percent from manufacturing and construction. In terms of its emissions by source, 62 percent comes from liquid fuels, reflecting the heavy use of privately-owned cars in the country, and 30 percent from gaseous fuels, with the remainder from the use of solid fuels and cement manufacturing. In recent years, the Latvian government has encouraged bicycling in the country to try to reduce dependence on cars for short journeys.

The main effects of global warming and climate change on Latvia have been a rise in the average temperatures in the country, which has allowed more land to be used for arable purposes. However, it has also led to degradation of some coastal lands, and the possibility of flooding in parts of the country. The Latvian government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and three years later ratified the Vienna Convention.

Latvia signed the Kyoto Protocol to the UN Framework Convention on Climate Change on December 14, 1998, and ratified it on July 5, 2002. It took effect on February 16, 2005. The Latvian government has undertaken to reduce CO_2 emissions by 8 percent by 2012.

LDEO Climate Modeling Group

THE CLIMATE MODELING and Diagnostics Group at the Lamont-Doherty Earth Observatory (LDEO) of the Earth Institute at Columbia University includes more than 200 researchers studying the origin, evolution, and future of the natural world. The Climate Modeling Group carries out research in climate modeling and climate change, also taking into account important issues in the phenomenon of global warming, such as El Niño/Southern Oscillation. Climate Group builds on the data produced from general circulation models (GCMs) to answer fundamental science questions.

LDEO is developing several climate models. The Lamont Ocean-AML GCM (LOAM) is a recent recreation of the Gent-Cane Primitive Equation Ocean Model with many supplementary elements. It was developed for modeling the equatorial Pacific on a stretched longitude/latitude A-grid. Most of the horizontal features have been kept in the present version. The fourth order time and space (horizontal) discretization has been retained, the Shapiro filters (reduced, conservative, narrow passage modifications) are still used, and most of the old options remain. The only major exception is that the reduced-gravity setup (assuming no motion at depth) is not currently supported in this version, but could be reintroduced. The major changes from the original Gent/Cane model are the vastly improved I/O handling, a barotropic solver, a new ocean mixed-layer parameterization and an atmospheric mixed layer (AML).

The Coupler for the Atmosphere with Multi Element LOAM (CAMEL) was partly funded by the Lamont-Doherty Earth Observatory Investment Fund (LIF). The underlying idea of this project is to create a simple tool to combine atmosphere, land, ocean, and sea-ice models. CAMEL interpolates the surface fluxes computed in the atmosphere model to land, ocean, and sea-ice models. It also interpolates the surface temperature computed in these models to the atmosphere model.

The models can be kept as separate executables and the communication is done by reading/writing netCDF files. The interpolations and scheduling is all done by CAMEL, with the separate models waiting for updated information. If any of the components are already coupled into one model, as in CCM3(atmosphere) and LSM (land) , then CAMEL does not interfere, but does the coupling only between separate models. More generally, CAMEL can be used to patch together the surface conditions of multiple models. In addition, in any geographic area, climatological surface conditions may be combined with model output.

The Climate Model Data Documentation Project (CMDDP) was born of the need to analyze model data to support the scientific conclusions. This raised problems regarding archiving, accessibility, and documentation of the group's results, and relating to the integrity and reproducibility of the group's modeling experiments. Typically, the published data of modelers consists of figures, processed data, and tables of area averaged, depth-integrated, time-smoothed data. Due primarily to size constraints, the computer output is not available for further analysis. In addition, the source code for the models themselves is not easily reproduced. Even scientists based at the same institutions who repeat a model run frequently report different results from some unknown combination of code evolution, change in personnel, migration of computer platforms and data storage, or lack of proper documentation of parameters. To address this problem, which risks compromising the scientific effort, the Climate Modeling Group launched a comprehensive, web-based procedure for ensuring the integrity of local GCM runs. Data can be supplied over the internet through the Distributed Oceanographic Data System (DODS) to the whole community. In addition, all necessary documentation, source code, and initialization and forcing data can be stored in one place. The creation and maintenance of this Climate Model Data Documentation Project has achieved a new standard for this type of research. All new published modeling results in the group will be added to this project. Existing projects will also be added to this effort.

The Climate Modeling Group has created the "Reduced Space Optimal Analysis for Historical Datasets: 136 years of Global Sea Surface Temperatures." This analysis uses present-day temperature patterns to enhance the meager data available in the past. The group also manages the Climate Data Library, which includes over 300 datasets from a variety of Earth science disciplines and climate-related topics. Through this facility, users are granted access to any number of datasets, they can create analyses of data ranging from simple averaging to more advanced Empirical Orthogonal Function (EOF) analyses, they can monitor present climate conditions with maps and analyses in the Maproom, they can create visual representations of data, including animations, and they can download data in a variety of commonly-used formats, including Geographic Information Systems- (GIS) compatible formats.

The group also monitors the phenomena of El Niño/Southern Oscillation. Researchers expect drought to worsen in the Plains and the West of the United States over the next several years because of La Niña-like conditions. Using observations and models, LDEO scientists learned that all the major dry and wet events in the American West since the late 19th century were forced by slowing varying tropical Pacific sea surface temperatures (SSTs). Climate Modeling Group scientists have shown how decadal variations of these SSTs are predictable to a modest degree a few years in advance. According to them, the American West might be entering one of the most serious period of drought since European settlement. The group's research in the area also includes predicting if rising greenhouse gases will induce an El Niño-like response, causing increased precipitation over the American West, or a La Niña-like response, causing less precipitation over the American West in the tropical Pacific Ocean.

Lebanon

LEBANON IS SITUATED on the eastern coast of the Mediterranean Sea and has boundaries with Syria and Israel. Lebanon is a small country with diverse geographical regions, including a narrow coastal strip, the Chouf Mountains, the Mount Lebanon range, and the Bekáa Valley in the arid rain-shadow area. In the Chouf Mountains, a nonporous rock layer forces water to the surface, resulting in waterfalls, and makes high-altitude cultivation possible. There are over 30 areas of natural areas protected by ministerial decrees of the Protected Areas Directorate of the Ministry of Environments. The climate of Lebanon is Mediterranean, with warm, dry summers and cool, wet winters, with some variation across the more diverse geographic regions. The coastal plain is subtropical. The mountain areas experience lower temperatures and increasing precipitation as elevation increases.

Lebanon imports over 75 percent of its food to support a population of over 4.4 million, with a steady population growth. The impact of global warming is apparent in current environmental concerns, including degradation of forests and woodlands for urbanization, and excessive water use for both domestic water supply and agriculture. Much of the land is littered with landmines from war. Areas susceptible to the effects of climate change include water resources, higher elevations affected by warming, and coastal flooding with increased storm probability and rising sea levels. Higher temperatures could affect the native vegetation that may be unable to adapt, and may be replaced with vegetation that thrives at higher temperatures.

In December 1994, Lebanon ratified the United Nations Framework Convention on Climate Change and prepared and submitted, through funding from the Global Environment Facility, Lebanon's First National Communication Report in 1995 to the Secretariat in November of 2006. Lebanon ratified the Kyoto Protocol (an international and legally binding agreement to reduce greenhouse gas emissions worldwide, which took effect on February 16, 2005). It took effect in Lebanon on February 11, 2007. Countries that are parties to the UN Framework Convention on Climate Change are required to undertake national communication, which can include assessment of potential impacts of climate change.

There are more than 30 nongovernmental environmental organizations active in Lebanon. Proposed projects aimed at reducing greenhouse gas emissions include assessing energy requirements and possible use of solar and wind energy as well as imported natural gas, improving efficiency of electricity use with advanced technology, improving waste management practices, and methane gas recovery. In addition to research studies on feasibility, the chief components necessary for mitigation of human-induced climate change in Lebanon are raising public awareness, educating policy makers on cost-effective environmental conservation practices, and access to education and experience with advanced technology for professionals.

Lesotho

THE LANDLOCKED KINGDOM of Lesotho, totally surrounded by South Africa, has a land area of 11,717 sq. mi. (30,355 sq. km.), a population of 2,008,000 (2006 est.), and a population density of 153 people per sq. mi. (59 people per sq. km.). Most of the people in Lesotho work in subsistence agriculture, with 11 percent of the land arable, and a further 66 percent used for meadows and pasture, mainly for low-intensity grazing of cattle, sheep, goats, and pigs. Because it is relatively undeveloped, the carbon dioxide emissions from the country are low on a per capita basis. Exact statistics for the country have not been published for several years.

The effects of global warming on Lesotho involve a possibility of rising temperatures leading to a reduction in the amount of farmland, with increased desertification and soil erosion, and the possibility of drought. The Leostho government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention in 1994. They also accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on September 6, 2000,; it took effect on February 16, 2005.

Liberia

THE REPUBLIC OF Liberia, located in West Africa, an independent country since 1847, has a land area of 43,000 sq. mi. (111,369 sq. km.), a population of 3,750,000 (2006 est.), and a population density of 75 people per sq. mi. (29 people per sq. km.). The economy of the country came largely from rubber, but since 1989 there has been extensive fighting in much of the country, leading to the installation of President Charles Taylor, and later his ejection from the country.

Some 39 percent of the country is forested, with 1 percent of the land arable, and a further 29 percent used for meadows and pasture. All of the country's electricity production comes from fossil fuels, with only the capital, Monrovia, covered by the country's electricity grid. Liquid fuels make up 99 percent of the country's carbon dioxide (CO_2) emissions, and the remaining 1 percent comes from cement manufacturing. The overall CO_2 emissions per capita fluctuated from 0.1 to 0.2 metric tons 1990–2003. These changes reflect the fact that the central electricity supply system in the country stopped working during fighting in July 1990, causing most people to have gasoline-driven power generators. It was not until 1998 that the first traffic lights since 1990 were brought into operation in the capital. However, the civil war has had a major impact on the country's rainforests, with the illegal timber industry used to raise money for various sides in the conflict. This deforestation has had a major impact on the country's environmental problems, leading not only to increased greenhouse gases, but also to soil erosion.

Monrovia has the second highest rainfall rate in Africa, and, located on a peninsula, it is at risk of flooding if climate change and global warming lead to even a moderate rise in water levels in the Atlantic Ocean. The Liberian government of Amos Sawyer took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention in 1996. The subsequent government of Charles Taylor accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on November 5, 2002, and ittook effect on February 16, 2005.

Liechtenstein

LOCATED IN CENTRAL Europe, the Principality of Liechtenstein is landlocked, with Germany as its northern neighbor, and Switzerland along its southern border. It has a land area of 62 sq. mi. (160 sq. km.), a population of 35,000 (2006 est.), and a population density of 557 people per sq. mi. (215 people per sq. km.). Twenty-four percent of the land is arable, with 16 percent used for meadows and pasture, and 20 percent of the country forested.

With a very high standard of living in the country, it has a relatively high level of per capita carbon dioxide emissions, largely because of its high per capita electricity production, and high private ownership of automobiles, in spite of having an efficient level of public transport in Vaduz, the capital. However, much of the automobile usage takes place outside of Liechtenstein.

In the foothills of the Alps, Liechtenstein is threatened by rising temperatures from climate change and global warming, noticeable in the lessening of the snow-covered Alpine peaks. The Liechtenstein government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and signed the Kyoto Protocol to the UN Framework Convention on Climate Change on June 29, 1998. It was ratified by the Landtag, the Liechtenstein parliament, on December 3, 2004, and it took effect on March 3, 2005.

Life Cycle Analysis

LIFE CYCLE ANALYSIS (LCA) is a means of quantifying how much energy and raw materials are used and how much (solid, liquid, and gaseous) waste is generated at each stage of a product, process, service, or system's lifetime. An LCA is the environmental impact over the entire lifespan of the entity in question, and can be used to help reduce anthropogenic impacts on the climate. Life cycle analysis is also known as a life cycle assessment, life cycle inventory, eco-balance, net energy analysis, materials flow analysis, cradle-to-grave analysis, cradle-to-cradle analysis, well-to-wheel analysis, resource analysis, and environmental impact analysis. The environmental impact can be converted to a carbon footprint or land area in ecological footprint (or eco-footprint) analysis.

There is no agreed-upon methodology for LCAs. The most institutionalized LCAs methodology is the codification into the ISO (International Organization of Standards) 14000 environmental management standards, which assists organizations to minimize negative environmental impacts, comply with applicable laws and regulations, and to continually improve on these metrics. ISO 14040 to 14044 covers LCAs and pre-production planning and environment goal-setting. LCA can, however, be very complex, and reliable data are difficult to compile. Thus, studies on similar systems, products, and processes often vary considerably in their final results. In the literature covering the LCA of controversial technologies (such as nuclear energy), the results may be biased. Provided all reports state the methodology used and the assumptions made, LCAs do, however, provide a useful indication of where to concentrate work on essential improvement, and which technologies should be adopted to reduce the environmental impact of a product or process, in terms of energy and raw materials used and wastes produced.

LIFE CYCLE ANALYSIS AND THE ENERGY SECTOR

In the context of climate change and its largest contributor, the energy sector, LCAs generally focus on an energy LCA that includes both tangible and intangible costs of energy production from the initial project conception, to the final step of returning the land to its original or its next-use state. Tangible costs have always been included in the industry analysis and include such items as facility construction, fuel source development, post-extraction land remediation, and waste disposal. Because different forms of energy use have adverse impacts, not only on nonusers, but also the entire biosphere, intangible costs are important. These include the impact of the release of carbon dioxide into the atmosphere.

In the past, conventional energy proponents often overlooked costs (both economic and energy-related) due to plant decommissioning because of weak regulations and oversight. This allowed some energy producers to hide the true lifetime costs of energy production, thus projecting a false image of both economic and environmental benefit. Examples include ignoring nuclear waste storage, or the cost of reclaiming strip-mined land, or mountaintop removal mining in the Appalachian Mountains. Complete LCA's are difficult to perform, especially on emerging technologies, such as solar photovoltaic cells, whose fabrication is constantly undergoing improvements, and which has not been in mass production long enough for recycling or disposal to become established. Often in the energy sector, energy LCA is used because it is less complicated than a full LCA; energy consumption data are more reliable (often metered for individual processes). Ideally, an energy life cycle analysis would include: raw material production energy, manufacturing energy of all components, energy-use requirements, energy generation (if any), end of use (disposal) energy, and the distribution/transportation energies in between each stage.

LCA AND CLIMATE CHANGE

To utilize LCA in policy decisions on climate change, it is imperative to understand the boundaries of the operations that produce the process, because if any part of the system contained within the boundaries is changed, the other inputs and outputs will also change. Deciding what constitutes the cradle and what is the grave (or next cradle) for such studies has been one of the major points of contention in the evolving discipline of LCA. For example, in calculating the embodied energy for transportation as just one component of the LCA in the recycling of plastic, the simplest case would be limited to the fuel used for the recycling trucks. In more detailed LCAs, the embodied energy of the trucks would be included; particularly if the trucks were only used for plastic recycling (otherwise, the fractional use would be taken into account). Such a study would normally ignore second, third, and greater generation impacts, such as the energy required to fire the bricks used to build the kilns used to manufacture the truck components.

In addition, recycling itself lends considerable complexity to LCAs. For some materials such as aluminum, which can technically be recycled an indefinite number of times (with some melt losses), there is no longer a grave. In the case of paper, however, taking into account recycling is even more complex. Paper can theoretically be reprocessed four or five times before fibers are too short to have viable strength for paper, but even then it may still be useful in a downcycled product like cellulose insulation.

For these reasons, an LCA can never produce one simple result. The results are tables of ranges of figures showing quantities of resources used and wastes produced. Any comparison between similar processes or products will depend on subjective judgments on the relative importance of energy consumption, raw material use, and waste generation.

Lindzen, Richard (1940–)

RICHARD SIEGMUND LINDZEN is the Alfred P. Sloan Professor of Meteorology in the Department of Earth, Atmospheric, and Planetary Sciences at the Massachusetts Institute of Technology (MIT), where he has taught since 1983. Though extremely accomplished and respected in his field, he is perhaps best-known in non-academic circles for his arguments against anthropogenic climate change, that is, human-influenced or induced climate change known as global warming. Lindzen was born in Webster, Massachusetts, on February 8, 1940, and received his Ph.D. from Harvard University in Physics and Applied Mathematics in 1964 after earning an AB in 1960 and an SM in 1961 from Harvard. He taught at the University of Chicago (1967–72) and Harvard (1972–83) before moving to MIT.

Lindzen is a dynamic meteorologist and climatologist, applying mathematics, computational modeling, and hydrodynamics to the study of atmospheric motions. His research interests and contributions involve Hadley Circulation, planetary waves, upper atmospheric dynamics, mesoscale systems, clear air turbulence, ozone photochemistry, radiative transfer, climate sensitivity, atmospheric eddies, global heat transport, cumulus convections and the greenhouse effect, tropical meteorology, monsoons, and the heating and drying of the atmosphere. His Earth climate models are used to study the atmospheric sensitivity to carbon dioxide (CO_2), ice cap stability, regional climate maintenance, and glaciation.

He was honored with the American Meteorological Society's Meisinger and Charney Awards, as well as the American Geophysical Union's Macelwane Medal. He is a member of the National Academy of Sciences, the Science and Economic Advisory Council of the Annapolis Center for Science-Based Public Policy, the National Academy of Science Committee on Human Rights, and the Nuclear Regulatory Commission Board on Atmospheric Sciences and Climate. He is a Fellow of the American Association for the Advancement of Science and served on the 11-member Committee on the Science of Climate Change of the National Research Council.

He consults for the National Aeronautical and Space Administration's Global Modeling and Simulation Group, and has been a Distinguished Visiting Scientist at California Institute of Technology's Jet Propulsion Laboratory.

A hole in the ozone layer of the atmosphere was discovered in 1985, and the earlier detection of the warming of the Earth (1980) gave impetus to the idea that one of the causes is human-induced climate change from manmade ozone-depleting gases. In 1988, the United Nations responded by creating and tasking the Intergovernmental Panel on Climate Change (IPCC) with studying the hypothesized phenomenon. The IPCC determined that the Earth had warmed over the prior 150-year period, and that this warming was due, in part, to human activity. The executive summary of the report concluded that the most of the observed global warming experienced in the last 50 years is due to the increase in greenhouse gas concentrations. The IPCC and former U.S. Vice President Al Gore were jointly awarded the Nobel Peace on October 12, 2007, for their work on global warming.

REJECTING ANTHROPOGENIC CLIMATE CHANGE

Lindzen rejects anthropogenic climate change and asserts that, though others in the field agree with him, political and academic pressure to adhere to the accepted knowledge construct or paradigm of the climate research establishment keep them from speaking. Lindzen asserts that there is a bias against those who reject global warming by those who accept it and who control key publications and research funding. Lindzen argues that the climate models used by the IPCC do not correctly model the physics of cloud formation, and intentionally heighten the warming effect of CO_2 and other greenhouse gases. He argues that this modeling flaw is apparent when the same model is used to explain or predict shorter-term changes in the atmosphere.

He argues further that climate change is the historic norm, and that there are periods when the Earth was warmer and that in those periods the emission of human-induced CO_2 was minimal.

Lindzen does not dispute that there is global warming in the 20th and 21st centuries, that there is a concurrent increase in the concentration of greenhouse gases in the atmosphere, or that there is some anthropogenic heating.

What Lindzen disputes is that this warming trend is necessarily and substantially due to human activity, or the increase in the concentration of greenhouse gases in the atmosphere. Lindzen argues that the observed temperature data are massaged or curved by the models. This curve fitting is primarily due to the inability of contemporary computer modeling to integrate all of the known human and natural variables that must be part of the equation.For example, Lindzen asserts that the IPCC models as constructed are too sensitive to atmospheric CO_2. Additionally, Lindzen asserts that there are many variables that are as yet unknown.

Lindzen does estimate the Earth will continue to warm over the next century, but asserts that that this warming will be far less than contemporaneous models predict, and that those predictions are alarmist. Lindzen also asserts that changes in human activity will do little to mitigate the current cycle, and that the impact of the Kyoto Protocol on the climate is much smaller than its political and social impact.

Even though he was the lead author on, or contributor to, a number of the IPCC Assessment Reports, he was not involved in producing the executive summary that he believes was filtered through the accepted anthropogenic climate change paradigm by those scientists, environmentalists, government bureaucrats, and industry representatives responsible for creating the summary supplied to policymakers. He also asserts that the press, which exaggerated the problem and its potential effects, selectively reported this paradigmatically-curved summary. The fault was not with the Assessment Reports or the real findings of the IPCC, but rather with how those reports and results were interpreted for the world's decision-makers and disseminated to the global populace.

Lithuania

THE SOUTHERNMOST OF the three Baltic Republics, Lithuania has a land area of 25,173 sq. mi. (65,200 sq. km.), a population of 3,390,000 (2006 est.), and a population density of 142 people per sq. mi. (55 people per sq. km.). The economy of the country is heavily agricultural, and 39 percent of the land is arable. In addition, 6 percent is used for meadows and pasture, mainly for rearing cattle and pigs, both of which contribute to global warming through methane emissions. However, 31 percent of the country is forested, which alleviates some of the overall greenhouse gas emissions of the country.

In 1990, carbon dioxide (CO_2) emissions per capita were 5.8 metric tons, but these had fallen to 3.7 metric tons per person by 2003. Seventy percent of these emissions come from the use of liquid fuels, 23 percent from gaseous fuels, 4 percent from solid fuels, and three percent from the manufacture of cement. In terms of emissions by sector, electricity production in the country contributes 39 percent of CO_2, with only 20.2 percent of electricity production coming from fossil fuels, 76.8 percent from nuclear power, and 3 percent from hydropower. Transportation accounts for 26 percent of the country's CO_2 emissions, with manufacturing and construction accounting for 15 percent, and residential use accounting for 5 percent.

The effects of global warming and climate change on Lithuania are potentially quite serious, especially around Klaipeda (formerly Memel) and the Courland Spit, which is at risk from flooding. There is also risk from flooding in other parts of the country, such as in the Aukstaitija National Park. To try to combat the effects of global warming, Lithuania has continued to invest heavily in its public transport system, and parts of many cities such as Klaipeda are pedestrian precincts that discourage the use of cars, with heavy encouragement of bicycling.

The Lithuanian government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention in 1995. They also signed the Kyoto Protocol to the UN Framework Convention on Climate Change on September 21, 1998, and ratified it on January 3, 2003. It took affect on February 16, 2005.

Little Ice Age

THE LITTLE ICE Age does not cover a clear and well-defined climatic regime and time-period upon which climate scientists agree. Glaciologists, to describe the most recent major glacial advance of the Holocene period, originally used the phrase. Subsequently, the Little Ice Age was associated with a period of advances of European glaciers 1450–1850. It is now often associated with a climatic regime with relatively cold temperatures. However, current research does not support a globally-synchronous period of unusual cold over this approximate period.

The Little Ice Age was originally used to denote a period of moderate glaciation covering the past 4,000 years. In more recent and seminal work on the subject by J.M. Grove, the concept refers, not directly to climate, but specifically to a time, or times, of glacial advance; more precisely, to a period lasting several centuries within the last millennium, when glaciers extended globally and remained enlarged. Pioneers of the use of historical records to reconstruct past climate, such as H.H. Lamb, were drawn to suggest a cold phase in Europe on the basis of accounts of the extent of snow and ice on land and sea 1450–1850.

Based on a variety of different types of data from many parts of the world, suggestions for the period covered by this most recent meaning of the Little Ice Age have ranged from 1200–1400, 1200–1900, 1550–1700, 1550–1800 and 1550–1850. Since some of these dates were put forward, the availability of data on the climate of the past has increased. At one time, it was believed that the Little Ice Age was a global phenomenon, but this is now less apparent. Spatial climatic patterns of the past 1,000 years are beginning to be mapped for large parts of the world, and the early 21st century have seen the development of multiple climate-proxy averages providing year-by-year estimates of average temperatures. These new series challenge the idea of global synchrony, often assumed when terms such as Little Ice Age and Medieval Warm Period are used.

Climate model results using best estimates of forcing factors over the past 1,000 years also show no clearly-defined global-scale warm or cold periods during this time, suggesting that any signals that exist are largely masked by the noise of shorter timescale variability. Although the concept of a global-scale cold climatic regime in the later half of the last millennium, lasting for several hundred years, is now outdated, there were episodes of relatively cold climate in many parts of the world during the past millennium. That glaciers advanced in the 1650s, for example, in the Swiss Alps, is well-known. However, while continental Europe suffered cold temperatures in the 1600s, Iceland enjoyed a relatively mild period with infrequent sea ice 1640–80. Particularly cold periods occurred in Iceland in the 1780s and 1880s. In the United States, winter 1780 was notably cold, and New York harbor froze, allowing people to walk on the ice.

A cold Little Ice Age climate has been suggested as a causal factor in a number of episodes in human history. However, in these cases, it is likely that several elements were involved, not just climate. A case in point is the loss of the Norse settlements in Greenland (1350 and 1450), where it is clear that many factors contributed to their demise, including a possible reluctance on the part of the settlers to learn from their environment and their Inuit neighbors.

The concept of the Little Ice Age has now evolved from the idea of a simple, centuries-long period of lower temperatures, to a more complex view of temporal and spatial climate variability. There were, nevertheless, distinct phases of cold and variable climate

General George Washington crossing the Delaware on the evening before the Battle of Trenton, December 25, 1776. The American revolutionary period experienced the effects of colder temperatures, particularly during the winter of 1780.

that occurred in many parts of the globe, although not necessarily synchronously, from 1200–1850.

Lorenz, Edward (1917–)

EWARD LORENZ IS an American mathematician and meteorologist who pioneered the chaos theory. Lorenz conceptualized the strange attractor notion and termed it the "butterfly effect." He is well-known for his work in the dynamics of atmospheric circulations, and the first to recognize what is now called chaotic behavior in the mathematical modeling of weather systems. In the words of the committee that presented him the Kyoto prize in 1991, Lorenz has established "the theoretical basis of weather and climate predictability, as well as the basis for computer-aided atmospheric physics and meteorology." The committee went on to compare the impact of Lorenz's discovery of "deterministic chaos" on a wide range of basic sciences to that of the ideas of Sir Isaac Newton. Lorenz's discovery of the sensitivity of weather predictions to the input is often invoked by global warming skeptics to challenge computer-based scenarios which continue to predict an exponential temperature increase on earth.

Born in West Hartford, Connecticut, on May 23, 1917, Lorenz received his undergraduate degree in mathematics from Dartmouth College in 1938, a master's degree in mathematics from Harvard University in 1940, the SM in meteorology from the Massachusetts Institute of Technology (MIT) in 1943 and the Sc.D. in meteorology in 1948. It was while serving as a weather forecaster for the U.S. Army Air Corps in World War II that he decided to do graduate work in meteorology at MIT. Upon his return from the war, he joined the staff of what was then MIT's Department of Meteorology in 1948. Seven years later he was appointed to the faculty as an assistant professor. He was promoted to professor in 1962 and was head of the department from 1977 to 1981. He became an emeritus professor in 1987.

In the early 1960s, in the course of his work on weather systems, Lorenz found that he was getting chaotic results from some of his calculations. Studying weather patterns, he realized that weather did not always change as predicted. He experimentally discovered that if he made two runs using the same initial conditions, but specified his input conditions in one to three decimal places, rather than two, or four rather than three, he always got different weather predictions. Small variations in the initial values of variables in his 12 variable computer weather model would lead to extremely different weather patterns. This sensitive dependence on initial conditions came to be known as the butterfly effect. In Lorenz's weather models, almost any two nearby starting points, indicating the current weather, will quickly diverge trajectories and quite frequently will end up in different "lobes," which correspond to calm or stormy weather. The shape this model took, with its twin-lobed outlook, gave rise to the somewhat ironic "butterfly effect" metaphor: the flapping of a butterfly's wings in Mexico today may cause a tornado in Kansas tomorrow.

Convinced that these inconsistencies were not caused by faulty data or computer errors, he began to study chaos itself. His early insights, published in his 1963 paper, "Deterministic Nonperiodic Flow," marked the beginning of a new field of study. Some scientists have since asserted that the 20th century will be remembered for three scientific revolutions: relativity, quantum mechanics, and chaos. The study of the rules of chaotic disorder is making an impact, not only on the field of mathematics, but in virtually every branch of science: biological, physical and social. In terms of the atmosphere, it has led to the conclusion that it may be fundamentally impossible to predict weather beyond two or three weeks with a reasonable degree of accuracy. For this conclusion, Lorenz is often a starting point for global warming critics. They point out that Lorenz's "butterfly effect" leads to predictions that may depart significantly over time from what happens in the real world, if the input conditions cannot be specified to arbitrary accuracy.

During leaves of absence from MIT, Lorenz has held visiting research or teaching positions at the Lowell Observatory in Flagstaff, Arizona, the Department of Meteorology at the University of California at Los Angeles, the Det Norske Meteorologiske Insitutt in Oslo, Norway, and the National Center for Atmospheric Research in Boulder, Colorado. He was elected to the National Academy of Sciences in 1975, and his groundbreaking research has won numerous awards, honors and honorary degrees. In 1983, he and former MIT Professor Henry M. Stommel were jointly-awarded the $50,000 Crafoord Prize by the Royal Swedish Academy of Sciences, a prize established to recognize fields not eligible for Nobel Prizes. His other honors include the Elliott Cresson Medal from the Franklin Institute in 1989, the Rossby Research Medal of the American Meteorological Society in 1969, and the Society's Meisinger Award in 1963. In 1991, he was awarded the Kyoto Prize in earth and planetary sciences.

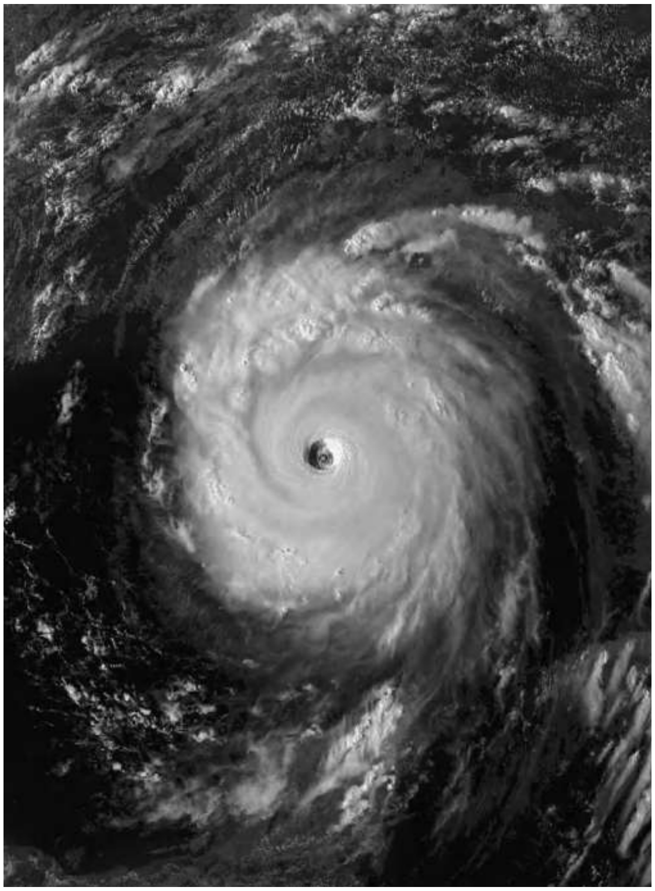
Louisiana

LOUISIANA IS A state in the south-central United States, bordered by the Gulf of Mexico, Texas, Arkansas, and Mississippi. Major physical features include the Mississippi River, which forms part of the state's eastern boundary and crosscuts southeastern Louisiana, and its Atchafalaya River distributary; extensive but rapidly diminishing coastal wetlands; and hogbacks and cuestas of the north. The uplands and terraces of the Gulf Coastal Plain of northwestern and east-central Louisiana are interrupted by the vast Mississippi River bottomlands, which fan southward to include the entire coastal lowland region. The highest elevation is only 535 ft. (163 m.), making Louisiana's highest point third lowest in the United States. Over 18 percent of Louisiana's area lies below 4.9 ft. (1.5 m.) above sea level. Much of the New Orleans metropolitan area lies below sea level.

The entire state has a humid-subtropical climate, with long, hot, rainy summers and cool, wet winters interrupted by mild-to-warm conditions. July temperatures average in the high 60s degrees F (20s degrees C) statewide, with January averaging approximately 43–55 degrees F (6–13 degrees C). Statewide, precipitation ranks among the highest of the states, but with a considerable gradient, ranging from nearly 48–71 in. (122–180 cm.) from northwest to southeast. Much of the rainfall, especially in summer, falls in short, intense downpours. The average number of thunderstorm days at a location exceeds that in any state except Florida, and tornado frequency per sq. mi. ranks sixth among the states. Louisiana is among the few places on Earth that frequently experiences tropical cyclones, tornadoes, rainfall rates exceeding 2 in. (5 cm.) per hour, floods, and winter storms.

Owing to its low-lying terrain, sultry climate, susceptibility to severe weather impacts, and high per capita rates of fossil fuel production and consumption, Louisiana is perhaps more vulnerable than any other state to environmental and economic impacts of long-term warming. These changes can be felt most directly in eustatic sea level increases from rising global temperatures, which could inundate the coastal zone and accelerate the already-rapid rate of coastal erosion. Continued warming would accelerate saltwater intrusion, which would remove the salt-intolerant coastal vegetation currently anchoring land in place. Drying conditions in much of the Mississippi River basin, as suggested by some general circulation models, would accelerate this effect of saltwater intrusion.

If global warming increases precipitation totals locally and across much of the Mississippi basin, as



Hurricane Katrina approaches the Louisiana coast in 2005. Questions remain about global warming's effect on the storm.

other models suggest, flooding hazards would be more problematic than increasing saltwater intrusion.

Although a causative link between global warming and severe/extreme weather has not been clearly established, Louisiana's susceptibility to such weather dictates that any climate change in frequency or intensity is likely to have a significant cumulative effect on environmental and social systems. In particular, if global warming increases the frequency and/or intensity of tropical cyclones as many climatologists suggest, acute loss of wetland habitats, human life, and property will accelerate. More chronic and insidious changes, such as in thunderstorm frequency and drought intensity, will also be important. Increased attention to emergency and disaster management, particularly in land-use planning and levee protection, is warranted. The degree to which the effects of Hurricanes Katrina and Rita of 2005 were exacerbated by global climatic change is still being debated.

Louisiana is also vulnerable to increased impacts on public health resulting from global climatic changes. Owing to its location near the poleward margin of the domain of tropical diseases, small increases in frost-free season length may be accompanied by significantly more cases of encephalitis, West Nile virus, dengue fever, and other tropical diseases. Increased impacts of heat waves will affect the disadvantaged and elderly disproportionately. Moreover, as summer temperatures rise under clear skies, tropospheric ozone is likely to become an increasing problem in the U.S. Environmental Protection Agency-designated Baton Rouge non-attainment zone and elsewhere. Effects of tropospheric ozone include respiratory illness, damage to plant membranes, and increased oxidation rates on physical structures. Rising temperatures will also increase the bacterial contamination of shellfish. Rises in water tables induced by additional precipitation and/or sea level rise would also place contaminants from dump sites and viruses and bacteria from septic systems closer to the surface, magnifying the impact on humans and livestock.

Agriculture and forestry in Louisiana will also be affected by global warming-induced climatic changes. Although some impacts may be positive, owing primarily to increases in growing season length, others place Louisiana in a more precarious situation. Pest populations would probably increase under longer frost-free seasons, and the additional "fertilization" by elevated carbon dioxide (CO_2) may benefit weeds more than crops, increasing expenses for pest and weed control. If precipitation decreases, the percentage of Louisiana farmland that is irrigated will increase from the current 25 percent, as will irrigation costs per acre. Landscape desiccation would also increase forest fire frequency, as in other states.

The costs of national and international policy changes regarding fossil fuel production and consumption may be felt more in Louisiana than in any other state except Alaska. Research on alternative energy sources and on reducing environmental impacts of fossil fuels may provide solutions that will preserve Louisiana's role as an energy producer while minimizing environmental impacts. Plans may involve using natural gas or methane hydrates from the Gulf of Mexico floor to produce hydrogen for fuel cells, sequestering the solidified carbon waste in the thousands of abandoned oil and gas wells throughout

Louisiana, and transporting hydrogen fuel via the vast network of existing pipelines.

Robert V. Rohli
Louisiana State University

Louisiana State University

RESEARCH IN CLIMATIC change and variability at Louisiana State University (LSU) in Baton Rouge, Louisiana has been ongoing since the 1930s when coastal geomorphologist Richard J. Russell completed maps showing spatial variation through time in the Koeppen climatic boundaries across the United States. Since that time, climatic change research at LSU has focused on synoptic-to-global-scale atmospheric circulation, hydroclimatology, paleoclimatology, and surface/atmosphere interactions. Researchers affiliated with the Department of Geography and Anthropology accomplished the majority of the work, but other scientists on campus also make contributions, from the Department of Oceanography and Coastal Sciences, Department of Geology and Geophysics, Hurricane Research Center, LSU AgCenter, and Earth Scan Lab.

Most of the work on atmospheric circulation trends has been at the multi-decadal timescale. The study of the long-term nature of atmospheric circulation at LSU was begun by Robert Muller, whose contributions to atmospheric circulation research over five decades have centered on manual synoptic typing and, more recently, long-term changes to tropical cyclone frequencies in the Atlantic/Gulf of Mexico basins. LSU climatologists have applied manual synoptic typing to New England and automated typing techniques to the Great Lakes region.

The work on temporal trends in cyclones has also been expanded to include extratropical coastal storms and winter storms in New England. Muller also introduced hydroclimatology to LSU through his work on long-term changes in the water balance of the United States.

Work since that time has expanded to include trends in heavy rainfall, precipitation in general, water balance-modeled streamflow and runoff, and dew-point variability in the southeastern United States.

Other work by LSU scientists has investigated decadal-scale changes to such features as surface anticyclones, the Northern Hemispheric circumpolar vortex, teleconnections and their relationship to the circulation and precipitation of the Gulf of Mexico region, and circulation impacts on east-African precipitation.

Other examples of recent work directly related to global climatic circulation changes have involved assessment of model representation of the North Atlantic Oscillation, and the association of the North Atlantic Oscillation to the Arctic Oscillation.

A third research emphasis has emerged since the 1990s, under the leadership of Kam-biu Liu, in paleoclimatology. One major focus is on Quaternary paleoenvironmental reconstruction using pollen and phytolith proxies. Thematic examples include palynological evidence for long-term changes in the Asian monsoon and Amazonian ecosystems, and high-resolution pollen records of El Niño-Southern Oscillation (ENSO) and monsoon changes from Andean and Tibetan ice cores. Another focus of this group has involved the use of coastal lake-sediment proxy records to infer the Holocene history of tropical cyclone landfalls—the new field of paleotempestology.

To date, Liu's research group has conducted paleoenvironmental and paleotempestological reconstructions throughout the Gulf-Atlantic coast of the United States, Central America and the Caribbean, the Amazon basin, the Bolivian Altiplano, East Africa, the Tibetan Plateau, Mongolia, and East Asia.

The impact of climatic changes on the lithosphere and ocean has also been the subject of recent research at LSU, in the tradition of R.J. Russell, James P. Morgan, and J.M. Coleman. For example, Mike Blum has investigated responses of large river systems to climate and sea-level change. Patrick Hesp's research on changes to barrier-island ecosystems under climatic forcing mechanisms also falls within this realm. Likewise, Gregory Stone has analyzed the effects of tropical cyclones and winter storms on coastal morphosedimentary dynamics and post-storm adjustment, and Masamichi Inoue observes deepwater circulation changes by a mooring deployed in the eastern Gulf of Mexico.

In addition to the research and teaching mission of LSU climatologists, service has traditionally played an important role. Four state climatologists (George Cry, Robert Muller, John "Jay" Grymes, and Barry Keim) have distributed climatic data for the state that has been used in research on climatic change. In addition, since 1990, staff associated with LSU's Southern Regional Climate Center, directed by Muller and later, Kevin Robbins, has archived and distributed data for the six-state region of Arkansas, Louisiana, Mississippi, Oklahoma, Tennessee, and Texas. Several papers have been published on the applicability, utility, and limitations of climatic data.

Luxembourg

THE LANDLOCKED GRAND Duchy of Luxembourg, which has land borders with Belgium, Germany and France, has a land area of 999 sq. mi. (2,586 sq. km.), with a population of 467,000 (2006 est.), and a population density of 469 people per sq. mi. (171 people per sq. km.). Approximately 58 percent of the electricity used in Luxembourg comes from fossil fuels, with 25.6 percent from hydropower. With a very high standard of living, Luxembourg has the sixth highest per capita levels of carbon dioxide (CO_2) emissions in the world, the highest rating for a country that is not reliant on petroleum for its economy. This was calculated at 26.3 metric tons per person in 1990, rising to a peak of 30.5 metric tons per person in 1992 (the second highest in the world in that year, after Qatar), falling to 17.4 metric tons by 1998, and rising again to 22 metric tons in 2003. Sixty-seven percent of the CO_2 emissions coming from liquid fuels, 19 percent from gaseous fuels, 10 percent from solid fuels, and 4 percent from the manufacture of cement. The high level of liquid fuels is because 50 percent of the emissions, by sector, come from transportation. In spite of excellent public transport in the country, there is still heavy use of privately owned automobiles. Manufacturing and construction make up 19 percent of CO_2 emissions, with 18 percent from residential use. These figures exclude the CO_2 generated by electricity and heat production.

Since the 1990s, green parties have been elected. The Luxembourg government ratified the Vienna Convention in 1988, and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. It signed the Kyoto Protocol to the UN Framework Convention on Climate Change on April 29, 1998, which was ratified by the Luxembourg Chamber of Deputies on May 31, 2002, on the same day as the other member states of the European Union; it took effect on February 16, 2005.

Macedonia (FYROM)

THE FORMER YUGOSLAV Republic of Macedonia (FYROM) has a land area of 9,779 sq. mi. (25,333 sq. km.), a population of 2,038,000 (2006 est.), and a population density of 205 people per sq. mi. (79 people per sq. km.). With a strong agricultural base, 24 percent of the country is classified as arable, with a further 25 percent used as meadows and pasture, and 39 percent is forested. Much of the pasture is for raising sheep, with large flocks reared on the Bistra Mountains.

In terms of carbon dioxide emissions, the per capita rate for Macedonia has been relatively stable, at 5.5 metric tons per person in 1992, falling slowly to 5.2 metric tons by 2003. As for the country's electricity production, 82.3 percent comes from fossil fuels, with 17.7 percent from hydropower. The result has been that 76 percent of emissions by source come from solid fuels, 22 percent from liquid fuels, and the remaining 2 percent from the manufacture of cement. By sector, electricity generation and heat production account for 71 percent of all carbon dioxide emissions, with 11 percent from transportation. The country has a relatively poor system of public transport, with a small railway network, only a third of which is electrified. Climate change and global warming are likely to have a severe effects on Lake Doiran, where fishermen from Macedonia source much of their fish stock.

The Macedonian government took part in the United Nations Framework Convention on Climate Change in May 1992, which they ratified in 1998. Macedonia also ratified in the Vienna Convention in 1994.

Madagascar

THE MOST RECENT effect of climate change and global warming in Madagascar has been an increase in El Niño effects, which are associated with drought conditions and increased wildfires. In addition, there has been an increase in the intensity and number of cyclones, which displaces human communities and leads to local famine and cholera outbreaks. Madagascar's western coast, mangrove forests are particularly susceptible to any increase in sea levels. Although warmer ocean temperatures caused by global climate change have been recorded in northern Madagascar, the effects of this change on the coral reefs in the region have been mitigated, at least temporarily, by cooler water from deep ocean currents. Madagascar's unique flora and fauna are also susceptible to climate change. For example, reduced rainfall has negatively affected endangered sifaka lemur populations. The impact of climate change and global warming in Madagascar is exacerbated by deforestation resulting from increased population and unsustainable swidden farming and logging that has reduced forest cover and increased desertification, causing higher temperatures, lower humidity, and diminishing annual rainfall.

Efforts to reduce the effect of climate change and global warming on Madagascar's flora and fauna include the U.S. Agency for International Development's attempt to reduce brush fires, which, in addition to destroying vegetation, release carbon into the atmosphere. The Wildlife Conservation Society, Conservation International, and the government of Madagascar's Makira Forest Project seek to protect over 300,000 hectares of rainforest in northeastern Madagascar. It is hoped that the Makira Forest will offset 9.5 million tons of carbon dioxide (CO_2) over 30 years through carbon sequestration, preserve habitat for threatened species, and provide economic opportunities for local indigenous communities.

Douglas William Hume
University of Connecticut

Maine

LOCATED AT THE northeastern tip of the United States, Maine is known chiefly for its wood and seafood products. Nearly 90 percent of its land area is forested, and 21,000 acres (85 sq. km.) are designated as state forests. Maine has 3,478 mi. (597 km.) of tidally influenced shoreline. These forests and coastlines are particularly vulnerable to climate changes caused by global warming. The U.S. Environmental Protection Agency reports that rainfall in parts of Maine has decreased by 20 percent over the last century. In the future, the sea level in Rockland is predicted to rise as high as 14 in. (36 cm.), leading to coastal flooding, beach erosion, and the loss of valuable wetlands. As a result of this vulnerability, Maine has taken decisive action in establishing policies, priorities, and actions designed to modify human behaviors associated with global warming and climate change.

PROGRESS

Between 1990 and 2001, the population of Maine increased by 5 percent. During that same period, carbon dioxide (CO_2) emissions rose by 20 percent to a total of 22.7 million metric tons. In 2005, Maine established new standards for motor vehicle emissions based on those already in place in California. As a result of these efforts, Maine now has the eighth lowest level of CO_2 emissions in the United States. The Public Utilities Commission acted in 1999 to move Maine toward renewable energy, requiring that 30 percent of all power come from renewable sources, such as fuel cells, tidal power, solar, wind, geothermal, hydroelectric, biomass, and solid-waste fueled generators.

In 2001, the New England governors and Eastern Canadian premiers began developing plans to reduce the levels of greenhouse gas emissions throughout the area. In addition to establishing a Greenhouse Gas (GHG) Emissions Inventory, the plan called on members to develop specific plans for reducing GHG emissions and for energy conservation, educating the public, leading by example, reducing GHG emissions from electric power plants, conserving energy, and reducing the overall impacts of climate change. In 2006, Maine received an overall grade of "B" for actions taken on accomplishing these goals. The report card cited progress in purchasing hybrid vehicles for the state, establishing LEED standards in

A Maine moose in wetlands. The state is also known for its extensive shoreline, but the sea level in Rockland is predicted to rise, leading to coastal flooding, beach erosion, and the loss of wetlands.

new and renovated state buildings, reducing travel miles of state employees, reducing energy consumption, increasing the use of clean energy, developing strict vehicle emission standards, and focusing on renewable energy and carbon-neutral generators. The report card stated that improvements were needed in the areas of fuel efficiency, education, research, and mandated building codes.

The responsibility for overseeing environmental factors that lead to global warming and climate change is divided among several departments in Maine. The Department of Environmental Protection encompasses the divisions of Air Quality, Land and Water Quality, and Remediation and Waste Management, as well as the Board of Environmental Protection. The Bureau of Health, which operates under the auspices of the Department of Human Services, manages the Health and Environmental Testing Laboratory, the Environmental Health Unit, and the Division of Health Engineering. Other agencies with environmental responsibilities include the Department of Agriculture, which includes the Board of Pesticide Control, the Department of Conservation, the Department of Inland Fisheries and Wildlife, the Department of Marine Resources, and the State Planning Office, which oversees land use, coastal management, natural resources, waste management, and recycling.

PROGRAMS

In 2003, Maine became the first state in the United States to set a specific target for reducing GHG emissions. Established by an act to provide leadership in addressing the threat of climate change, the Greenhouse Gas Reduction Target Program mandates that emissions be restored to 1990 levels by 2010, and reduced an additional 10 percent by 2020. Long-term plans entail drastic reductions that may reach 75 to 80 percent of 2003 levels. The new standards work in conjunction with Maine's Clean Car Program, which was established in 1999. The program encourages residents to commit to reducing vehicle emissions, the greatest source of pollution in the state. Vehicles that meet established standards are allowed to display a "Cleaner Cars for Maine" sticker. To cut down on toxic emissions, consumers are advised to make sure that all car purchases are green, and drivers are encouraged to reduce driving time, avoid idling engines, accelerate gradually, avoid speeding, fill gas tanks during cooler periods of the day, refrain from spilling gas and topping off tanks, and reduce use of air conditioning. Since maintenance habits may also affect the environment, Maine drivers are requested to use energy-conserving motor oils, get regular check-ups, replace filters and oil frequently, keep tires properly inflated and aligned, and repair all leaks.

Maine's State Planning Office began working on the issue of climate change in the mid-1990s. When the working grant from the U.S. Environmental Protection Agency was exhausted, some members reformed as Maine Global Climate Change, Inc., for the purpose of educating the public about human behaviors that affect global warming and climate change. The group was successful in convincing the legislature to appoint a state climatologist. In 2004, Maine established a Climate Action Plan, targeting the transportation, industrial, commercial, institutional, and residential sectors as a means of controlling the emission of greenhouse gases by protecting the state's resources. The Department of Environment Protection announced 54 specific actions that had been proposed by working groups from all sectors, including forestry, land use, and transportation. Reporting and assessments were considered essential to keeping policies and responses up-to-date.

In 2007, Maine launched the Whole House pilot plan designed to provide homeowners with a one-way stop to transform their homes into energy-saving dwellings capable of reducing energy costs, fuel consumption, and greenhouse gas emissions. Using a plan developed by Energy Star, the Whole House project initially targeted 1,500 homes in southern and central Maine. Proponents of the plan promise the residents of Maine that, by working with a certified Home Performance contractor, they will be able to reduce energy costs, improve family health and safety, increase comfort, lower carbon footprints, and increase equity.

Maine's Smart Tracks for Exceptional Performers and Upward Performers (STEP-UP) program offers recognition and incentives to businesses that become involved in sustainable practices designed to mitigate the results of global warming and climate change. Actions taken are dependent on the type of businesses involved in the endeavor. For instance, Pratt & Whitney, which manufactures aerospace engine parts in North Berwick, pledged to reduce total energy consumption by 10 percent, total air emissions by 20 percent, water discharge by 30 percent, and the total amount of transported solid waste by 30 percent by 2008.

Malawi

THE LANDLOCKED REPUBLIC of Malawi, formerly the British colony of Nyasaland, has a land area of 45,747 sq. mi. (118,484 sq. km.), a population of 13,925,000 (2006 est.), and a population density of 282 people per sq. mi. (109 people per sq. km.). About 34 percent of the country is arable, with a further 20 percent used for meadows and pasture. In addition, 50 percent of the country is forested.

As for the production of electricity in Malawi, 97 percent comes from hydropower, with only 3 percent from fossil fuels. The introduction of hydropower was remarkably recent, with the first water turbine and generator brought into the country in 1966 and installed at Nkula Falls on the Shire River in 1966, with plans having been drawn up for it as early as 1942. As a result of this reliance on hydropower, and the country remaining largely undeveloped, per capita carbon dioxide emissions were 0.1 metric tons in 1990, falling to 0.07 metric tons by 2003, far lower than most other countries in sub-Saharan Africa. Eighty-two percent of the total carbon dioxide emissions in the country are from liquid fuels, 6 percent from solid fuels, and 12 percent from the manufacture of cement.

By 1995, the population had reached the limit at which it could be sustained on the existing arable land of the country, and from then on, parts of the country experienced occasional shortages of firewood. The effects of global warming and climate change are expected to impact heavily on Malawi, which has already experienced periods of drought throughout its history, leading to migrations around Lake Nyasa. However, there are extensive underground water resources in the country, and these have been tapped since the 1950s, providing a water source that could help Malawi through a short period of drought.

The Malawi government ratified the Vienna Convention in 1991 and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, which they ratified in 1994. It accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on October 26, 2001, which took effect on February 16, 2005.

Geelong Grammar School, Australia

Malaysia

THE FEDERATION OF Malaysia, located in Southeast Asia, has a land area of 127,355 sq. mi. (329,847 sq. km.), with a population of 27,278,100 (2007 est.), and a population density of 213 people per sq. mi. (82 people per sq. km.). Three percent of Malaysia's land is arable, and 58 percent is covered in forests, although there has been a rise in the rate of deforestation from the 1980s.

With a large increase in industrialization, and the enlarging of manufacturing industry, the demand for electricity in Malaysia has increased considerably since the 1970s, with 88 percent of its electricity coming from fossil fuels, and only 12 percent from hydropower. As a result, electricity contributes to 28 percent of the country's carbon dioxide emissions, with 23 percent from manufacturing, and 28 percent from transportation. The latter figure comes from a high rate of private ownership of cars which, since the development of the Proton, has become more affordable for many people in the country, in spite of a relatively good system of public transport, mainly buses, covering much of the country. This has helped contribute to the fact that 54 percent of carbon dioxide emissions come from liquid fuels, 30 percent from gaseous fuels, and 6 percent from gas flaring (Malaysia has its own petroleum and natural gas industries). Solid fuels account for only 6 percent of emissions, with cement manufacturing making up the remaining 4 percent.

EFFECT OF GLOBAL WARMING

Malaysia has been affected in a number of ways by global warming and climate change. Rising temperatures have resulted in the bleaching of coral reefs along Malaysia's coasts, and have raised potential problems for marine life, especially fish and turtles (the latter nesting on some beaches in Terengganu, on Malaysia's east coast). Penang, off the west coast of Peninsular Malaysia, was affected by the Boxing Day 2004 Tsunami, and there has been increased risk of flooding in Sarawak and Sabah, leading to the possibility of a rise in insect-borne diseases such as malaria and dengue fever.

The Mahathir government of Malaysia ratified the Vienna Convention in 1989, and took part in the United Nations Framework Convention on Climate

Change signed in Rio de Janeiro in May 1992, which they ratified two years later. The Malaysian government signed the Kyoto Protocol to the UN Framework Convention on Climate Change on March 12, 1999, which was ratified on September 4, 2002, and took effect on February 16, 2005.

Justin Corfield
Geelong Grammar School, Australia

Maldives

LOCATED IN THE Central Indian Ocean, the Maldives is a country composed of more than 1,190 low lying coral islands, many of which contain a large number of endemic species. With no coal, oil, or natural gas reserves, the country is reliant on imported oil and domestic wood resources to meet the majority of its energy needs. As a result, the Maldives is not a major producer of greenhouse gases and is not a significant contributor to climate change. Despite this, the Maldives, like other small island developing states, is likely to be greatly affected by climate change.

The Maldives faces many of the development challenges confronting other small island states. These include geographic isolation, dependence on tourism, and reliance on coastal and marine resources. In addition, though the country's population is small in absolute terms, many of the islands have high population densities and the country's population is distributed among various islands. While these characteristics represent obstacles to economic development, they also render the country vulnerable to the impacts of climate change, particularly as the country has limited resources with which to offset its impacts.

Given its relatively large coastline, the Maldives is vulnerable to an array of marine threats such as wave surges, tropical storms, and coastal erosion. These natural phenomena are expected to increase in severity or frequency as a result of climate change and are therefore a source of growing concern. However, it is sea-level rise that poses the greatest threat to the Maldives. With a maximum elevation of 7.8 ft. (2.4 m.) above sea level, small fluctuations in sea level could render much of the country uninhabitable as a result of inundation and saltwater infiltration into agricultural soils and groundwater resources, necessitating the relocation of many of the country's inhabitants.

THREAT TO ITS EXISTENCE

The population and government of the Maldives have long been aware of the threat that climate change and sea-level rise in particular pose to their country. In numerous statements, the president of the Maldives, Maumoon Abdul Gayoom, has pleaded with the international community to reduce greenhouse gas emissions. For example, in his 1992 speech at the United Nations Conference on Environment and Development in Rio de Janeiro, Maumoon Abdul Gayoom highlighted that global climate change threatened the very existence of his country and that global concerted action was required to save the Maldives and other low lying countries. However, given the Maldives's modest political influence, the government's ability to bring about such reductions is limited. In addition, the Maldives has been actively involved in the Alliance of Small Island States (AOSIS), a lobbying and negotiating body representing the needs of small island developing states at the level of the UN. Through AOSIS, the Maldives has continued to lobby for reductions in greenhouse gas emissions globally.

Mali

THE REPUBLIC OF Mali is located in western Africa, covering 478,767 sq. mi. (1,240,000 sq. km.), equivalent to an area twice the size of Texas. Mali has a population of 12,291,529 people (2005 est.) with about 80 percent of the labor force engaged in agricultural production and processing. Mali is among the poorest countries in the world, with a per capita gross domestic product of $900 (2004 est.). 64 percent of the population lives in poverty. Significant agricultural products include cotton, cereal crops, vegetables, peanuts, and livestock. Three geographic and meteorological zones characterize Mali: Saharan (desert/arid), Sahelian (shrub savanna/subtropical); and Sudanese (wooded savanna/tropical). Likewise, there are three distinct seasons: hot and dry (March to May); rainy (June to October); and cool and dry (November to February). Temperatures in Mali can drop as low as 41 degrees F (5 degrees C) at night in January and then reach 104–113 degrees F (40–45 degrees C) during the day from April to June.

Five environmental issues facing the country are deforestation, soil erosion, desertification, inadequate supplies of drinking water, and the poaching of wildlife. Mali is a party to the following International Environmental Agreements: Biodiversity, Climate Change, Climate Change-Kyoto Protocol, Desertification, Endangered Species, Hazardous Wastes, Law of the Sea, Ozone Layer Protection, and Wetlands. Given that Mali is periodically prone to droughts, the general population does have some sense of climate change awareness, as older generations have witnessed significant changes within their lifetimes. The development priorities of the Malian government also include addressing climate change.

The contributions that Mali makes to human-induced climate change are minimal compared to the rest of sub-Saharan Africa and the world. For example, per capita carbon dioxide emissions in 1998 were only 100 metric tons, compared to an average of 800 tons for the sub-continent, and the global average of 4,100 metric tons. Likewise, sulfur dioxide emissions in 1995 totaled 14,000 metric tons (less than one-third of 1 percent of the entire total for sub-Saharan Africa), while nitrogen oxide and carbon monoxide emissions (also in 1995) represented just 0.006 percent and 0.007 percent, respectively, of the total for all of sub-Saharan Africa.

Climate change could have significant consequences for the people, environment, and development of Mali. Climatic change, leading to a shorter rainy season and higher average temperatures, would lead to desertification of currently farmed areas in the central part of the country. Less rainfall would also impede the country's ability to produce hydroelectricity, which is already a problem during the dry season. Also, the intensification of rainfall could have serious effects on soil erosion. Finally, changes in rainfall patterns may also lead to changes in cropping patterns and, ultimately, changes in people's livelihoods, as both farmers and herders retreat toward the south in search of arable land and grazing areas.

Malta

THE REPUBLIC OF Malta consists of three main islands in the Mediterranean Sea, and has a land area of 121 sq. mi. (316 sq. km.), consisting of the islands of Malta (246 sq. km.), Gozo (67 sq. km.), Comino (2.7 sq. km.) and the uninhabited islets of Cominotto, Filfla, and St. Paul. It has a population of 407,000 (2006 est.), and a population density of 3,339 people per sq. mi. (1,282 people per sq. km.), making it the 7th most densely populated country in the world. Although officially, 32 percent of the land is arable, with wheat and potatoes grown widely, the soil is poor.

Because of its hot temperature and extensive tourist industry, Malta has a relatively high per capita rate of carbon dioxide emissions, with 6.2 metric tons per person in 1990, rising to 8.7 metric tons per person in 1997, and then falling steadily to 6.2 metric tons by 2003. With 53 percent of all emissions in the country from electricity, heavily used for air conditioning, the entire electricity production in the country comes from fossil fuels, accounting for 40 percent of all carbon dioxide emissions coming from solid fuels. The remaining 60 percent of the carbon dioxide emissions is from liquid fuels, with transportation making up 15 percent of the country's entire emissions. In spite of its small size, there is a high private ownership of automobiles, many of which are increasingly old and inefficient in their use of fuel, resulting in heavy congestion and noticeable smog coming not only from traffic, but also from coal-fired power stations and factories.

The effects of global warming and climate change on Malta will be dramatic. The country already suffers from low agricultural production, and has shortages of water, resulting in Malta needing to build several large desalination plants, further increasing the strain on the power grid. It is also expected that rising temperatures in the Mediterranean might result in a decline in the number of fish, further hurting an already declining fishing industry. The Maltese government ratified the Vienna Convention in 1988 and took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. The government signed the Kyoto Protocol to the UN Framework Convention on Climate Change on April 17, 1998. It was ratified on November 11, 2001, and took effect on February 16, 2005.

Manabe, Syukuro (1931–)

AS A JAPANESE meteorologist generally regarded as the world's leading scientist in the field of numerical modeling of climate and climate change, Syukuro Manabe pioneered the use of computers to simulate global climate change and natural climate variations. Manabe was one of the first scientists to study the phenomenon of global warming in the 1970s, when he investigated the possibility that the emissions of great quantities of carbon dioxide and other greenhouse gases from the combustion of fossil fuels such as coal, oil, and natural gas could affect climate.

Born in 1931, Manabe graduated from the University of Tokyo in 1958. The post-war period was a difficult time for scientists in Japan. Manabe was among those who, like Akio Arakawa, found better career opportunities in the United States, where the Cold War kept steady government funding for fields such as geophysics and computer science. Manabe was hired as a researcher by Joseph Smagorinsky, then the director of the U. S. Weather Bureau near Washington, D.C. Smagorinsky wanted to develop the insights of John von Neumann and Julie Charney into a general circulation model of the entire three-dimensional global atmosphere, built directly from the primitive equations.

PIVOTAL MODEL

Smagorinsky and Manabe put into their model details that would be influential for the discovery of global warming. Their model accounted for the way rain fell on the surface and evaporated, how radiation passing through the atmosphere was impeded, not only by water vapor but also by ozone and carbon dioxide gas (CO_2), how the air exchanged water and heat with simplified ocean, land, and ice surfaces, and much more. Manabe had always been interested in the effects of CO_2, and the impact of CO_2 on the future climate. Manabe's interest stemmed from the consideration that the gas at its current level was a significant factor in balancing the planet's heat. When Fritz Möller theorized that even mild perturbations and human actions could cause a global catastrophe, Manabe decided to work on a model that might account for how the climate system might change. He came to the conclusion that the entire atmosphere had to be studied as a tightly interacting system. In his model, Manabe took full account of water in all its forms. It included the feedback between the air's temperature and the amount of moisture the air would hold. In particular, Manabe calculated the way rising columns of moisture-laden air conveyed heat from the surface into the upper atmosphere.

In 1967, Manabe used a one-dimensional model to test what would happen if the level of CO_2 changed. He targeted the climate's "sensitivity," a feature that would eventually become a central preoccupation of modelers. Together with his group, he set out to calculate how much the variation of incoming and outgoing radiation would alter temperature. The answer they reached was that if the levels of CO_2 doubled by the end of the century, as seemed possible, global temperature would rise roughly 3–4 degrees F (around 2 degrees C). This was the first time a greenhouse warming calculation included enough of the essential factors, including the correct estimate for water vapor feedback, to seem reasonable to many scientists. Many of them who were to play an influential role in global warming debates, such as Wallace Broecker, recalled that it was these data that made them embrace research into the phenomenon.

In 1968, Smagorinsky and Manabe's group, which had been renamed the Geophysical Fluid Dynamics Laboratory in 1963, moved from the Washington, D.C., area to Princeton, and it eventually came under the wing of the U.S. National Oceanic and Atmospheric Administration. Manabe continued to work, together with fellow meteorologists, on general circulation models of the atmosphere, trying to make them more complex and comprehensive. In 1967, he and Richard Wetherald demonstrated that increasing atmospheric CO_2 absorptions would increase the height at which the Earth radiated heat to space. In 1969, Manabe and Kirk Bryan published the first simulations of the climate which combined ocean and atmosphere models. This was the first time that the role of oceanic heat transport was taken into account in determining global climate. Throughout the 1970s and 1980s, Manabe's research group published influential papers using these models to explore the sensitivity of the Earth's climate to the variations of greenhouse gas concentrations. These papers formed a major part of the first global assessments of climate change, published by the Intergovernmental Panel on Climate Change (IPCC), established in 1988.

From 1997 to 2001, Manbe went back to Japan at the Frontier Research System for Global Change serving as Director of the Global Warming Research Division. In 2002, he returned to Princeton University as a visiting research collaborator at the Program in Atmospheric and Oceanic Science. During his distinguished career, Manabe has received many honors and awards. He is a member of the United States National Academy of Sciences, and a foreign member of Academia Europaea and the Royal Society of Canada. In 1992, he was the first recipient of the Blue Planet Prize of the Asahi Foundation. In 1997, Manabe was awarded the Volvo Environmental Prize from the Volvo Foundation. Manabe has also been awarded the American Meteorological Society's Carl-Gustaf Rossby Research Medal, the American Geophysical Union's Revelle Medal, and the Milutin Milankovitch Medal from the European Geophysical Society.

Marine Mammals

MARINE MAMMALS ARE members of the Class Mammalia possessing significant adaptations to allow them to live in an aquatic environment (to a greater or lesser extent) and derive all (or most) of their nutritional needs from the sea. Some marine mammals are entirely aquatic, while others may spend part of their lives on land. The polar bear, for example, is considered a marine mammal, as it typically inhabits pack ice (up to 807 mi., or 1300 km. from shore); it will attack prey in the water and relies almost entirely on marine species for prey; it has adaptations for a marine environment; and is able to swim long distances. Most significantly, the polar bear is dependent upon the marine environment ecologically.

Other marine mammals include two species of otter (Order Carnivora; family Mustelidae): the marine otter (*Lontra felina*) and sea otter (*Enhydra lutris*). *Myotis vivesi,* the marine-dependent fishing bat (Order Chiroptera), might also be considered to be a marine mammal. Less debatable marine mammals are the manatees and dugongs (Order Sirenia), whales, dolphins, and porpoises (Order Cetacea) and the various species of seal (Order Pinnipedia). The pinnipeds include true seals (family Phocidae), walruses (family Odobenidae), and eared seals (family Otariidae), the last of which, in turn, contains sea lions (sub-family Otariinae) and fur seals (sub-family Arctocephalinae).

There has been much concern about the impacts of climate change on marine mammals, particularly polar bears, cetaceans, and pinnipeds. Likely effects include shifts or depletion of important prey species, changes in distribution, exposure to new diseases and predators, and habitat loss. Several arctic-dwelling seal species haul out onto ice to give birth, and may be vulnerable to reductions in area, or thinning, of sea ice. Loss of ice as a haul-out substrate and fierce storms have led to several seasons of high harp seal pup (*Pagophilus groenlandicus*) mortality in the Gulf of St. Lawrence, Canada. As humans cull juveniles of this population, this adds an additional stressor to the population. Pinnipeds are also very well-adapted to cold temperatures and global warming may lead to heat stress.

Marshall Institute

THE GEORGE MARSHALL Institute (GMI) is a nonprofit organization founded in 1984. The mission of the Institute is to improve the use of science in making public policy about important issues for which science and technology are major considerations. Current research programs focus on such issues as national security and the environment.

The Marshall Institute seeks to counter this trend by providing policymakers with rigorous, clearly written and unbiased technical analyses on a range of public policy issues. Through briefings to the press, publication programs, speaking tours and public forums, the Institute seeks to preserve the integrity of science and promote scientific literacy. The Marshall Institute is located in Washington, D.C., and run by President Jeff Kueter as well as governed by a board of directors. Among the many programs at GMI is the climate change program. This program involves a critical examination of the scientific basis for global climate change policy. The intent is to promote a clear understanding of the state of climate science and assess the implications for public policy. A major component of this effort is communicating the findings to policy makers, the media, and the public policy community.

CONTROVERSY AND UNDERSTANDING

There has been an ongoing debate about the contribution of human activities to the global warming of the past century and how they may contribute to warming that may occur during the 21st century. International efforts to reach agreement on inferences about human influence on the climate system that can be drawn from science and policy prescriptions for addressing the climate change risk have been controversial.

Effective climate policy flows from a sound scientific foundation and a clear understanding of what science does and does not tell us about human influence and about courses of action to manage risk. Much of the data collected from temperature probes and computer models used to predict climate change are themselves uncertain. Reducing these many uncertainties requires a significant shift in the way climate change research is carried out in the United States and elsewhere.

The Institute has compiled a list of commonly asked questions and answers regarding global warming and climate change. These have been posted on the institute website to further educate the public and direct policy. GMI works on a range of issues, including civic environmentalism, climate change, national defense, bioterrorism, and missile defense. GMI publishes papers and holds roundtables. Many of these roundtables have featured climate change skeptics such as Roger Bate, Willie Soon, Margo Thorning, and GMI's own Sallie Baliunas.

In 1989, GMI released a report arguing that "cyclical variations in the intensity of the sun would offset any climate change associated with elevated greenhouse gases." Although it was refuted by the IPCC, the report was used by the George H.W. Bush Administration to argue for a more lenient climate change policy. GMI has since published numerous reports and articles attacking the Kyoto protocol and undermining climate science. GMI is a former member of the Cooler Heads Coalition.

Between 1985 and 2001, the institute received $5.5 million in funding from five foundations, including the Earhart Foundation, Sarah Scaife Foundation, and Lynde and Harry Bradley Foundation. In 2003, GMI's climate-change program received $95,000 from the Exxon Education Foundation, and $60,000 from the American Petroleum Institute. GMI's CEO, William O'Keefe, formerly an executive at the American Petroleum Institute and chairman of the Global Climate Coalition, is a registered lobbyist for ExxonMobil. The GMI was described in a 2007 report by the Union of Concerned Scientists as an ExxonMobil-funded "clearinghouse for global warming contrarians". ExxonMobil still continues to provide funds to the Marshall Institute.

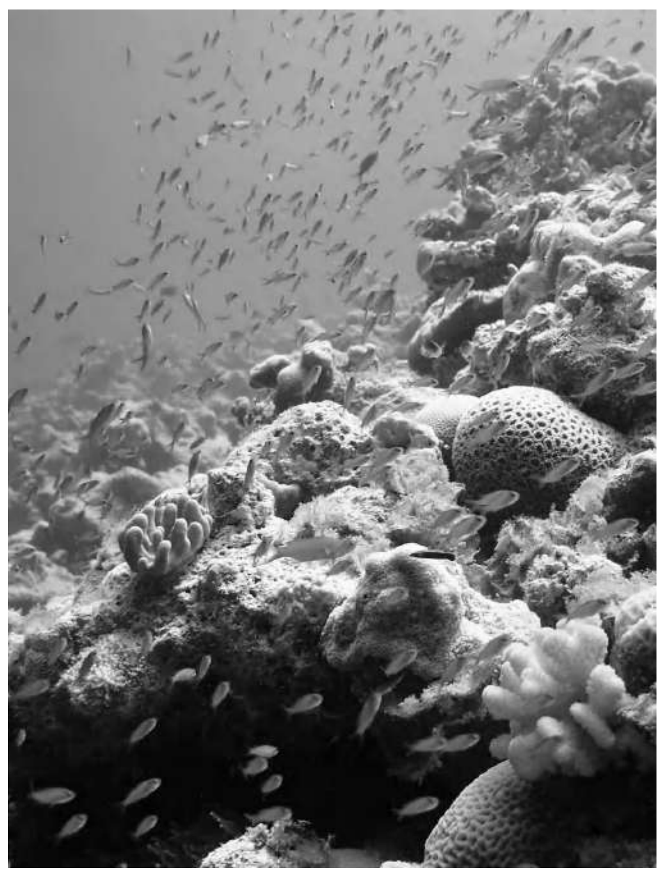
Fernando Herrera
University of California, San Diego

Marshall Islands

THE REPUBLIC OF the Marshall Islands (RMI) is a Pacific island nation that inhabits a fragile atoll ecosystem with no significant elevation above sea level. Susceptibility to tropical storms and economic dependence on coral reef ecology combine to produce a high risk that climate change will threaten the nation's survival. RMI can do little to ameliorate or reduce potential impacts. It is likely that land mass will be reduced, storm damage will increase, and the coral reef ecosystem will disintegrate with increasing ocean temperature, rising sea level, and atmospheric disturbances. RMI has been among the leading nations advocating a planetary response to these issues, most notably through testimony before the United Nations Climate Change Conference and UN Security Council, and active involvement in the Alliance of Small Island States. RMI consists of 29 coral atolls organized into the Ratak and Ralik chains in the western Pacific Ocean



Damselfish swarm around a coral reef in the Republic of the Marshall Islands, which consists of 29 Pacific coral atolls.

located between 2–14 degrees north and 160–173 degrees east. Total land area of RMI is 69.5 sq. mi. (180 sq. km.), with an average elevation of less than 6.5 ft. (2 m.). RMI population is 59,071 (2005 est.), with 38.2 percent of the population under age 15. The Marshallese are Micronesians who migrated from Asia several thousand years ago. More than half of the population is concentrated in two locations: Majuro, an atoll containing the capital city of Majuro; and Ebeye, an islet adjacent to the U.S. military base on Kwajalein Atoll.

RMI became an independent nation in 1986, but remains economically dependent on the United States due to historic and current military installations. Most commercial fishing is by licensed foreign fisheries. Small farms produce coconuts, tomatoes, melons, and breadfruit. Small-scale industry is limited to handicrafts, fish processing, and copra. Cultural integrity has historically been tied to land- and ocean-based food production. Environmental degradation accelerated by nuclear testing and military uses of some atolls complicates the challenge of developing sustainable lifestyles on these overpopulated, resource-poor atolls. The undeveloped economy results in low greenhouse gas emissions by the RMI.

Global climate change effects on RMI will include sea level rise, coral bleaching, saltwater intrusion, and the increased frequency of tropical storms. Solid waste disposal, availability of potable water, fisheries depletion, and overpopulation reduce the ability of the nation to react to climate change. For example, on March 21, 2007, the RMI government declared a state of emergency after a prolonged drought. Erosion of the extensive ocean/land interface, already escalating with a relatively small sea level increase, presents a serious challenge. Bleaching and coral death have interrupted the natural cycle of coral replenishment and may cause the collapse of the coral reef ecosystem. Prevailing wind patterns have largely protected these islands from severe tropical storm damage, but shifts in storm movement patterns are allowing more frequent and direct storms.

Western Illinois University

Maryland

MARYLAND HAS AN area of 12,407 sq. mi. (32,134 sq. km.), with inland water making up 680 sq. mi. (1,761 sq. km.) and coastal water making up 1,843 sq. mi. (4,773 sq. km.). Maryland's average elevation is 350 ft. (107 m.) above sea level, with a range in elevation from sea level on the Atlantic Ocean, to 3,360 ft. (1,024 sq. km.) at Backbone Mountain. Chesapeake Bay is an estuary (were salt water and fresh water meet). The Chesapeake region is a flat coastal plain, and the western edge has the Appalachian Mountains. The Chesapeake Bay divides Maryland in half. Maryland's three major land regions are the Appalachian Mountains, the Piedmont Plateau, and the Atlantic Coastal Plain.

The climate of Maryland is characterized by generally hot, humid summers and cool winters. In comparison with the eastern shore and other lowland areas, the upland sections in the west have colder and longer winters, and cooler and shorter summers. Baltimore's average annual temperature is about 55 degrees F (13 degrees C), with an average January temperature of 32 degrees F (0 degrees C), and an average July temperature of 76 degrees F (24 degrees C). The highest temperature recorded in the state was 109 degrees F (43 degrees C) on July 10, 1936 and the lowest temperature recorded in the state was minus 40 degrees F (minus 40 degrees C) on January 13, 1912. The average annual precipitation is 43 in. (109 cm.). The Atlantic Coastal Plain, warmed by the Gulf Stream, has a high humidity, with the majority of precipitation in the form of rain. Winter snowfall potential in the Appalachian Mountain region is 80 in. (203 cm.), but in the Piedmont Plateau it is only 10 in (25 cm.).

Tobacco is grown in the southern region. Much of the state grows corn, especially the Piedmont region. Soybeans are grown in the eastern region along with peaches, strawberries, and melons. Maryland's economy also relies on livestock and poultry, greenhouse products, and dairies. Manufacturing includes chemicals and scientific instruments, and mining is primarily for crushed stone.

IMPACT OF CLIMATE CHANGE

Maryland has already experienced rising sea levels (7 in. or 18 cm. per century in Baltimore) and beach erosion. Climate models vary on temperature increases for Maryland, from 1–7 degrees F (1.8–12.6 degrees C) in spring, and from 2–9 degrees F (3.6–16.2 degrees C)in summer, autumn, and winter by the end of the century. Potential risks include rising sea levels (affecting barrier islands, developed ocean front, the eastern shore of the Chesapeake Bay with freshwater and salt marshes, causing flooding, loss of coastal wetlands, beach erosion, saltwater contamination of drinking water, and damage/decreasing stability of low-lying property and infrastructure), decreased water supplies, population displacement, changes in food production with agriculture improving in cooler climates and declining in warmer climates, and change in rain pattern to downpours with the potential for flash flooding and health risks of certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents. Warmer temperatures can cause heat-related illnesses and lead to higher concentrations of ground-level ozone pollution, causing respiratory illnesses (diminished lung function, asthma and respiratory inflammation), especially in cities with smog, like Baltimore and the suburbs of Washington, D.C.

HUMAN-INDUCED CONTRIBUTIONS

Based on energy consumption data from the Energy Information Administration, Maryland's total carbon dioxide emissions from fossil fuel combustion in million metric tons for 2004 was 81.36, made up of contributions by source from: commercial, 5.00; industrial, 7.80; residential, 7.13; transportation, 31.01; and electric power, 30.42. Maryland passed legislation to join the New England and some mid-Atlantic states in the Regional Greenhouse Gas Initiative (RGGI), a mandatory cap-and-trade program. Carbon emissions from power plants will be capped at current level, 2009–15, and will be incrementally reduced by 10 percent before 2019.

The governor of Maryland established the Climate Change Commission (MCCC) on April 20, 2007 by executive order. The commission is made up of members of the Maryland Department of the Environment, the Maryland Energy Administration, and others affected by potential initiatives (such as businesses and energy providers) to assess climate change impact, develop a strategy for greenhouse gas and carbon footprint reduction, and recommend actions for reducing vulnerability to risks associated with climate change. Maryland joined the Climate Registry, a voluntary national initiative to track, verify, and report greenhouse gas emissions, with acceptance of data from state agencies, corporations, and educational institutions beginning in January of 2008.

Maryland provides tax credits for commercial developers meeting certain energy-efficiency standards, for generating and selling electricity from biomass, and for purchasing electric or hybrid vehicles. Additional legislation new in 2007 includes the Maryland Clean Cars Act, requiring stronger emissions regulations. The Maryland Green Council is tasked with advising policy makers on using environmentally friendly technology in future construction projects, and the Stormwater Management Act of 2007 will improve management of storm water runoff. On a local level, the city of Annapolis has created several environmental initiatives, including a commitment to replace the city vehicle fleet and public transit vehicles with alternative fuel vehicles and to search for renewable energy options.

The University of Maryland is setting an example for public and private sectors; the president of the university joined other college presidents and chancellors around the country in taking a community leadership role in minimizing global warming emissions. In addition to the Center for Integrative Environmental Research, the university is assisting regionally in understanding the complex challenges of global warming and developing information and research to supply to policy makers like the MCCC for creating strategies to mitigate global warming.

Independent Scholar

Massachusetts

MASSACHUSETTS HAS AN area of 10,555 sq. mi. (2,737 sq. km.), with inland water making up 423 sq. mi. (1,095 sq. km.), and coastal water making up 977 sq. mi. (2,530 sq. km.), and access to territorial water of 1,314 sq. mi. (3,403 sq. km.). Massachusetts's average elevation is 500 ft. (152 m.) above sea level, and most of the state is quite level. Massachusetts has several river systems, and many lakes, ponds, and reservoirs.

Massachusetts has a humid, continental climate, with long, hot summers and cold winters. New England weather and climate are influenced by latitude (warm, moist air from the south and cold, dry air to the north), coastal orientation (position within the zone of the westerlies), and elevation changes. The sea breeze circulation, particularly along the east coast, tends to mitigate frequencies and intensities of thunderstorms in the coastal zone, while bringing relief in the form of mild temperatures in the peak summer heat. In winter, these waters remain warm relative to land. Cape Cod and the islands of Martha's Vineyard and Nantucket experience cooler summers and warmer winters because of the moderating effects of the Atlantic Ocean. Annual average precipitation is 40–46 in (16–18 cm.) per year.

Massachusetts's agriculture includes diverse crops of cranberries, apples, corn, potatoes, and dairy products. Massachusetts has extensive commercial fishing, both in coastal waters and in the colder currents of more distant fishing banks, including the Grand Banks of Newfoundland and Georges Bank off Cape Cod.

IMPACT OF CLIMATE CHANGE

Massachusetts already experiences the effects of higher temperatures and rising sea levels with eroding coastlines. On average, 65 acres of land are submerged each year due to a combination of rising seas and subsiding land in the state, with much of the loss occurring along the state's south-facing coast, including along Nantucket and Martha's Vineyard. A blizzard in 1996 caused severe flooding.

Climate models vary for the Northeast on the amount of temperature increase during the 21st century, from 5–12 degrees F (2.7–6.6 degrees C) during the winter months, to 3–14 degrees F (1.6–7.7 degrees C) during the summer months. Anticipated rising sea level (7–14 in. [18–36 cm.] on the low-end, and 10–23 in. [25–58 cm.] on the high-end) is projected to increase shoreline erosion and wetland loss. Using these estimates, the city of Boston might expect a coastal flood equivalent to today's 100-year flood every two to four years on average by mid-century, and almost annually by the end of the century under either scenario. Sea-level rise is also projected to increase shoreline erosion and wetland loss, particularly along the vulnerable coasts of Cape Cod, and will exacerbate flooding in the Charles River basin from storm surges stretching the limits of Boston's aging wastewater infrastructure.

The commercial fishing industry will suffer with rising ocean temperatures, with a northward habitat shift of many fish and shellfish species like cod and lobster. Under either high-end or low-end emissions scenarios, cod are expected to disappear from the region's waters south of Cape Cod during this century, and lobster populations south of Cape Cod are expected to dwindle by mid-century. With higher emissions, the fishing grounds of Georges Bank will likely lose their cod stocks. Impact is more severe under the higher-emissions scenario, with heat stress in cows decreasing milk production and the climate no longer suitable for cranberries and some apple varieties. Weeds and pests would proliferate. Under the lower-emissions scenario, changes would be less severe. Higher temperatures are expected to increase the frequency of summer heat waves. Health risks associated with rising temperatures include a potential increase in certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents, and heat-related illnesses.

ADDRESSING HUMAN-INDUCED CONTRIBUTIONS

Based on energy consumption data from Energy Information Administration, Massachusetts's total carbon dioxide emissions from fossil fuel combustion in million metric tons for 2004 are 83.21, made up of contributions by source from: commercial, 6.54; industrial, 4.65; residential, 14.94; transportation, 33.41; and electric power, 23.67.

Massachusetts was the lead petitioner in a case on global warming that went to the U.S. Supreme Court. In this case, *Massachusetts, et al., v. EPA*, Massachusetts challenged the federal Environmental Protection Agency's refusal to regulate greenhouse gases under the Clean Air Act. On April 2, 2007, the court ruled in favor of Massachusetts. In May 2007, President George W. Bush announced that federal agencies, including the EPA, would develop regulations to reduce motor vehicle gasoline consumption and greenhouse gas emissions. Massachusetts's Greenhouse Gas reduction target is to meet 1990 levels of six greenhouse gases by 2010, be 10 percent below 1990 levels by 2020, and 75–85 percent below 2001 levels in the long term. Massachusetts adopted California's law requiring vehicle tailpipe emissions reductions of approximately 30 percent below 2002 levels by 2016, beginning with the 2009 model year. Current state regulations also allow the purchase of tax-deductible wind energy certificates from a wind company with a turbine in Hull, and Massachusetts Electric offers a renewable energy option for consumers to purchase renewable electricity from small hydro, wind, biomass, and solar sources in New England.

Massachusetts joined the Climate Registry, a voluntary national initiative to track, verify, and report greenhouse gas emissions, with acceptance of data from state agencies, corporations, and educational institutions beginning in January of 2008. Massachusetts has joined all the states in New England (as well as others in the mid-Atlantic area) in the Regional Greenhouse Gas Initiative (RGGI), the first multiple-state, market-based mandatory cap-and-trade program to reduce heat-trapping emissions from power plants. Carbon emissions from power plants will be capped at current level, 2009–15, and will be incrementally reduced by 10 percent before 2019.

Massachusetts Institute of Technology

THE MASSACHUSETTS INSTITUTE of Technology (MIT) is a private, coeducational research university located in Cambridge, Massachusetts. MIT has five schools and one college, containing 32 academic departments, with a strong emphasis on scientific and technological research. MIT is one of two private land-grant universities, as well as a sea-grant and space-grant university. The mission of MIT is to advance knowledge and educate students in science, technology, and other areas of scholarship that will best serve the nation and the world in the 21st century.

William Barton Rogers founded MIT in 1861, in response to the increasing industrialization of the United States. Although based upon German and French polytechnic models of an institute of technology, MIT's founding philosophy of "learning by doing" made it an early pioneer in the use of laboratory instruction, undergraduate research, and progressive architectural styles. As a federally-funded research and development center during World War II, MIT scientists developed defense-related technologies that would later become integral to computers, radar, and inertial guidance. After the war, MIT's reputation expanded beyond its core competencies in science and engineering into the social sciences, including economics, linguistics, political science, and management. MIT's endowment and annual research expenditures are among the largest of any American university. MIT graduates and faculty are noted for their technical acumen (63 Nobel Laureates, 47 National Medal of Science recipients, and 29 MacArthur Fellows), entrepreneurial spirit (a 1997 report claimed that the aggregated revenues of companies founded by MIT affiliates would make it the 24th largest economy in the world), and irreverence (the popular practice of constructing elaborate pranks, or hacking).

The Department of Earth, Atmospheric, and Planetary Sciences offer several undergraduate and graduate courses of study in the geophysical sciences: geology, geophysics, geochemistry, geobiology, atmospheric science, oceanography, climate, planetary science, and astronomy. More specifically, the Program in Atmospheres, Oceans, and Climate oversees a broad curriculum, with emphasis in three areas of study: Atmospheric Sciences, Climate, and Oceanography.

PROGRAMS AND INITIATIVES

The MIT Joint Program on the Science and Policy of Global Change is as an interdisciplinary organization, founded in 1991, that conducts research, independent policy analysis, and public communication on issues of global environmental change. The Joint Program combines the capabilities of two pre-existing MIT research centers: the Center for Global Change Science (CGCS) and the Center for Energy and Environmental Policy Research (CEEPR). It brings together an interactive group of faculty, staff and student researchers. Resources of the parent centers are strengthened by links to the Marine Biological Laboratory's Ecosystems Center in Woods Hole, Massachusetts, the MIT Climate Modeling Initiative, and other MIT environmental programs.

The MIT Joint Program's work is focused on the integration of natural and social science aspects of the climate issue, to produce analyses relevant to ongoing national and international discussions. Cooperative efforts engage it with leading research institutions and nonprofit organizations worldwide. Financial support is provided by an international group of sponsors from government organizations, foundations, and industry. The Program's cornerstone is the MIT Integrated Global System Model (IGSM) of economic and environmental change. The IGSM is a comprehensive research tool for analyzing potential anthropogenic global climate change and its social and environmental consequences. The IGSM includes consideration of climate science, technical change, and economic and social science, in an interacting set of computer models designed for study of the sensitivities and uncertainties that are crucial to policy evaluation.

MIT's Climate Modeling Initiative (CMI) is a collaborative effort among scientists in the Center for Global Change Science of MIT, to develop a state-of-the-art model of the atmosphere and ocean for study of Earth's climate. CMI is developing a new generation of climate model utilizing improved process models, which exploit our latest understanding of ocean, land, atmospheric and bio-geochemical processes, and new developments in algorithms, computing technology, and software design.

The Center for Global Change Science (CGCS) at MIT was founded in January 1990, to address fundamental questions about climate processes with a multidisciplinary approach. In July 2006, the CGCS became an independent center in the School of Science. CGCS's goal is to improve the ability to accurately predict changes in the global environment. The CGCS seeks to better understand the natural mechanisms in ocean, atmosphere, and land systems that together control the Earth's climate, and to apply improved knowledge to problems of predicting climate changes. The Center utilizes theory, observations, and numerical models to investigate climate phenomena, the linkages among them, and their potential feedbacks in a changing climate. CGCS builds on existing programs of research and education in the Schools of Science and Engineering at MIT. The interdisciplinary organization fosters studies on topics as varied as oceanography, meteorology, hydrology, atmospheric chemistry, ecology, biogeochemical cycling, paleoclimatology, applied math, data assimilation, computer science, and satellite remote sensing. The CGCS sustains a program of basic scientific research on the natural processes controlling global climate, with a concentration on the cycles, circulations and interactions of water, air, energy, and nutrients in the Earth system. The Center's research effort is focused primarily on five fundamental components of the global climate system.

CLIMATE AND ENVIRONMENTAL STUDIES

There are several suggested academic undergraduate programs leading to Bachelor of Science (S.B. or B.S.) degrees at MIT that can effectively accommodate interests in climate and environmental studies. The Department of Earth, Atmospheric and Planetary Sciences (EAPS), and its Program on Atmospheres, Oceans and Climate (PAOC) offer degrees in Physics of Atmospheres & Oceans and Environmental Science, both of which expose students to a wide range of Earth science topics, while allowing the flexibility to choose a specific area of focus. Similarly, the Department of Civil and Environmental Engineering (CEE) degree in Environmental Engineering provides a solid understanding of, and ability to apply the fundamentals of, the physical, chemical and biological sciences, treatment and control, economics, and public policy, as they relate to environmental engineering. A bachelor's degree from either EAPS or CEE provides an excellent foundation for graduate study and research in both basic and applied environmental science and engineering disciplines. Terrascope provides opportunities for first-year students to explore basic science and engineering concepts through the study of Planet Earth. Both major and minor degree programs are offered by CEE, EAPS, and PAOC. Several undergraduate research opportunities for hands-on field studies and laboratory work are also available. All MIT undergraduate students are strongly encouraged to become involved in research through the Undergraduate Research Opportunities Program (UROP).

Mauritania

LOCATED IN WEST Africa, and a former French colony, Mauritania has a land area of 397,954 sq. mi. (1,030,700 sq. km.), a population of 3,124,000 (2006 est.), and a population density of 7.8 people per sq. mi. (3 people per sq. km.). It is one of the most sparsely populated countries in the world. The Sahara Desert covers much of the country, with less than 1 percent of the land arable, and 38 percent used for low-intensity meadows and pasture. Some 5 percent of the country is forested, mainly with gum arabic, which is the major cash crop of the country.

Regarding electricity production in the country, some 84.4 percent comes from fossil fuels, with the remainder from hydropower. However, electricity usage in the country is extremely low, and per capita carbon dioxide emissions also remain low, ranging from 1.3 metric tons per person in 1990 to 0.87 metric tons per person by 2003. Overall, 98 percent of the carbon emissions in the country come from liquid fuels, with the remainder from solid fuels and cement manufacturing.

Mauritania has suffered much from deforestation, and there is the likelihood that climate change and global warming will lead to further desertification, leading to a decline in agricultural production. Rising sea levels could lead to the flooding of Nouadhibou (formerly Port Étienne, the country's former capital). The deliberate stranding of ships off the coast of Nouadhibou has only added to the environmental problems there. The Mauritanian government of Maaouya Ould Sid'Ahmed Taya took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, ratifying the Vienna Convention two years later. The government accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on July 22, 2005; it took effect on October 20, 2005.

Mauritius

THE REPUBLIC OF Mauritius, located in the Indian Ocean, has a land area of 787 sq. mi. (1,860 sq. km.), a population of 1,262,000 (2006 est.), and a population density of 1,564 people per sq. mi. (616 people per sq. km.). About 49 percent of the country is arable, with a further 3 percent used for meadow and pasture. An additional 31 percent of the island is wooded, with extensive forest plantations.

Regarding electricity production in the country, 91 percent of it comes from fossil fuels, with the remaining 9 percent from hydropower. In 1990, Mauritius had a per capita carbon dioxide emission rate of 1.4 metric tons per person, rising to 2.6 metric tons per person by 2003. Ninety percent of these emissions come from the use of liquid fuels, with the remainder from solid fuels.

The effects of global warming and climate change will have a major impact on Mauritius. The rise in the temperature of the Indian Ocean is likely to have a serious adverse effect on the coral reefs located around the island, with those to the north of the island particularly popular with tourists. There is also the possibility of increased flooding of low-lying parts of the country, especially around Grand Baie.

In 1990, the World Bank was critical of the lax environmental laws in Mauritius, and the government responded by quickly establishing a Ministry for the Environment. The government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention in the same year. On May 9, 2001, it accepted the Kyoto Protocol to the UN Framework Convention on Climate Change, which took effect on February 16, 2005.

Maximum Sustainable Yield

MAXIMUM SUSTAINABLE YIELD is a term population ecologists and economists use to define the theoretical top catch or yield of a species that can be taken indefinitely without depleting the population. The maximum sustainable yield is assumed to be half of the carrying capacity of a species. Commonly, the maximum sustainable yield is more than the optimum sustainable yield, which ends when yield is no longer economical.

Maximum sustainable yield is a long-term management approach, not a crisis recovery method. The European Union (EU), for instance, uses it for all stocks, not just those that are approaching unsustainability. According to the logistic model of growth, population in a new habitat, or one that is depleted will initially experience a slow growth rate, but will grow rapidly once it reaches a foothold level. Rapid growth will slow when the population nears the carrying capacity of the habitat. The goal of maximum sustainable yield is to raise or lower population to the level where the highest growth rate is most likely. The new population level should be capable of indefinite maintenance. Maximum sustainable yield is highly variable, depending heavily on weather-influenced factors. Global warming affects maximum sustainable yield by altering the weather.

BACKGROUND

A sixth of the Earth's population depends on the sea for over a third of its animal protein (the world average is 16 percent). Fishing and processing employs 200 million people worldwide. The current annual catch is about 88 million U.S. tons, or 80 million metric tons. The total is down from 1989, the peak year with 86 million metric tons. The 1989 catch culminated a 50-year process in which the catch rose by a factor of four. However, the world total conceals the disparities in different parts of the world—the Indian Ocean catch continues to rise, while 13 of the 15 major areas have shown declines (the Atlantic cod catch is down by a factor of almost three since 1970.)

In November 1992, a collection of scientists warned that nature and humanity were on a collision course because of the damage human activity was doing to the environment and resources. They warned that unless change occurred, humanity risked creating a world incapable of sustaining life as we know it. They said that Earth had too many people. The scientists warned of atmospheric damage from ozone depletion, air pollution, and acid rain. They noted critical depletion of the water supply, putting world food production at risk. They cited soil depletion that degraded land and cut food production. They decried the loss of tropical rainforests. They also talked of the destruction of ocean life, particularly the world's supply of food fish. They noted that the world's farmers, industrialists and urbanites were sending pollutants into the oceans, that fishermen were taking more than the maximum sustainable yield, and some fisheries were showing signs of collapsing. They calculated that by 2100, upwards of one-third of all extant species might disappear. Among other steps to prevent the disaster, humanity needed to find alternatives to fossil fuels, become more efficient in using nonrenewable resources, and manage critical resources more effectively. The developed world had to help the undeveloped world to make these changes.

The earlier approach to fisheries management was to keep stocks from falling too low. At the World Summit on Sustainable Development in Johannesburg, in September 2002, EU members agreed to limit fishing to sustainable levels, and to maintain or restore stocks to maximum sustainable yield levels. The goal was to replenish depleted species by 2015. The attendees also committed to act against illegal, unregulated, or unreported fishing, another priority. Four years after the agreements, the EU reported that it had many species outside safe limits. According to an International Council for the Exploration of the Sea (ICES) analysis, 81 percent of the stocks in the northeast Atlantic and adjacent waters were over-fished, some as much as five times maximum sustainable yield. The EU implementation of maximum sustainable yield sought to maximize the catch without endangering the stock. The EU noted that small stocks could provide only small yields, because too few adults were available to replenish the stock. When stock was too great, reproduction slowed because of lack of food and decreased competition. The maximum sustainable yield lies between too small, and too large.

NATURAL CAUSES AND HUMAN IMPACT

Maximum sustainable yield is common in fisheries management. In modern fisheries, maximum sustainable yield is around 30 percent of the unexploited population, but it varies depending on the life history of the species and the fishing method chosen.

The stock of a given type of fish varies over time, from natural causes and human impacts. A fishing fleet that has doubled in the past 25 years suffers when the variation is adverse, and as the catch trends down for commercially valuable varieties, concern arises that the ocean may not be able to supply the protein need of an ever-growing population without conservation and management. There are increasing disputes over who gets to fish for how much in which waters at which time of year—jurisdictional rights versus open access. There are disagreements over how many fish are left. Estimates are notoriously unreliable, because too many uncontrollable factors affect the total. Particularly important are environmental changes, which can affect mortality in larval fish and significantly impact the grown population. Factors include the number of predators, the available nutrients, and the temperature of the water. Water temperature is critical because fish can not regulate their own body temperature. Warming and cooling encourage populations to move to more suitable waters. Turbulence also affects the supply by putting the larvae at a disadvantage against larger and less susceptible predators. Turbulence changes reflect, among other factors, changes in regional climate.

The EU implemented maximum sustainable yield through long term plans prescribed by the Common Fisheries Policy, plans that define the fishing rate and the rate of annual adjustment. The approach was gradualist to avoid short-term harm to the fishing industry, while the changes took place. The EU also authorized closing fishing areas and restricting types of fishing gear on a case-by-case basis. Before implementing any plan, the EU prepared a

Scientists have warned for over a decade of a critical depletion of food fish production due to the destruction of ocean life.

social and economic impact statement. Maximum sustainable yield was assumed to keep stocks from collapsing, reducing discards of too small/too low value/caught beyond quota fish. It was also expected to reduce by-catches and cut down on impact on the environment. After the initial reduction to allow fish to grow, fishing could resume with presumed lower costs and greater profit, as catches of larger/better fish cut down fishing time and fuel consumed. The EU, in 2006, was dependent on imports for 60 percent of its fish products.

CLIMATE CHANGE

The Intergovernmental Panel on Climate Change (IPCC) released a study on probable impacts of greenhouse warming. Acknowledging that impacts vary from species to species, and that climate change models are only approximate, the IPCC predicted that global warming will have a small impact if global warming impacts are restricted to changes in surface temperature.

Warming will have a greater impact if local economic impacts of shifting fisheries are taken into account. The global total catch should remain about the same because the fish can move easily. The regions where fishing is viable will change, as will the species available, because some species are more susceptible to warming than others. A more significant impact could be the climate change that could alter winds, thereby changing currents and modifying the flow of nutrients and larval fish. Warming's rising waters would alter the area near shore or in river mouths, changing the ecosystem and modifying the types of marine life.

Determining maximum sustainable yield can be inaccurate when insufficient data are available. Miscalculation of the sustainable yield of roughy occurred in New Zealand when initial quotas assumed that the species lived a relatively short life and bred quickly. In fact, the roughy lives 30 years and breeds slowly. By the time this was known, the available roughy stock was mostly gone. That climate change affects maximum sustainable yield is indisputable, but exactly what the impacts will be is disputed, because sufficient data are not yet available.

Measurement and Assessment

MEASUREMENT AND ASSESSMENT issues are central to debates about the nature and impact of global warming. Global warming models require information about the parameters in these models (measurement) and exploration of the meaning of the predicted results (assessment). Inference, lack of replicability, cyclical variables, and parameter attributes all shape these models and their predictions. Models can be attacked or defended, based primarily on their underlying measurements and assessments; thus, it is vital to understand the role measurement and assessment have in building and understanding these models.

The essence of science is the development of ideas that produce predictions to explain measurable phenomena. Measurement and assessment are central components of this process. The difference between these two concepts is tied to the modeling concept: measurement refers more to the evaluation of phenomena, and assessment refers more to the evaluation of models. Another link is the quality of the measured data: it is impossible to produce detailed assessments if the measurements are not detailed.

THREE ATTRIBUTES

It is axiomatic that any parameter has three attributes, only two (any two) of which can be simultaneously maximized. Furthermore, the more the third is minimized, the more the other two can be maximized. These three parameters are precision (minimizing the variance of the parameter), accuracy (the congruence between the calculated value of the parameter and the actual value of the parameter), and generality (the degree to which the parameter can be applied to a wide range of scenarios).

Two complications in the development and assessment of global predictive models are the nature of both reductionistic and experimental approaches. First, science is particularly good at a reductionist approach, that is, to isolate a situation as much as possible and manipulate or explore it to understand it better. However, the planet is not particularly amenable to attempts to isolate one segment of its atmosphere. Second, experimental approaches use multiple subjects to test the effects of changes in variables. Experimental approaches produce models that most confidently assess the predictive power of the model being tested because other variables are controlled. Situations in which experimental manipulation of variables is impossible or unethical (for example, many medical questions) are normally solved by the application of multivariate statistical techniques to extremely large groups of subjects. Planetary questions, such as global warming, are not desirable questions to be answered experimentally; the sample size is currently set at one planet.

Experimental approaches are not ethical or feasible, nor is it feasible to obtain multiple planets (unless additional planets are assigned to experimentation). However, situations such as these are still within the realm of scientific investigation, particularly through the use of inference and model assessment and calibration. The precision, accuracy, and generality of such results are both more difficult to determine and more likely to be challenged by skeptics. Evolution, global warming, and various factors influencing human health are all examples.

CLIMATE MODEL MEASUREMENT, ASSESSMENT

The modeler's ideas about relationships among variables need to be specified as precisely as possible. The actual variables have to be measured, the model implemented, and the results determined. Then, model assessment requires: the systematic testing of the degree of influence each parameter put into the model has upon the output. Typically, modeling is an iterative process, in which the assumptions of the model are sequentially considered and more powerful models that reduce the stochasticity or the probable impact of assumptions on precision, accuracy, or generality are reduced. Just as with other variables, assumptions can maximize two of the three attributes; typically, as with other aspects of the scientific method, modelers prefer to reduce generality. Thus, for example, more complicated models that consider each tree separately have replaced models of forest dynamics that treated forests as blocks of area. Models of global climate divide the globe into different areas. Each area has its own dynamics driven by the various parameters modeled, and each area impacts adjacent areas. The size of these areas within climate models has steadily decreased, and the number of parameters and the complexity of the interactions between areas have increased.

Because of lack of computing power, the tension among the three parameter attributes, and the amount of stochastity within complex systems, models themselves cannot be precise, accurate, and generalizable. Models are usually wrong in some way, but even a "wrong" model can still have substantial conceptual and scientific value. Models are especially good at identifying areas of weakness in understanding, areas that will be productive avenues for further research.

Within the context of global warming models, an additional challenge is the incorporation and assessment of cyclical variables. Cyclical variables are difficult to understand because they are constantly changing. A clear understanding of a cyclical variable should include a reasonable mechanistic explanation for the cycle, the periodicity, and the magnitude of variation. Global warming models are particularly complicated because there are multiple cyclical variables, each with its own mechanism, periodicity, and variation. For instance, sunspots, carbon dioxide, and climatic variation (both annual and era) have some degree of cycling. A comprehensive model, thus, needs to incorporate both stochastic variation and periodic variation for each of these variables. It is particularly hard to effectively incorporate a cyclical variable when the periodicity is much greater than the range of time during which measurements have been obtained.

These difficulties do not invalidate attempts to model global climate patterns. Science is not just the art of exploring easy problems. Computational power, the collection of more and better measurements, and richer forms of assessment (such as comparisons between different models through the development of metamodels) all contribute to a deeper understanding of the planet. Measurement and assessment are important issues and are not insurmountable obstacles.

Media, Books and Journals

ISSUES RELATED TO climate change and global warming have been an important part of scientific literature. These questions have been brought from academic circles to the public sphere. For example, an article on global warming appearing in a newspaper such as the *Wall Street Journal* is likely to reach an immediate audience, even though this newspaper is not an academic science publication.

BOOKS AND ENCYCLOPEDIAS

In the 21st century, books have posed emerging theories of climate change, in some cases beyond basic debates about the existence of global warming. Many contemporary scientists claim to have published the "first book on climate change," however, French mathematician Jean Baptiste Fourier (1768–1830) first theorized the greenhouse effect in 1827. In 1989, Bill McKibben wrote what is often regarded as one of the first modern books on climate change, titled *The End of Nature: Humanity, Climate Change and the Natural World*. Before he released his famous book, *An Inconvenient Truth* (with the same title as his popular documentary), Al Gore published a similar lesser-known book, *Earth in the Balance: Ecology and the Human Spirit*.

Among prior encyclopedias produced on climatology are John Oliver's *The Encyclopedia of Climatology*, and the 1996 illustrated *Encyclopedia of Climate and Weather*, edited by Professor Stephen Henry Schneider. Among the new interdisciplinary encyclopedias is Paul Robbins' *Encyclopedia of Environment and Society*.

JOURNALS ON CLIMATE CHANGE

Scientific journals about climate have existed for centuries, but in the 21st century, some have focused solely on climate change and global warming. Among these are the *Journal of Climate*, the interdisciplinary journal *Climatic Change*, and the journal *Global Environmental Change*. The journal *Climate Policy* is published in the United Kingdom. In France, scientific journals and popular magazines often carry articles on global warming, such as in *Science et Vie*, and *Pour La Science*. Such journals do not include sensationalistic media coverage on global warming that has been recently labeled "climate pornography," because of its alarmist language and impressive, sometimes graphic images of catastrophic climate change.

BOOKS FOR CHILDREN

A bestseller book on global warming written for children is Laurie David's and Cambria Gordon's *Down-to-Earth Guide to Global Warming.* Another book for children, *Who Says Kids Can't Fight Global Warming?*, by Patrick Harrison and Gail Bunny McLeod, explains everyday efforts that children can make in order to reduce consumption, waste, and therefore pollution and global warming.

CHALLENGING THE IDEA OF GLOBAL WARMING

Many books, not always written by scientists or experts, bring a divergent theory or highlight contradictory arguments to the concept of global warming, such as S. Fred Singer's and Dennis Avery's *Unstoppable Global Warming: Every 1,500 Years*. The authors express doubts that the 1,500-year climate cycle can be changed or controlled. In the French book titled *Ecologie, La Grande Arnaque* (translated as *Ecology, the Big Hoax*), the president of the French Automobile Club, Christian Gerondeau, argues that ecological problems and global warming are real, but the solutions and ongoing strategies made by the French state are neither adaptive nor efficient.

RECENT THEORETICAL FRAMEWORKS

Many academics in social sciences agree that these issues related to environmental threats will remain for a long while. For instance, in his book, *Postmodern Climate Change*, Leigh Glover argues that the ongoing climate crisis will never be resolved, but will remain an environmental issue for decades, as it has since 1970, mainly because we seem to live in an "international climate change régime."

In the book *The Social Construction of Climate Change: Power, Knowledge, Norms, Discourses*, the contributors do not propose responses, but argue that climate change is socially made and remains a matter of knowledge and power.

Unless they have great interest in the topic, most people are not likely to read books on climate change and global warming, so they may be reliant on what they read in popular magazines and the mass media. Therefore, they might only get a partial view of this complex phenomena.

Media, Internet

THE SCIENTIFIC COMMUNITY has considered media coverage about science, in general, as inadequate, and coverage about global warming and climate change, in particular, as distorted. Scientists have maintained that their consensus about the causes and consequences of global warming has been overshadowed by coverage that portrays global warming as a source of scientific controversy and debate. The peer-reviewed findings of the Intergovernmental Panel on Climate Change represent more than 2,000 scientists from 100 countries who have reached the joint conclusion that the burning of fossil fuels is causing significant climate shifts, findings that have been substantiated by the National Academy of Sciences, among other prestigious scientific bodies.

Nonetheless, the media have tended to give importance to climate change skeptics. For example, the Western Fuels Association, a cooperative that supplies coal to consumer-owned electric utilities, hired such detractors, including scientists Robert Bailing, Patrick Michaels, and S. Fred Singer, as spokespersons in the early 1990s, as part of a strategy to shift the focus of global warming from fact to speculation. By 1997, only 22 percent of respondents in a *Newsweek* poll indicated that they worried a large amount about climate change, down from 35 percent in 1991, before the Western Fuels campaign began. Although mass media are not the only avenues which shape public opinion, it affects public perceptions, and, in turn, public policy. Western Fuels ultimately sued environmental groups for publicly linking global warming to the burning of fossil fuels, but the U.S. federal district court in Wyoming dismissed the suit.

A comparison in 2000, climate change coverage in major newspapers found that global warming received three times more coverage in the United Kingdom than in the United States. In the United States, Andrew Revkin of the *New York Times* has been praised as one writer who has covered global warming steadily. Additionally, it was not until 2004 that the Weather Channel began citing global warming in relationship to its projections. In recent years, however, awareness of global warming has grown and the media have begun to cover climate change more expansively. In those countries with greater media coverage, the public are more concerned about the effects of global warming. A 2007 study found that citizens in Brazil, where media coverage of global warming is regular, are among those most concerned about global warming in the developing world; South Korea's citizens are among the least concerned.

INTERNET COVERAGE

In January 2007, following a report by the United Nations, global warming ranked in the top 5 percent of news stories for the first time. In addition to traditional news sources, technology has significantly increased the number of options for obtaining news and information. Among these options are blogs, online journals that are frequently updated and published in reverse chronological order. Blogs have been in existence since the late 1990s. Numbers suggest that each day, more than 12 million American adults contribute to blogs, and more than 7 million Americans read them. In a situation that parallels other news media formats, however, much of the content is not original, less than 5 percent in the case of blogs.

In 2004, blogs became increasingly commonplace. In an effort to combat the failure of the media to effectively cover the common consensus about global warming shared by scientists worldwide, nine climate scientists launched RealClimate in December 2004. RealClimate was designed as a climate science site by working climate scientists for journalists and members of the public. The site has won a number of awards, including a 2005 Science & Technology Web Award by *Scientific American*, and recognition by the *Guardian Unlimited* as a Top 10 Environmental Site. The scientists' goal is to provide rapid rebuttals to distortions about climate change, often made by American-based, industry-sponsored think tanks.

Music Television (MTV) generated interest in global warming by implementing a yearlong, daily public service announcement campaign, "Break the Addiction," on Earth Day in 2006. The campaign included daily suggestions on changes viewers could make to lead more environmentally friendly lives, coupled with educational messages about the reasons for, and consequences of, climate change and the political context in which climate change issues are addressed.

Additionally, MTV included a monthly online segment featuring young people making a difference in environmental issues. MTV estimated nearly 90 million households had potential contact with the campaign each day, and one million people turned to www.think.mtv.com as an additional resource about global warming. In 2007, *CNN News* further demonstrated the significance of the internet on American politics by selecting those questions that would be used in a televised presidential debate from among almost 3,000 questions posted to YouTube, a video-sharing website created in 2005, and ranked as one of the top sites in 2006, attracting close to 20 million visitors per month. An analysis of data by Hitwise, the leading online competitive intelligence service, found that online searches for environmental information increase alongside greater media coverage about environmental issues. During the most recent two-year period studied, online searches for information about global warming by internet users in the United Kingdom increased by 22 percent. Much of the online searching directed users to websites based in the United States, which suggests that U.S. sites potentially have greater influence on the public, and subsequently on policymaking, than do UK sites.

Paralleling earlier findings in the United Kingdom, Hitwise data indicated that Australian internet users visited former U.S. Vice President Al Gore's website at a significant rate when he was making media appearances in Australia in September 2006 to promote his documentary, *An Inconvenient Truth*, which later won the Academy Award for best documentary film. Hitwise also determined that Australian internet users searching for climate change information are more likely to be redirected to media and government websites, while those searching for global warming tend to visit environmental and educational sites. The question raised by these data is whether or not climate change is now viewed as the more emotionally charged term, which, when thought to be more benign, was the term of choice by U.S. President George W. Bush, and, subsequently, viewed as representing the interests of industry and political conservatives.

In late 2006, ACNielsen, the world's leading marketing-information company, surveyed more than 25,000 internet users in almost 50 markets about global warming. Of those questioned, 91 percent were aware of global warming, and more than half considered global warming to be a critical issue. Internet users most aware and concerned about global warming were those from countries most affected by the consequences of climate change. The three countries that ranked the lowest in awareness were the United Arab Emirates, where 18 percent of consumers said they had not heard of global warming, followed by the United States, with 13 percent, and Malaysia with 11 percent. Latin Americans ranked with those consumers most likely to believe that global warming is the direct result of human activity, and the users from Eastern Europe, the Middle East, and Africa followed closely. Research suggests that greater media coverage and increased awareness by individuals, however, do not inevitably lead to changes in individual behavior.

EVALUATING ONLINE INFORMATION

With the increasing availability of websites that focus on global warming, the complexity of scientific issues, and the presence of climate change skeptics disputing the consensus of the scientific community, a critical issue for internet users searching for reliable information is the evaluation of online resources. Accuracy and objectivity are critical to sound information. Graduate programs in library and information science routinely incorporate website evaluation and analysis as components of their curricula. Additionally, public and academic libraries post evaluation criteria on their own websites and teach patrons how to assess online information through individual user instruction or group orientation sessions. Johns Hopkins University, for example, offers not only website evaluation criteria, but an introduction to information counterfeits, including: propaganda, misinformation, and disinformation, on its library's website.

According to this overview, propaganda is frequently misused because of its pejorative historic context. Propaganda is often thought of as information with no basis in truth, when, in actuality, it is the representation of the facts in a manner to solicit a specific response that defines propaganda as such. Misinformation, on the other hand, is not based in facts. Misinformation is not an intentional effort to mislead, but is simply incorrect information passed from one person to the next. Urban legends, which are untrue tales, comprise much of the misinformation online. Disinformation is the intentional propagation of false information, often with the purpose of influencing the media and the public to gain support for a political or policymaking position. The internet may be fertile ground for disinformation, but it is most likely the propaganda found online that scientists and scholars have attempted to debunk.

The number of factors recommended for analyzing a website can be as few as five or more than 20. Generally, however, criteria can be reduced to 10 categories: the publisher, author, currency, audience, perspective, content, quality, style, organization, and stability. The publisher of the website is critical, particularly if the site does not credit authors for their content. The publishing body should be recognizable and reputable.

Online searches for environmental information increase alongside greater media coverage about environmental issues.

There should be a link on each page of the site back to the home page and a link to email the webmaster. The authors' credentials are also central in determining whether or not a site should be used as a reliable, authoritative source. There should be information about the authors or links to other documents about and by the authors. The perspective of the site should represent an objective, balanced presentation of information. If there is an intended bias, then it should be clearly stated on the site. Government sites reflect the positions and policies of government leaders, just as industry sites represent the positions of corporate interests, although the perspectives of each may not be clearly defined. The user must sift through information to determine bias on these sites, as well as those representing other public and special interests.

The currency of the site refers to the frequency of updates. Dates of revision to the site as a whole and to the site's individual web pages should be posted.

Frequent updates are important if the site provides time-sensitive information. If a page or site has not been revised for some time, then it is possible that it is an orphaned page, or a site that has been superseded. The audience refers to the primary users of the site and the target audience. The intended users should be readily apparent on the site.

The stability of the site and its overall quality, including obvious faults, known errors, or inconsistencies, also play a central role in determining whether or not the site is credible. Finally, the site should be well organized, user-friendly, and easy to navigate. These factors influence the decisions by users on whether or not to return to sites. Sites with valuable reliable information are not useful if the users cannot find what they need.

RECOMMENDED WEBSITES

There is a profusion of websites about climate change and global warming. Even with evaluation criteria, choosing among them can be difficult for internet users. There are a number of portal sites that provide links to information on a wide range of topics, including environmental science. These sites link to other sites that have been reviewed by information professionals and subject specialists.

For example, Intute, created by a network of universities and partners in the United Kingdom, contains more than 300 pages with information about global warming. Multiple pages may be found on the same site, so the number of websites is actually lower. Bulletin Board for Libraries (BUBL), prepared by and maintained at Strathclyde University in Glasgow, Scotland, links to nine individual websites about global warming, including those of the U.S. Environmental Protection Agency, the World Wildlife Fund, and the Public Broadcasting Service. BUBL links to 30 sites about climate change, but there is some duplication of these sites and the sites about global warming.

The Internet Public Library, founded by the University of Michigan School of Information, and now maintained by the College of Information Science and Technology at Drexel University, with support from the College of Information at Florida State University, includes approximately 200 entries about global warming and 133 about climate change, with some repetition among the sites. The Librarians' Internet Index, a publicly-funded, librarian-maintained website with more than 20,000 entries, includes more than 70 sites about global warming and 70 about climate change, but includes duplication of sites.

Each year, the Reference and User Services Association (RUSA) publishes a list of Best Free Reference Websites. RUSA is a division of The American Library Association, the oldest library association in the world, and the largest, with more than 65,000 members. RUSA's combined index includes Earthtrends: the Environmental Information Portal by the World Resources Institute (2004); GrayLit Network: A Science Portal of Technical Reports by the United States' Department of Energy's Office of Scientific and Technical Information (2005); the Internet Public Library (1999); Librarians Index to the Internet (2000); U.S. National Aeronautics and Space Administration (2003); National Weather Service of the U.S. National Oceanic and Atmospheric Administration (2006); The *New York Times* on the Web (2003); and *Science Daily* Magazine (2004).

In the late 1990s, the environmental resources librarian at Harvard College Library identified a number of websites representing campus initiatives online, many of which are still viable sites today. Among those listed were the National Wildlife Federation, Second Nature, and the Institute for Sustainable Development. Stanford University's recommended internet resources also include the National Wildlife Federation, in addition to EcoNet, National Institute of Environmental Health Services, and Earth Trends.

The State University of New York at Buffalo has a comprehensive list of recommended sites about global warming that encompass domestic policy issues, international policy issues, New York State, data relevant to specific sites, materials for teachers and students, and guides to additional information. The list is thoroughly annotated and included among its recommendations are: Community Planning and Development: Environment, the U.S. Department of Housing and Urban Development; Office of Community Viability; Congressional Research Service Reports, National Council for Science and the Environment; the U.S. Environmental Protection Agency, which includes links to 250 documents about climate change, representing a broad range of local, national, and international websites; the National Library of the Environment, National Council for Science and the Environment; Environment: United Nations (UN) System Pathfinder, UN Dag Hammarskjöld Library; the World Bank, and the World Resources Institute.

The Petroleum and Energy Resources Division of the Special Library Association (SLA) published its own list of recommended online resources in August 2007. Al Gore was a keynote speaker at the SLA's annual conference. Suggested publications could be found at websites by the Intergovernmental Panel on Climate Change; The Climate Institute, based in Washington, D.C.; RealClimate; Massachusetts Institute of Technology; the ResourceShelf, a site that includes librarians and researchers among its contributors; and the National Academies Press. Websites recommended by other sources, including members of the State & Local Climate Change Program, are the U.S. Environmental Protection Agency, the National Science Teachers Association, the Climate Action Network, the Climate Institute, Environmental Defense Fund, the Natural Resources Defense Council, the National Environmental Trust, Physicians for Social Responsibility, the Union of Concerned Scientists, and the Pew Center of Global Climate Change. A number of factors, technological and human-driven, determine whether or not internet traffic is successfully directed to any of these recommended resources. The Western Fuels Association website has been cited as representing aggressive interests to downplay the impact of global warming and climate change.

Media, TV

IN MOST COUNTRIES, there are at least two kinds of television programs that carry news about environmental issues and climate change. First, there are the general, daily news reports, which, on occasion, might introduce scientific matters into the broad agenda, whenever something new happens: either a catastrophe related to the weather, or any public event that centers on a decision related to climate change. On the other hand, there are many scientific series (or programs about popular science) specially made for television, usually in a one-hour format that can address some selected aspects of climate change and global warming, in general terms.

For instance, in the United States, there is *NOVA* and *Journey to Planet Earth* on PBS; in Canada, there is *Découverte* produced weekly by Radio-Canada; in England, there are many programs that are produced by the BBC. Many non-experts who have an interest in nature would consider television their main source of information about scientific matters, rather than scientific magazines or academic journals.

CLIMATE CHANGE IN THE EVENING NEWS

In most Western countries, television news segments need two elements, no matter what the topic is: an event that has just happened, and actual images that prove that it is true, such as a tornado or a handshake, depending on topic. Sometimes, a complement, such as an analysis of the issue by an expert can be a plus, in order to give meaning to the news, or at least a context, but it is not essential. Most journalists try to present both sides of every issue; so whenever there is a press conference, a decision by authorities, a new law, a demonstration, or a political event related to the environment, the media will report the issue in order to cover what has been announced in a previous press release or memorandum on a press wire.

For instance, when presenting an ongoing debate or a new controversy, journalists will try to get comments and opinions from an official voice of the administration (or government), who will be criticized (or contradicted) by a politician from the opposing party, an expert from civil society, or some representative from an environmental movement such as Greenpeace. Greenpeace receives the full attention of many news teams when they organize a spectacular event, fulfilling the media's quest for breaking news with striking images.

In some exceptional cases, the media will present events that are not new, but rather a part of history. On special occasions, for instance during the 10-year anniversary of the signing of the Kyoto Protocol, or a number of years following the *Exxon Valdez* disaster, the media might review the years that have passed, but only if there are significant events that are organized by groups or associations regarding that timeframe. This would be an opportunity for evaluating the progress and consequences that might have been witnessed during that period.

Television news is one of the most common ways to communicate scientific issues to a general audience. In that context, reporters who are neither scientists, nor experts, but just communicators who report what they have witnessed, translate scientific news into ordinary terms. Although experts and scientists are often consulted and quoted, journalists have the capacity to interpret, edit, quote outside the context, holding the ability to have the last word on the subject. On these occasions, some hypotheses, models, intuitions, or trends explained in detail and with much nuance by scientists can be misinterpreted or misunderstood by facts being stated by inexperienced journalists, who at times need to cover the entire subject in under a minute. That is the price scientists have to pay to find a wider audience, quite different from a university chair, a conference for scholars, or a scientific article. However, some devoted journalists specialize in scientific news and will often join various networks of colleagues who share the same interests in science, nature, and environmental issues. Associations such as the Society of Environmental Journalists allow such cooperation, although there is still much debate about climate change and related issues in these circles.

THE FUTURE OF CLIMATE CHANGE

There are many programs and special features related to environmental risks, climate change, and global warming. Laboratory life and science are not exciting as such; but for most producers, stories about science made for television have to be. Most of these programs are often produced and structured according to the same patterns. First, there must be a few experts who confirm the main arguments that are brought to the table. But to avoid showing a series of talking heads of scientists on television, most television directors try to borrow some stylistic elements from fiction feature films in order to create an original narrative that is easy to follow, with all the common ingredients: a strong intrigue, some background music that dramatizes the problem, plus illustrations and moving images. However, because events about climate change and global warming are complex and evolving quickly, programs that discuss these matters tend to become obsolete in a short period of time. New-media and specialized networks can offer other sources, for instance, the National Aeronautics and Space Administration (NASA) Television (NTV), in the United States.

CLIMATE CHANGE AS A MERCHANDISE

Programs about the environment and related issues have become merchandise that can be bought and sold by producers to distributors and television networks. As with any other program, the value of a one-hour feature on climate change will depend, among other factors, on the audience it gathered when it was first aired. Other elements are the year it was produced, the cost of its rental, and its original language (if a translation is needed). Some television programs are sold on videocassette or DVD for further uses, for example, as instruments of environmental education for use in classrooms.

Other events promoting awareness about climate change and global warming are specially conceived for television, like Al Gore's Live Earth Concert on July 7, 2007, which attracted an audience of two billion on radio, television, and over the internet. On that occasion, more than 100 groups and artists performed live in diverse locations, on all seven continents, including Antarctica. Many news reports mentioned the event and focused on the most unusual dimension, which was the musicians playing in Antarctica in front of cameras. The whole event was staged to attract media awareness and target a new audience for the cause of climate change.

ADVOCACY

While it is easy for audiences to be reached by the media (for example, by listening to the radio, watching television, or picking up a newspaper); the access for an individual to go inside the media, on the other hand, is harder, and often impossible, especially with national media and large television networks, for an unknown citizen to discuss an issue, a problem, or an opinion of his/her own. In most cases, groups and associations have more opportunity to be heard than a single individual.

Every day, most journalists receive phone calls from people defending a cause, who want media coverage, and, thus, journalists have to select according to what is relevant, to societal norms, the opinions of their colleagues or bosses, and regarding how audiences might react, according to Lawrence Wallack and colleagues.

When activists want to have access to television to express their position, for example, about environmental issues, climate change, and global warming, they often face the same institutional barriers: lack of time, no specific program to host them, and too many topics to cover. Often, the local media become the easiest entry to present a point. National networks and global networks like CNN (or Al-Jazera in Katar and for the Middle East) are among the most difficult media to reach. Some community media, often run by persons who do not get paid, can add another dimension. In his book about advocacy communication, John P. McHale recognizes both local and cable television as the most efficient media for people who want to advocate environmental causes and topics, because these channels are easier to access and have an audience that is often overlooked by their competitors. In some cases, these parallel media can become a first step in a strategy toward creating a broader media presence.

Meridional Overturning Circulation

THE MERIDIONAL OVERTURNING circulation is an oceanic system driven by physical forces related to temperature, salinity, and momentum. The circulation is a generally closed system with an important role in redistributing heat on a global scale. Regions of intense heat loss at high latitudes produce cold (dense) water that sinks to the oceans' depths. This abyssal water spreads toward the equator, while the sinking water is replenished by warmer water flowing poleward near to the ocean surface. The upper level waters link the circulation, fed in regions of upwelling from the oceans' depths. Although other areas of subduction exist, especially in the Waddell Sea in Antarctic waters, a key source of the cold abyssal water is in the North Atlantic Ocean. It is the Atlantic Meridional Overturning Circulation (AMOC), which has garnered the largest amount of attention from researchers.

The usually stratified ocean surface layers in the North Atlantic may become disturbed by a weather system, allowing the particularly cold surface water in this region to sink, adding to the North Atlantic deep water, driving the circulation. In the return flow, the heat flux into the North Atlantic carried by the North Atlantic Drift (a part of the meridional overturning circulation, as opposed to the wind-driven Gulf Stream) makes a substantial contribution to keeping the region warmer than at comparable latitudes in the North Pacific. Because the circulation involves the movement of surface waters to abyssal depths and vice versa, it also plays a key role in the redistribution of dissolved carbon dioxide and inorganic carbon in oceanic waters. The role of this in modulating or enhancing climate change is an area of active investigation.

The accumulation of evidence from studies of past climates provides one of the most persuasive links between the meridional overturning circulation and climate change. Studies of deep sea sediments, glacial ice cores, varves, and peat sediments show that, as the North Atlantic region emerged from the Pleistocene glacial period, the general warming process was punctuated by periods of intense cold (such as the Heinrich, and the Younger Dryas cold events). The transition between events was very rapid. In the case of the Younger Dryas, temperatures may have declined by 9–18 degrees F (5–10 degrees C) in as little as 10 years. Although there are alternative hypotheses, the most compelling explanation for these oscillations in climate is a disruption in the North Atlantic circulation. Evidence suggests that the circulation was entirely, or almost completely eliminated during these events. The periods of a strengthening meridional overturning circulation also experienced the most rapid warming. Variations in the meridional overturning circulation in the North Atlantic have been significant in driving abrupt climate change.

The meridional overturning circulation exhibits considerable variability. In recent years, the upper layers of the North Atlantic appear to be warming, and the fluxes associated with the meridional overturning circulation appear to be diminishing. It is not yet clear if the observations are part of a process of natural variability or represent a longer-term trend. However, a majority of computer models suggest a general weakening of the circulation during the coming century as a result of climate change.

In a warming world, any melting of the Greenland Ice Sheet could enhance ocean layering, thereby impeding the processes of convection and reducing the warming flow of the North Atlantic Drift. Increased precipitation in the region could produce a similar effect. In models, if the meridional overturning circulation is shut off, results indicate a significant cooling of several degrees C in the surrounding continental areas. However, indications are that the region has been warming. Also, a complete shutdown of the circulation in the North Atlantic in the coming century is unlikely.

Mesosphere

THE EARTH IS surrounded by an atmosphere which is the blanket of gases that has no definite outer edge. Over 80 percent of the gases in the atmosphere are held by gravity within 12.4 mi. (20 km.) of the earth's surface. The physical and chemical structure of the atmosphere and the interactions occurring there make the atmosphere an integral part of the earth system. It is held near the surface of the planet by the earth's gravitational attraction.

Without the atmosphere there would not be life on earth. The atmosphere contains the air people breathe, protects life from harmful radiation from the Sun and helps keep the planet's heat from the Sun from escaping back into space. The atmosphere is made up of a mixture of gases, especially nitrogen, oxygen, argon and carbon dioxide. It reaches over 310 mi. (500 km.) above the surface of the planet. There is no exact boundary between the atmosphere and outer space. Atmospheric gases, however, become thinner the higher up the space.

TWO LAYERS OF THE ATMOSPHERE

Based on chemical composition, the atmosphere is divided into two broad layers: the homosphere and the heterosphere. The homosphere extends up to the height of 56 mi. (90 km.) and is characterised by uniformity in chemical composition. It consists of three thermal layers, namely, the troposphere, the stratosphere, and the mesosphere. Each sub-layer is separated from the adjoining layer by a shallow transitional zone. The heterosphere has heterogeneous chemical composition, with layered structure, of nitrogen, oxygen, helium, and hydrogen, respectively. Generally, the atmosphere consists of five layers, namely, the troposphere, the stratosphere, the mesosphere, the thermosphere, and the exosphere. The thickness of these layers is slightly different around the globe, and also varies with respect to temperature and season. These five layers of the atmosphere act as safety blankets, regulating the Earth's temperature and maintaining life forms in it.

The mesosphere is the third highest layer and is separated from the stratosphere by the stratopause and from the thermosphere by the mesopause. The top layer of the mesosphere is called the mesopause. The regions of the stratosphere and the mesosphere, along with the stratopause and mesopause are called the middle atmosphere. The mesosphere is the layer of the earth's atmosphere that is immediately above the stratosphere and below the thermosphere and is located from about 31 mi. (50 km.) to 50–56 mi. (80-90 km.) altitude above the earth's surface. Within this layer, temperature decreases with increasing altitude. The mesosphere spreads above the stratosphere from 31–50 mi. (50–80 km.). Temperatures in the upper mesosphere fall as low as minus 148 degrees F (minus 100 degrees C), varying according to latitude and season. Millions of meteors burn up daily in the mesosphere as a result of collisions with the gas particles contained there, creating enough heat to vaporize the falling objects before they reach the ground, resulting in a high concentration of iron and other metal atoms. The meteors, which fall to the Earth withgravitational force, burn due to the friction with the wind at this level. This layer protects the Earth from the falling meteors. It is characterized by a broad temperature maximum (near 32 degrees F, 0 degrees C) at its base, from which the temperature decreases to a minimum of about minus 130 degrees F (minus 90 degrees C) at the mesopause level. Mesosphere displays high wispy clouds in high latitudes during summer because of reflected sunlight from meteriotic dust particles.

The mesosphere is the coldest layer of the atmosphere, where the temperature drops rapidly with altitude. Temperatures are warmest at the lowest level of the mesosphere and become colder at its highest level. The mesosphere is that region of the atmosphere where the air masses are relatively mixed together and the temperature is constant with altitude. The region receives balanced heating from below and above, and cools off about as fast as it warms up. Elevated temperatures can sometimes cause a molecule to become ionized; therefore, the ionosphere and thermosphere can overlap. The main dynamic features in this region are atmospheric tides, internal atmospheric gravity waves, and planetary waves. In the mesosphere, gravity-wave amplitudes can become so large that the waves' dissipation transmits so much energy that it largely drives the global circulation of the mesosphere. Because it lies between the maximum altitude for aircraft and the minimum altitude for orbital spacecraft, this region of the atmosphere has only been accessed through the use of sounding rockets. As a result, it is the least understood part of the atmosphere.

Mesozoic Era

THE MESOZOIC ERA is one of three geologic eras of the Phanerozoic eon. Lying between the Paleozoic and the Cenozoic these three eras comprise the Phanerozoic eon. The Mesozoic was a time of tectonic, climatic, and evolutionary activity. The continents gradually shifted from a state of connectedness into their present configuration. The climate was exceptionally warm throughout the period, also playing an important role in the evolution and diversification of new animal species. By the end of the era, the basis of modern life was in place. The Mesozoic era extended roughly 180 million years, from 251 million years ago (Mya) to when the Cenozoic era began 65 Mya. This Era is further separated into three geologic Periods. From oldest to youngest: Triassic (251 Mya to 199 Mya), Jurassic (199 Mya to 145 Mya), Cretaceous (145 Mya to 65 Mya).

The lower (Triassic) boundary is set by the Permian-Triassic extinction, during which approximately 90–96 percent of marine species and 70 percent of terrestrial vertebrates became extinct. It is also known as the Great Dying because it is considered the largest mass extinction in history. The upper (Cretaceous) boundary is set at the Cretaceous-Tertiary (KT) extinction, which may have been caused by the meteor that created the Chicxulub Crater on the Yucatán Peninsula. Approximately 50 percent of all genera became extinct, including all of the non-avian dinosaurs.

DRAMATIC RIFTING

After the vigorous convergent plate mountain-building of the late Paleozoic, Mesozoic tectonic deformation was comparatively mild. Nevertheless, the era featured the dramatic rifting of the supercontinent, Pangaea. Pangaea gradually split into a northern continent, Laurasia, and a southern continent, Gondwana. Laurasia became North America and Eurasia, while Gondwana split into South America, Africa, Australia, Antarctica and the Indian subcontinent, which collided with the Asian plate during the Cenozoic, the impact giving rise to the Himalayas. The Triassic was generally dry, a trend that began in the late Carboniferous, and highly seasonal, especially in the interior of Pangaea. Low sea levels may also have exacerbated temperature extremes. Because much of the land that constituted Pangaea was distant from the oceans, temperatures fluctuated greatly, and the interior of Pangaea probably included expansive areas of desert. Abundant evidence of red beds and evaporites, such as salt, support these conclusions. Sea levels began to rise during the Jurassic, probably caused by an increase in seafloor spreading. The formation of new crust beneath the surface displaced ocean waters by as much as 656 ft. (200 m.) more than today, which flooded coastal areas. Furthermore, Pangaea began to rift into smaller divisions, bringing more land area in contact with the ocean by forming the Tethys Sea. Temperatures continued to increase and began to stabilize. Humidity also increased with the proximity of water, and deserts retreated.

WIDELY DISPUTED

The climate of the Cretaceous is less certain and more widely disputed. Average temperatures were higher than today by about 18 degrees F (10 degrees C). In fact, by the middle Cretaceous, equatorial ocean waters may have been too warm for sea life, and land areas near the equator may have been deserts, despite their proximity to water. The circulation of oxygen to the deep ocean may also have been disrupted. Large volumes of organic matter accumulated because they were unable to decompose and were eventually deposited as black shale.

The extinction of nearly all animal species by the end of the Permian period allowed for the radiation of many new lifeforms. Large archosaurian reptiles that appeared a few million years after the Permian extinction dominated animal life during the Mesozoic era.

The climatic changes of the late Jurassic and Cretaceous provided for further adaptive radiation. The Jurassic was the height of archosaur diversity, and the first birds and placental mammals also appeared. Angiosperms radiated sometime in the early Cretaceous period. As the temperatures in the seas increased, the larger animals of the early Mesozoic gradually began to disappear, while smaller animals of all kinds, including lizards, snakes, and perhaps the ancestor mammals to primates, evolved. The large archosaurs became extinct, while birds and mammals thrived.

During the early Mesozoic era, researchers do not conclusively predict high-latitude ice-free environments during the Cretaceous period. Various explanations have been proposed for the discrepancy, and subsequently incorporated into further modelling studies. Two of these include ocean circulation changes and the role of CO_2. Of these, only an elevated atmospheric CO_2 concentration could come close to reconciling the models with geological evidence. High levels of CO_2 seem reasonable, considering the high global sea level and ensuing break-up of Pangea. In addition to increased outgasing of

CO_2, the reduced continental area would result in a decreased rate of weathering of silicates and removal of CO_2 from the atmosphere.

Unfortunately, there is little reliable evidence to support the CO_2 model. M.A. Kominz and colleagues have estimated that average rates of the velocities of major tectonic plates were higher in the late Cretaceous and ocean ridge volumes were greater. In addition, Cretaceous sea-beds were dominated by calcite minerals, implying higher aqueous, and, consequently, atmospheric, CO_2 concentrations.

Methane Cycle

METHANE HAS MANY sources, both natural and human-related, but just two major sinks: its destruction in the atmosphere, and its use by certain soil bacteria. Methane is a powerful greenhouse gas, each kg. emitted to the atmosphere having a global warming potential (GWP) 23 times greater than that of a kg. of carbon dioxide over a 100-year time horizon. Since the pre-industrial era, the concentration of methane in the atmosphere has more than doubled, rising from around 715 parts per billion (ppb) in 1800, to more than 1,770 ppb today—higher than at any time in the preceding 650,000 years. Methane emissions resulting from human activities now exceed those from natural sources, comprising around 60 percent of the 600 million metric tons of methane emitted globally to the atmosphere each year.

Methane (CH_4) is the main component of natural gas, first discovered in 1776, by Alessandro Volta. It has a relatively short lifetime in the atmosphere, most molecules having been destroyed within 10 years of release. Despite this limited lifespan, it is a powerful greenhouse gas, having a global warming potential (GWP) of 23. This means that every kg. of methane emitted to the atmosphere has the equivalent forcing effect on the Earth's climate of 23 kg. of carbon dioxide over a 100-year period.

The global methane cycle is comprised of a wide range of sources and sinks. Major natural sources include wetlands, termites, the oceans, and release from hydrates (lattice-like structures of ice and methane, also known as clathrates, occurring in polar regions and in oceanic sediments). Recently, living vegetation has also been suggested as an important natural source of methane. Of known sources, wetlands dominate natural emissions, with between 100 and 200 million tons of methane emitted from these waterlogged soils each year. Wetland methane emissions arise from methane-producing bacteria known as methanogens, which are active in the anaerobic, carbon-rich environments common to wetland soils.

Human activities are to blame for around 60 percent of global methane emissions into the atmosphere each year.

The rate of wetland methane production increases rapidly with increasing temperatures, raising concerns that human-induced climatic warming, particularly at high latitudes, may increase global methane emissions and amplify warming.

While the methanogens in the anaerobic soils of wetlands are major producers of methane, soils also represent significant sinks for methane. Methane-utilizing bacteria, called methanotrophs, oxidize much of the methane produced in wetland soils before it can escape to the atmosphere. In well-aerated soils, such as those common to forested areas, the methanotrophs are also able to remove methane from the atmosphere. Globally, soil methanotrophs are estimated to remove around 30 million tons of methane from the atmosphere each year. By far the largest sink for atmospheric methane is that of destruction in the troposphere by the hydroxyl (OH) radical, this process removes around 500 million tons of methane each year. Additional destruction of methane OH radicals in the stratosphere is thought to remove 40 million tones of methane per year.

At around 320 million tons per year, methane emissions related to human activities are estimated to exceed those from all natural sources. The bulk of these emissions come from losses occurring during fossil fuel extraction and transport, from ruminant livestock and waste treatment, from landfill sites, from rice cultivation, and from biomass burning. Mitigation policies designed to reduce human-induced methane emissions include the capture of methane produced during fossil fuel extraction and by landfill sites, for flaring or use as an energy source; the use of feed additives to reduce methane production by ruminants; changes in rice cultivation methods to reduce the length of time that rice paddy soils are in a waterlogged, methane-producing state.

Concentrations of methane in the atmosphere have more than doubled since the pre-industrial period, rising from around 715 parts per billion (ppb) in 1800, to the current level of around 1,770 ppb. This concentration is higher than at any time in the last 650,000 years, and has arisen due to an imbalance between methane sources and sinks. Since the early 1990s, the rate of increase has slowed markedly, with atmospheric methane concentrations remaining relatively constant since 1999. Analyses indicate that this recent stabilization may be the result of transient reductions in emissions from wetland areas from unusually low rainfall. If rainfall in these areas returns to normal, atmospheric methane concentrations may increase still further, unless emissions from human activities are reduced.

Mexico

THE REPUBLIC OF Mexico has a land area of 758,249 sq. mi. (1,972,550 sq. km.), a population of 106,535,000 (2006 est.), and a population density of 142 people per sq. mi. (55 people per sq. km.). About 12 percent of the country is arable, with a further 39 percent used for meadow or pasture (often for low-intensity grazing), and 24 percent of the country is forested. The climate of Mexico varies considerably; while some of the northern parts are arid desert, the central plateau is much colder, especially in winter, and the southern part of Mexico is largely tropical jungle. As well as the regional variations in climate, there have also been studies of Mexico's climate over recent centuries. Many historians now believe that the Mayan civilization collapsed in about 950 C.E. as a result of lack of food supplies, possibly through an earlier episode of climate change. It coincided with a period of prolonged drought. This has led some global warming skeptics to suggest that both global warming and climate change are historical cycles, rather than solely a result of human activity.

Largely because of its heavy industry and the size of its population, Mexico has a high rate of carbon dioxide emissions per capita, at 4.5 metric tons per person in 1990, reduced to 3.9 metric tons per person by 1991, after which it rose slightly, to 4.24 metric tons in 1993. The vast majority of Mexico's carbon dioxide emissions (73 percent) come from the use of liquid fuels, and 17 percent come from gaseous fuels. This is not just from the use of automobiles (transport makes up 27 percent of the country's carbon dioxide emissions), but also from the proliferation of gasoline-driven generators. Approximately 75.9 percent of electricity in Mexico is generated from fossil fuels. For the remainder of the electricity production in the country (accounting for 31 percent of carbon dioxide emissions), 16.8 percent of the power comes from hydropower, and 4 percent from nuclear power. Mexico's other major contributions to global warming are from cement manufacturing (4 percent) and gas flaring (1 percent).

The effects of global warming in Mexico have been marked in parts of the country. The Pacific coastline of Mexico has seen an increase in the numbers of tornados, and there is clear evidence of coral reef bleaching. In 1998, the country recorded its worst fire season on record up to that point, with fires destroying 1.25 million acres (505,857 hectares). The smoke from this triggered a statewide health alert in Texas. Pollution in Mexico City also remains particularly bad, with 4 million automobiles, 200,000 buses, 35,000 taxis, and 60,000 factories responsible for considerable carbon dioxide and sulfur emissions. Traffic congestion is serious throughout the day, and the city is located in a 70-mi.- (113-km.-) wide basin, which prevents the fumes from dispersing. In some parts of the country, there has been an increase in the number of rainstorms, which in turn has led to the prevalence of insect-borne diseases such as dengue fever, which had previously been limited to an elevation limit of 3,300 ft. (1,006 m.), but has now been found at 5,600 ft. (1,707 m.). Concern about climate change and global warming has led to more publicity for the Green Party in Mexico.

The Mexican government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. They signed the Kyoto Protocol to the UN Framework Convention on Climate Change on June 9, 1998, with was ratified on September 7, 2000, with it entering into force on February 16, 2005.

Michigan

MICHIGAN LIES IN the northern United States and is located between 41 degrees N and 49 degrees N in latitude and between 82 degrees W and 88 degrees W in longitude. Michigan's area is 253,793 sq. km. (97,990 sq. mi.); its population is 10.1 million (2006 est.); in comparison, in 1950, the population was about 6.4 million. Its largest cities are Detroit and Grand Rapids. Lansing is Michigan's capital.

The territory consists of two peninsulas. The southern peninsula is between Lakes Huron and Erie on the east, and Lake Michigan on the west. The northern peninsula is between Lakes Huron and Michigan on the south, and Lake Superior on the north. The Michigan topography is mostly hilly uplands, with many lowlands in the eastern portion of both peninsulas. The central part of southern Michigan is a plateau, surrounded by a chain of ancient shore terraces. On the western sections of the northern peninsula, the landmasses are up to 1,968 ft. (600 m.) in height. The highest point in Michigan is Mount Arvon 1,981 ft. (604 m.). The Ontonagon River, which flows into Lake

Superior, is the largest river in Michigan. Ancient soft sandstone, limestone, and lake and glacial deposits compound the landmasses.

Michigan is located in the Great Lakes Region and has a shoreline with Lakes Superior, Michigan, Huron, and Erie. The Great Lakes Region is geographically located at the edges of the Northern Hemisphere polar vortex, and thus Michigan lies in the path of traveling cyclones and anticyclones. On a global scale, the Michigan climate is affected by three air masses: the Continental Polar air mass, with dry, cold winters and summers; the Marine Polar air mass, with cold, snowy winters and cool wet summers; and the Marine Tropical air mass with humid and hot summers. Which combination of air mass or masses dominates at a particular time of the year depends on the Earth's general circulation and its global teleconnection patterns. The El Niño–Southern Oscillation (ENSO) phenomenon dominates, both phases of which—the ENSO warm phase (El Niño) and cold phase (La Niña)—have been linked to anomalous climatic patterns in the areas adjunct to the Great Lakes Region. The warm phase of ENSO brings heavy snow in winters to northern Michigan.

At the local scale, the Michigan climate is influenced by the lakes and local topography and, in general, has mild winters and cool summers. The climate in northern Michigan is cooler than the climate in the south. In southeastern Michigan, the average January temperature is 25 degrees F (minus 4 degrees C). In the northwestern part, it is as low as 14 degrees F (minus 10 degrees C); the July temperature ranges are from 64–74 degrees F (64–74 degrees C). Michigan annual precipitation ranges within 2–33 in. (50–850 mm.), with the highest amounts at the southern shore of Lake Superior and at the southwest shore of Lake Michigan, with the minimum amount at the western shore of Lake Huron. The summer lake surface temperatures range from the coldest temperatures of deep Lake Superior (the deepest point 1,330 ft., or 405.38 m.) to the warmest temperatures of shallow Lake Erie (the deepest point 210 ft., or 64 m.), with very small inter-annual variability for the latter. In contrast, the lake-level pressures have very similar mean values and amplitudes for all lakes, which indicates the homogeneity of the circulation pattern over the Great Lakes Region.

Most of the Michigan territory is occupied by agriculture and forestry. Michigan is a significant producer of livestock, cherries, blueberries, cranberries, black beans, soybeans, corn, dairy, wheat, and beets. In the 20th century, the number of farms decreased from the 19th century number, but had stabilized by the beginning 21st century. Climatologically, the annual growing period is 180 days on in the southwest portion of the state. The number of growing days decreases moving north (to 80 growing days per year), due to the lower temperatures. Spruce, hemlock, and fir forests occupy the northern part of Michigan. The main Michigan trees are sugar and red maples. Forestry was the main industry at the end of 19th century, but, due to the introduction of Michigan conservation policies, has fallen in importance. Other important Michigan industries are manufacturing (automotive), mining (iron ore, magnesium compounds, gypsum, cement, sand and gravel, salt and calcium chloride, crushed stone, natural gas, and petroleum) and fishing (chub, whitefish, yellow perch, lake herring, yellow pike, carp, catfish, smelts, suckers, white bass, lake trout, and pacific salmon). The Michigan ports on Lake Michigan have access to the Mississippi River and thus to the Gulf of Mexico.

The Michigan economy depends on fresh water supply from the lakes, groundwater, and rainfall. A combination of rainfall, evaporation, and groundwater recharge rates define the freshwater balance in Michigan. There is a seasonal cycle in precipitation, temperature, and runoff, which affects the lake water levels. The highest lake levels are in the spring (because of high runoff from melting snow), and the lowest levels are in the autumn (because of high evaporation rates). The consumption of fresh water increases with population growth and economics needs. Historically, the lowest lake level was recorded in 1930, which corresponds to the fast development of the city of Detroit.

CONSEQUENCES OF ECONOMIC ACTIVITIES

Michigan's human economic activities increase pressure on Michigan's environment and the global environment. Air and water pollution from industry, traffic, and greenhouse gases increase because of industrial and domestic fossil fuel combustion; soil erosion from fertilizers and farm runoff are the main consequences of human economic activities, which can be reduced by investigating and implementing alternative energy sources (such as atomic, wind, solar power, bio-fuels, and land-field fuel), developing new technologies (for example, solar and electric cars), and discovering new efficiencies in human economic activities. If the climate shifts even slightly from its averages, Michigan will face changes in crop yield, changes in pests population, a shift in forest composition and health, a loss of bird diversity, a change in local mammal populations (such as raccoons, skunks, white-tailed deer, and moose), a change in the distribution of fishes; spread of invasive species, release of nutrients and contaminants, change in groundwater recharge, and a change in lake levels.

Micronesia

THE FEDERATED STATES of Micronesia have contributed very little to global greenhouse gas emissions, but are likely to be severely affected by global warming. An excess of 600 small islands and atolls constitute Micronesia, which is divided into the states of Chuuk, Kosrae, Pohnpei, and Yap. Micronesia is situated in the tropics of the western Pacific Ocean, just north of the equator.

Between 1947–86, Micronesia was a part of the United Nations Trust Territory of the Pacific Islands, which was administered by the United States. Since 1986, Micronesia has been in a Compact of Free Association with the United States. Micronesia became a member of the UN in 1991, ratifying the UN Framework Convention on Climate Change (UNFCCC) on November 18, 1993. Micronesia signed the Kyoto Protocol on March 17, 1998, and ratified it on June 21, 1999. The UNFCCC came into force in 1994, and the Kyoto Protocol was effective as of 2005.

Micronesia is a member of the Alliance of Small Island States (AOSIS), which was formed to enable small island states to have a greater say in international relations, primarily with regard to climate change and sea-level rise. The country is particularly vulnerable to sea-level rise and to storm surges. Sea-level rise and loss of land are already occurring. Low lying islands are under threat. On islands that have higher ground, it is the low-lying coastal areas that are most heavily inhabited. Micronesia is affected by El Niño and La Niña weather events, and these may become more frequent and more intense as a result of global warming. El Niño causes drought conditions, while La Niña brings heavy rains, high waves, and storm surges. In the 1997–98 El Niño Southern Oscillation, Micronesia suffered drought conditions, reduced availability of drinking water, loss of agricultural crops, salt water intrusion of agricultural land, extreme sea-level variations, and erosion.

THREE STRATEGIES

The Micronesian government has identified three strategies through which to address the challenges faced because of the adverse effects of climate change. These are: to promote sustainable economic growth by reducing its economic, environmental, and social vulnerabilities; to balance resource conservation and management; and to ensure and improve quality of life for all its citizens and for future generations. Micronesia works with a number of bodies in its efforts to adapt to climate change, these include the Asian Development Bank, the South Pacific Regional Environmental Programme, and the Global Environment Facility-funded Pacific Island Climate Change Assistance Programme.

Midwestern Regional Climate Center

THE MIDWESTERN REGIONAL Climate Center (MRCC) is a cooperative program of the Illinois State Water Survey and the National Climatic Data Center, part of the National Oceanic and Atmospheric Administration, U.S. Department of Commerce. The MRCC is a partner in a national climate service program that includes the National Climatic Data Center, Regional Climate Centers, and State Climate Offices. The Center is based in Champaign, Illinois, and serves the nine-state Midwest region (Illinois, Indiana, Iowa, Kentucky, Michigan, Minnesota, Missouri, Ohio, and Wisconsin). The services and research provided by the MRCC help to gain a more in-depth understanding of climate change and its impacts on the Midwest. They also attempt to provide practical solutions to specific climate problems, and supply climate information for the Midwest on climate-sensitive issues, such as agriculture, energy, the environment, human health, risk management, transportation, and water resources.

The MRCC is committed to provide high-standard weather data for the midwestern area, to monitor and assess regional climate conditions and their consequences on the local environment, to compile historical datasets and to coordinate applied research on climate-related issues and problems. The MRCC has two research programs: the Climate Database Modernization Program and the West Nile Virus Project.

The Climate Database Modernization Program (CDMP) aims to preserve and make available online a wide range of observations about the climate from the last three centuries, including those carried out at U.S. Army forts starting in the early 1800s. Following these early observations, in the second half of the 19th century, the Smithsonian Institution and the U.S. Department of Agriculture directed volunteer observer networks, which eventually evolved into the Weather Bureau's Cooperative Observer Network. The Network remains in operation today for the National Weather Service. The creation of a digital database of the daily Forts/Volunteer Observer data from the 1800s will allow a more comprehensive analysis of daily climate variables and a more complete picture of climate change in the region. Thirty-nine distinct data types have been identified for digitization, including observations of temperature, pressure, precipitation, wind, clouds, state of the weather, river-gauge height, and surface water temperature. The Center carries out quality control tests on the digitized data to guarantee their accuracy in representing the observations recorded on the original documents. The MRCC is also developing a comprehensive set of metadata to complement the dataset. These metadata account for changes in instrumentation and observation practices, by classifying changes in the forms used by the observers. The metadata incorporates detailed information about each station as recorded on the forms, such as station name and location, and barometer correction and other instrument adjustments. This interest in extending weather data also applies to climate extremes, like heat waves, cold waves, and heavy precipitation events, to better understand their changes over time.

Within its interest in climate change, the MRCC is also investigating the topic of drought. The drought projects examine what causes alterations in drought frequency over decades, the impacts of recent droughts on the nature of winter in the Midwest, and the development of improved tools that can further the understanding of recent and ongoing drought.

The West Nile Virus Project aims to construct weather models to determine the period of the year when the northern house mosquito, the most common type of mosquito, becomes dominant in the Midwest, causing a higher risk of transmission to humans and other mammals. The white-spotted mosquito and the northern house mosquito are supposed to maintain the natural transmission cycle of West Nile Virus (WNV) between birds and mosquitoes in Illinois. During the spring and early summer, the white-spotted mosquito, which feeds on birds, is the dominant species, and is responsible for bird-to-bird transmission of WNV. As temperatures become warmer, the northern house mosquito, the most common night-flying mosquito, becomes more dominant. The female of this species is probably responsible for the rapid spreading of the arbovirus among birds, and may act as the major bridge vector to mammals, including humans, in the Midwest. Two types of climate models have been developed to provide an estimate of the likely date when the northern house mosquito begins to become the dominant species, and, thus, when the risk of WNV to horses, humans, and other wildlife is likely to increase.

The MRCC also has a comprehensive section on its website on weather resources, including material for teachers and schools related to climate change. Dr. Steven Hilberg has been the director of the MRCC since 1998. In that same year, Michael Paleki became the Regional Climatologist for the MRCC.

Milankovitch, Milutin (1879–1958)

MILUTIN MILANKOVITCH, BORN in Dalj, Serbia on May 28, 1879, graduated from the Institute of Technology in Vienna, Austria in 1904. He worked as an engineer in Vienna before returning to Serbia, in 1905, to teach applied mathematics at the University of Belgrade. During the first Balkan War in 1912, he served in the military, assigned to the Danube division of the Serbian army. Milankovitch had begun a project to calculate temperatures at different latitudes and how temperature changed as a result of astronomical rhythms.

His goal was to explain the role played by astronomical cycles on ice ages by determining where various astronomical cycles coincided and combined to influence the amount of solar radiation leading to climate change.

After World War I, Serbia joined with other Balkan countries to become part of Yugoslavia. The political environment of the Balkan area remained in flux, including involvement in the Balkan War, World War I, and World War II. In spite of the unrest in the region, and an arrest and imprisonment as a prisoner of war, Milutin Milankovitch continued his work to determine, mathematically, the cycles of ice ages. He built on the theory that the ice ages were cyclical, and the work on astronomical rhythms by Scottish geologist James Croll.

Milankovitch completed a series of astronomical calculations using only his brain as the calculator, a writing implement, and paper. His calculations took into account the factors of the Earth's orbit, including tilt, axis of rotation, and axis of spin to determine the amount of insolation (sunlight, or the amount of solar radiation received by the Earth). He calculated detailed insolation curves for a few different northern latitudes, ranging back 650,000 years, and then calculated how ice sheets would respond to temperature changes. In addition, he performed similar insolation curve calculations for Mars and Venus.

His climate calculations took into account the distance from the Sun, the latitude and angle at which the Sun struck the surface of the planet. He focused on obliquity (the amount of axial tilt) and the precession of the equinoxes. He concluded the effect of eccentricity (the elliptical path of the orbit around the Sun) would be small, though later scientists have shown the importance of eccentricity. He postulated that insolation in the Northern Hemisphere drove the climate system because two-thirds of Earth's land mass lies in the Northern Hemisphere. He believed summer insolation levels at a boundary of 65 degrees N latitude, just south of the Arctic Circle, played a crucial role. If the ice caps survived the higher temperatures of summer below that specific latitude, the ice caps would have an increased chance of advancing, and by extrapolation, if the ice caps grew, the climate would cool.

His theory and calculations caused excitement among his contemporaries, but with no means of corroboration, his theory was shelved. Milutin Milankovitch died on December 12, 1958, before his research and theories had returned to prominence in the field. Since his death, in addition to using computers for improved accuracy, scientists have used carbon dating and the advanced ability to take remove cores from the ocean floor for comparison. Milankovitch's work returned to prominence. Despite flaws, and the fact that astronomical factors are not the only causes of climate change, scientists have shown a significant correlation between the climate record and Milankovitch's cyclical calculations. His work was established as a scientific model called the Milankovitch cycles in the 1970s.

Milankovitch Cycles

THE MILANKOVITCH CYCLES are recurring variations in the Earth-Sun orbital geometry. They collectively account for deviations in the amount and intensity of solar radiation received by the Earth. The cycles are named after Serbian astrophysicist Milutin Milankovitch (1879–1958), who developed the modern mathematical theory and formulas upon which these orbital perturbations are based. The central assertion of the Milankovitch theory is that the Earth's orbital relationship with the Sun is not stagnant, but dynamic, with three cyclic modes, which, when precisely combined, may significantly alter the Earth's insolation, resulting in a major global climate shift. While the Milankovitch theory was first proposed in the 1930s, the first supporting scientific evidence was not brought forth until the 1970s, when researchers of the CLIMAP project linked the timing of changes found in ocean sediment core data with associated orbital shifts of the Milankovitch cycles.

The three astronomical attributes constituting the Milankovitch cycles are: eccentricity or shape of the Earth's orbit about the Sun; obliquity or tilt of the Earth's axis from the perpendicular plane to the Earth's orbit; and precession or orientation of the Earth's rotational axis relative to the Sun. All three cycles fluctuate gradually at different rates with periodicities of thousands of years. These oscillations can operate jointly to control the strength and timing of seasons, including being a forcing mechanism for the frequency of glacial retreats and advancements.

Eccentricity is the change in the shape of the Earth's orbit around the Sun, fluctuating from a more circular (low eccentricity) to a more oval-shaped (high eccentricity) orbit. This cycle operates on several time periods depending on the Earth's juxtaposition to the gravitational pull of other planetary bodies (such as Jupiter), with a cycle of approximately 100,000 years most prominent. Currently, the Earth's orbit is in a low eccentricity phase, denoting a nearly circular orbit and a relatively small 3 percent difference in distance between the point of longest (aphelion) and shortest (perihelion) Earth-Sun distance. Because perihelion occurs on July 3 (Southern Hemisphere summer), this distance difference translates to approximately 7 percent more solar radiation received in the Southern than the Northern Hemisphere. At maximum eccentricity, the distance difference between aphelion and perihelion can be about 10 percent and account for over a 25 percent difference in solar radiation between the two hemispheres.

Obliquity is the deviation in the tilt of the Earth's axis away from the orbital plane. The current tilt of the Earth's rotational axis is 23.5 degrees, varying between 22.1 and 24.5 degrees over its 41,000-year cycle. Since the last peak obliquity occurred approximately 10,000 years ago, the current cycle is nearly at the midpoint of its range.

While the limits of the axial tilt cycle appear relatively small, the impact on seasons can be considerable, minimizing (exaggerating) seasonal differences with decreasing (increasing) obliquity, especially for the middle and high latitudes. During periods of less tilt, the severity of extratropical winters and summers is reduced, resulting in milder winters and cooler summers. This reduction in a seasonal contrast may promote the growth of ice sheets by decreasing the amount of summer melting and increasing high latitude winter snowfall accumulation, as higher winter temperatures increase the moisture capacity of the air. The present decreasing obliquity of the Earth has expanded the temperate latitudes and reduced the tropical and polar regions, effectively altering the position of the tropics and the polar circles at a rate of about a mi. (more than a km.) per century.

Precession is the change in the direction of the Earth's rotational axis, influencing the timing and intensity of the seasons. Often compared to the winding-down of a spinning top, the Earth wobbles on its axis, moving slightly forward as it travels in orbit around the Sun. During its average 26,000-year cycle, the Earth's axis of rotation pivots such, that the celestial poles are shifting, altering the current pole star of Polaris to other stars such as Vega in 14,000 C.E.

As a consequence of this wobble, the orbital locations at which the summer and winter solstices transpire periodically reverse; such as will be the case when Vega is the North Star. In 14,000 C.E., aphelion (perihelion) will coincide with the Northern Hemisphere winter (summer) solstice, resulting in the colder winters and warmer summers for the Northern Hemisphere and weaker seasonal temperature contrasts for the Southern Hemisphere. Precession is the only orbital parameter that is noticeable on a time scale of hundreds of years, influencing the timing of seasons by 1–2 days per century, on average. For the Northern Hemisphere, changes in precession during the past century have delayed the onset of winter and lengthened the summer.

Minnesota

CONSIDERED THE TRADE center of the Midwestern United States, Minnesota has a population of approximately 5 million people, ranking 21st in population among American states. Around 60 percent of the population resides in the Twin Cities of St. Paul, the state capital, and Minneapolis. The Twin Cities are home to the third largest trucking center in the United States. Minnesota is known as the Land of 10,000 Lakes, and Duluth, the fourth largest city in the state, is the largest inland trade center in America. Global warming and climate change impact Minnesota in a number of ways. Animal and plant habitats are threatened by shifting forests and grasslands. Floods and violent storms are threatening lives and property. Pests and diseases are expected to migrate into the state. Air and water quality is threatened, and smoggy summer days pose serious risks to health and the environment. The habitats of coldwater fish are jeopardized. Tourism and recreation are placed at risk from shorter winters. The focus of Minnesota's actions to reduce global warming and climate change is on educating the public, reducing pollution, ensuring clean air and water, instituting responsible land use, promoting conservation, and ensuring sustainable community development.

Between 1900 and 2001, the population of Minnesota increased by 13 percent. During that period, carbon dioxide (CO_2) emissions rose by 22 percent, reaching 95.9 million metric tons. Minnesota consumes some 2,600 million gallons of gasoline each year, and transportation accounts for 45 million tons of CO_2 emissions annually. The state has the 22nd highest level of CO_2 emissions in the country. Since the 1990s, Minnesota has placed restrictions on CO_2 emission levels. As a result of these concentrated efforts to reduce greenhouse gas emissions, Minnesota increased CO_2 efficiency by 20 percent 1990–2001. Ethanol is increasingly replacing gasoline in Minnesota. Ethanol plants provide farmers with an outlet for low-priced corn, and the 14 plants in the state produce more than 350 gallons of ethanol each year. Minnesota is one of more than 30 states that have agreed to develop a Greenhouse Gas Registry as part of a cooperative effort to reduce global warming and climate change.

In 2005, the Office of Environmental Assistance and the Pollution Control Agency were combined to create the new Minnesota Pollution Control Agency, which was given responsibility for promoting recycling, controlling pollution, educating the public, providing environmental assistance to local governments and the business community, advancing the concept of sustainable community development, generating policy, supporting environmental research, promoting green building practices, and providing grants and financial assistance for environmentally-motivated projects. The Department of Agriculture, the Department of Natural Resources, and the Board of Water and Soil Resources also have a role in protecting the state's environment.

In 2007, Minnesota began implementing the governor's Next Generation Energy Initiative. The legislature passed the 25x25 Renewable Electricity Requirements bill, which mandated that 25 percent of Minnesota's electricity be renewable by 2025. As part of the Next Generation BioEnergy and BioFuels provisions, the legislature appropriated $35 million for energy projects and research directed toward the development and use of alternative energy sources. The Next Generation Energy Act also calls for statewide greenhouse gas emission reductions of 15 percent of 2005 levels by 2015, 30 percent by 2025, and 80 percent by 2050. The bill also established the goal of having 1,000 environmentally friendly Energy Star Buildings in Minnesota by 2010. The governor further proposed an increase from 300 to 1,800 E85 gasoline pumps by 2010, promising that grants would be available for service station owners who install the new pumps, which dispense a fuel mixture of 85 percent ethanol and 15 percent gasoline.

PROGRAMS

In 2006, the governor of Minnesota proposed the Next Generation Energy Initiativem designed as a means of developing strategies for focusing public attention on renewable energy, energy conservation, and the need to lower carbon emissions. The following spring, the state created the Minnesota Climate Change Advisory Group (MCCAG), composed of 51 individuals representing business, utilities, environment, academics, religious organizations, the private

Although Minnesota is known as the Land of 10,000 Lakes, air and water quality is being threatened by climate change. Recreation and tourism are being placed at risk by shorter winters, and the habits of coldwater fish are being jeopardized.

sector, farming, local government, and Native Americans. MCCAG was charged with developing a statewide plan for reducing and sequestering greenhouse gas emissions and promoting the use of clean energy.

In 2006, Minnesota's proposed plan to reduce toxic power plant emissions won approval. The plan required Minnesota Power and Xcel Energy to cut mercury emissions at coal-fired power plants by 90 percent. As a result, Minnesota Power announced that it would spend $200 million purchasing pollution control equipment that would lower sulfur dioxide (SO_2) and nitrogen oxide (NO_x) emissions by 80 percent and mercury emissions by at least 90 percent.

Clean Air Minnesota was created under the auspices of the Minnesota Environmental Initiative. Composed of representatives from government, business, and the public, the organization promotes voluntary reductions in emissions from volatile organic compounds, nitrogen oxides, and fine particulate matter. In 2005, government agencies, business, and private organizations again came together to create Project Green Fleet, which focused on reducing pollution emitted by the state's 500 school buses. Recognizing that levels of pollution were five times higher inside school buses than outside, the group expressed concern about the health of Minnesota's children. Over a two-year period, school buses were retrofitted with pollution control equipment. Project Green Fleet also joined with local businesses to protest rising levels of heart and lung disease and asthma that were attributed in part to toxic emissions from motor vehicles.

In 1991, the Releaf Program was established for the purpose of reducing CO_2 levels by planting, maintaining, and improving trees. Funding for the program was derived from an environmental trust fund, the lottery, and private and corporate sources. In the first 10 years of operation, 361 trees were planted, and approximately 200 communities became involved in the project. The Releaf Program also serves in an advisory capacity, encouraging homeowners to reduce global warming and climate change in such simple ways as planting shade trees and wind breaks. Despite assurances that tree planting is essential to the sequestering of carbon, the future of the Releaf Program is in question because of a lack of funding.

Mississippi

LOCATED IN THE Deep South and bordering the Gulf Coast, Mississippi is one of the poorest states in the United States, and funding for environmental programs is not always considered high-priority. Parts of Mississippi are predominately agricultural, particularly in the fertile Black Delta of the northeast and in the Mississippi Delta of the south. More than half on the state's land area is forested. The Mississippi River, from which the state takes its name, is the state's major geographic feature, and the river has a significant influence on the economy and the environment. Mississippi is susceptible to hurricanes, and Hurricane Katrina devastated sections of the state in 2005. Each year, an average of 27 tornadoes touch down in Mississippi. All of these factors play a part in making the state vulnerable to global warming and climate change.

Scientists are predicting that, if global warming is not checked, sea levels around the world may rise from 7–23 inches by the beginning of the 22nd century. In Mississippi, this would drastically increase costal erosion and lead to loss of habitat, particularly along the Gulf Islands National Seashore. The number of destructive storms and hurricanes is likely to increase in Mississippi in response to climate change. Both economics and the environment of the state may be affected as a result of a decrease in agricultural productivity. Hotter temperatures may encourage the spread of tropical diseases and lead to major health problems, even death, in the hot summer months. Mississippi's responses to rising threats of global warming and climate change focus on improving air and water quality, protecting coastal areas, preventing pollution, educating the public, safely disposing of hazardous waste, and recycling.

Residents who blamed oil, chemical, and utility companies for global warming and damage to the states' wetlands that occurred in the wake of Hurricane Katrina filed a class-action lawsuit in Mississippi and Louisiana in 2005. Plaintiffs accused the companies, which included Columbia Gulf Transmission, Shell Pipeline, and Exxon Mobil Oil of precipitating global warming by destroying the natural protection that wetlands would have provided, had the companies not dredged pipeline canals in the area. An additional suit charged oil companies with responsibility for increasing the area's vulnerability to global warming and destroying property as a result of hazardous emissions released during the storm.

According to the nonpartisan Washington-based research organization, U.S. Public Interest Research Group, carbon dioxide (CO_2) emissions in Mississippi rose by 255 percent 1960–2001. PIRG believes that the increase was due to a combination of CO_2 emissions from motor vehicles and coal-fired power plants. Between 1990 and 2001, the population of Mississippi grew by 11 percent. During that time, CO_2 emissions rose by 44 percent to a total of 69 million metric tons, and CO_2 efficiency declined by minus 5 percent. Mississippi now ranks 34th in the nation in CO_2 emissions. Although most states have banned the use of conventional motor gasoline because of its influence on global warming and climate change, Mississippi authorizes its use statewide. Coal-fired power plants provide around a tenth of Mississippi's total energy. Eight states and the City of New York have filed suit against energy companies that are accused of generating most of the pollution in the United States. Two of the companies involved in the suit operate in Mississippi. The Southern Company is second on the list; and the Tennessee Valley Authority is third.

The Mississippi Department of Environmental Quality (MDEQ) has the chief environmental responsibility in Mississippi and is charged with ensuring clean air and water, preventing pollution, and safeguarding public health. The agency is supported by the seven-member Commission on Environmental Quality appointed by the governor. The Office of Pollution Control, the Office of Land and Water Resources, and the Office of Geology are subdivisions of MDEQ. Other state agencies involved in generating responses to global warming and climate change are the Department of Agriculture and Commerce; the Department of Marine Resources; the Department of Wildlife, Fisheries, and Parks; and the Forestry Commission.

PROGRAMS

Mississippi has a number of specific programs designed to deal with protecting the environment and reducing threats of global warming. As part of the Ambient Air Monitoring for Criteria Air Pollutants Program, MDEQ regularly tests levels of sulfur dioxide, ozone, carbon monoxide, nitrogen dioxide, and particulate matter in the air. The agency has the authority to enforce compliance with state and federal laws. MDEQ also oversees the Hazardous Air Pollutant Monitoring Program that examines levels of volatile organic compounds and carbonyl compounds in the air. The Mississippi Source Water Assessment Program was set up in 1996 to oversee Mississippi's compliance with the Federal Safe Drinking Water Act Amendments, which required all states to identify contaminants in drinking water and to take actions to improve water quality. The AGChem Program was established in 1987 to assess the impact of chemicals used in agriculture on the state's groundwater. The focus has historically been on areas in which pesticides are used extensively. Some of the other programs supervised by MDEQ include the Mississippi Waste Pesticide Disposal Program and the Household Hazardous Waste Program.

In the wake of Hurricane Katrina in summer 2005; Mississippi, Louisiana, and parts of Alabama were faced with massive cleanups along their coasts. The Mississippi Gulf Region Water and Wastewater Plan was created to deal with some of these environmental impacts of the storm, including spills of hazardous chemicals, fuels, and oils and with debris from oil pumps that had been destroyed. Katrina damaged a number of underground fuel tanks, leaking additional fuel into the atmosphere. In six coastal counties, Katrina rendered all city water treatment facilities inoperable. The Federal Emergency Management Agency (FEMA) estimated that Katrina generated approximately 45 million cubic yards of debris in Mississippi, with potentially devastating impacts on global warming and climate change. Massive amounts of solid waste had to be dealt with, and 300 debris management sites were set up in affected areas. Millions of fish, crayfish, freshwater mussels, and blue crabs were killed during the storm. Oyster reefs and habitats were destroyed and ecosystems threatened, posing threats for many decades.

Mississippi State University

MISSISSIPPI STATE UNIVERSITY offers several educational options in the areas of meteorology and climatology. The Department of Geosciences offers on-campus undergraduate and graduate degrees in Geosciences, with optional emphases in broadcast meteorology, professional meteorology, climatology, geology, geography, and geographic information systems (GIS). The department also offers a distance-learning graduate degree specifically for Kindergarten–12 teachers and distance-learning certificate programs in broadcast meteorology, operational meteorology, and GIS. The university, located adjacent to the city of Starkville, is a land-grant university established in 1878. As of October 2006, the university enrolled 12,630 undergraduate students and 3,576 graduate students.

The Department of Geosciences began during the first year courses were offered by the university (1880–81), when meteorology and geology were both required courses for all students. The present department was started in 1916 as the Department of Geology and Geography; it was ultimately renamed the Department of Geosciences in 1993. In 1987, the department expanded its course offerings in meteorology and climatology, in order to support weather-related specializations for B.S. and M.S. on-campus students. Since that time, enrollment has steadily increased, and the department now enrolls approximately 120 meteorology majors each year. There are 20 courses currently taught on campus in the areas of meteorology and climatology.

The department is perhaps best known for its certificate in broadcast meteorology. Since 1987, the distance-learning Broadcast Meteorology Program has educated those that are already employed in the television industry. This program has continued to experience tremendous success, with more than 60 students earning certificates in broadcast meteorology each year, and more than 40 taking courses simply to continue their education. The department also offers a similar certificate program for military personnel through the Operational Meteorology Program.

Based on the success of the distance-learning certificate in broadcast meteorology, the department now offers a distance-learning graduate degree (M.S.) specifically for in-service teachers. The program, Teachers in Geosciences (TIG), which trains K–12 teachers in the areas of meteorology, climatology, geology, and environmental science, enrolled its first students in 1998. This program has been quite successful, as approximately 125 students complete it each year. As of August 2007, the Department of Geosciences employed 16 resident faculty (five with expertise in meteorology and/or climatology), three adjunct faculty (two with expertise in meteorology) and nine resident instructors (five with expertise in meteorology and/or climatology). Recent research topics by faculty, instructors, and students include: health, wildfire risk, tornado variability, continental snow-cover variability, and roles and perceptions of broadcast meteorologists.

The Department of Geosciences is home to the Office of the Mississippi State Climatologist and the Mississippi State University Climatology Laboratory. The department is also affiliated with Mississippi State University's GeoResources Institute and the Northern Gulf Institute. Mississippi State University's Department of Geosciences is producing qualified operational and research meteorologists, broadcast meteorologists, and geoscience teachers. The graduates of these degree and certificate programs contribute to the major components of weather research, forecasts, dissemination, and education. At least one-third of all U.S. television weathercasters have been educated by Mississippi State University, so a large portion of the public is likely to encounter graduates of the Department of Geosciences as they seek information regarding weather forecasts and/or climate change.

Mississippi State University

Missouri

MISSOURI HAS A land area of 69,709 sq. mi. (180,693 sq. km.), a population of 5,817,211 (2000 est.), and a population density of 80.3 people per sq. mi. (31 people per sq. km.). Although it has historically been a southern state, it is located in the Midwest. As accurate statistics for the weather in Missouri exist from 1893, it has been possible to study changes during the early 20th century, and during the period from the 1970s when climate change was recognized. The climate in Missouri ranges from cold winters to hot and humid summers. As the state has neither large mountains nor coastline, it is heavily influenced in winter by cold Arctic air, and in summer by the hot and humid winds from the Gulf of Mexico.

The prospect of warmer weather, with the probable detrimental effects on agriculture, water supplies, and lifestyle, has caused many in Missouri to reconsider their existing lifestyle. One study in St. Louis projects that, by 2050, there could be as many as 200 people dying from heat-related deaths each summer, a 170 percent rise from the current rate of about 80 deaths per summer. There is also expected to be a decline in forested parts of Missouri by as much as 10–20 percent. Areas with poorer soil are expected to becoming rapidly unusable for agricultural purposes. Declines in the yield of corn and soybeans are probably, as is a fall of up to 30 percent in the amount of hay produced.

There are many industries located in Missouri, which has a heavy input into the aerospace and transportation industries. Many areas are also heavily reliant on agriculture, with half of the industry involving the raising of cattle for beef and dairy products. With large deposits of limestone, Missouri is heavily involved in the production of Portland cement, and is the state that produces the largest amount of lead. As a result of this, Missouri has much to offer, and potentially much to lose over plans to combat global warming and climate change. The emissions from aircraft are a major factor in greenhouse gas emissions, and the aerospace industry would be one of the first to suffer, should federal U.S. laws be introduced to combat climate change. Cattle emitting methane have also been identified as a major problem, and the production of cement is a major producer of carbon dioxide emissions.

To study the effects of the change in climate in the state, in 1989, the legislature of the State of Missouri ordered the formation of the Commission on Global Climate Change and Ozone Depletion, with its final report published in 1991. A Statewide Energy Study, published in the following year by Missouri's Environmental Improvement and Energy Resources Authority. To try to monitor changes to the climate in the state, which has helped coordinate the projects to reduce greenhouse gas emissions, the Missouri Climate Center was established in July 1995, as a section of the Atmospheric Science program of the Department of Soil and Atmospheric Sciences of the University of Missouri-Columbia's College of Agriculture, Food and Natural Resources.

The first focus of the plans to reduce greenhouse gas emissions was on electricity generation. With some 98 percent having come from coal-fired power plants, the government encouraged greater efficiency in generation, with increased use of renewable energy sources, with wind power, solar thermal energy, and photovoltaic cells and panels. There were also new regulations regarding the building of residential and commercial buildings to encourage changes in design to help with energy efficiency. This saw the introduction of Home Energy Rating Systems and Energy Star labeling. There were also moves to promote fuel-efficiency of automobiles, and to encourage public transport.

In July 2002, John Noller prepared the Missouri Action Options for Reducing Greenhouse Gas Emissions, highlighting further methods of helping reduce carbon dioxide emissions. He built on previous suggestions, including urging for the capture of methane gas from the state's landfills, and encouraging wider use of waste reduction schemes. He also supported making significant reductions in emissions from the transportation sector, with improved driving behavior, vehicle maintenance, and better public fleet management, as well as helping with the use of alternative fuel vehicles.

Mixed Layer

A MIXED LAYER is a quasi-homogeneous turbulized layer in the world's ocean. Its upper boundary directly contacts with the atmosphere boundary layer, while the mixed layer bottom contacts with underlying thermocline. That is why mixed layer is also called the upper mixed layer. Vertical gradients of temperature and salinity within the mixed layer usually do not exceed 0.01 Kelvin degrees and 0.01 promille per meter. Mixed layer is formed as a result of turbulent mixing by thermohaline convection, vertical shear of oceanic currents, and surface waves (periodically breaking when their slope reaches some critical level).

The process of mixed layer deepening is accompanied by entrainment of more cold water of thermocline into the upper turbulized layer. This leads to negative mixed layer heat fluxes at its bottom. That is why mixed layer deepening is accompanied by its cooling. As a result of entrainment, the sharp interface between turbulized mixed layer and unturbulized thermocline is formed. If surface sources of turbulence are too weak to mix stably stratified thermocline, the mixed layer turbulence is decaying and the depth of mixed layer is decreasing. The mixed-layer shoaling causes its isolation from thermocline, because the new turbulized upper mixed layer is joined with the underlying old (relic) mixed layer with decaying turbulence. As a result, the heat fluxes at the bottom of new upper mixed layer is close to zero, and this does not prevent the upper mixed layer from the warming as, for example, from a generalized analysis of this processes discussed by Eric Kraus.

The mixed layer occupies almost the whole world's ocean. Its thickness is at a maximum in the sub-Arctic and sub-Antarctic regions in winter, when north Atlantic deep water and Antarctic bottom water are sinking up to 1.2–3.7 mi. (2–6 km.). In the tropics and subtropics, the typical mixed layer depth is of about 32–328 ft. (10–100 m.) throughout the entire year. It is controlled not only by intensity of surface turbulent mixing, but also by regular vertical motion, because of the divergence or convergence of oceanic currents. Therefore, in the vicinity of oceanic jets (such as the Gulf Stream or Equatorial Undercurrents/Countercurrents), the mixed layer thickness is changed significantly, and horizontal in-homogeneity should be taken into account for simulation of the mixed layer evolution.

In middle and high latitudes of the ocean interior, there is a strong seasonal cycle of mixed-layer parameters depending on heat fluxes at the surface. In winter, mixed layer is cooling and deepening as a result of net heat lost at the ocean surface and mixed-layer bottom. In that time, intense thermal convection is a principal cause of the mixed-layer deepening. A maximum mixed-layer thickness in the end of winter is, in fact, the depth of penetration of seasonal variations of temperature, salinity, and density. In spring and summer, the typical mixed-layer thickness is at a minimum as a result of surface heating. In that time, mixed-layer is turbulized by dynamic processes (that is, the vertical shear of oceanic currents and surface waves) and its thickness does not exceed a few to tens of meters.

Buoyancy forcing due to thermal convection is a principal cause of winter mixing of mixed layer elsewhere in subtropics, middle, and high latitudes of the world's oceans. However, haline convection also may be important, especially in the subtropical ocean bounded by large desert (such as the north subtropical Atlantic and Sahara), where very dry conditions lead to intense evaporation and sinking of salty waters to the depth. In these specific regions, buoyancy mixed-layer forcing by haline effects prevails. The same is true for the some close or semi-close seas situated in the arid zone (such as in the Red Sea and the Dead Sea).

Modeling of Ice Ages

MODELING ICE AGES and their inception can reveal aspects of the climate system that are not able to be measured, and provide a key to the drivers of climate change. Ice age model results can also allow an analysis of the global and regional conditions at that time, and provide a comparison with proxy field evidence. Models range from simple conceptual models, to full global climate models that include vegetation growth and ocean dynamics. To simulate ice ages or their inception, modelers consider several forcing factors. Low greenhouse gas levels are critical. A continental configuration that limits the oceanic transfer of heat from the tropics to the poles is also important. Ice ages can be instigated by orbital conditions that lend themselves to cool summers in high latitude continents or by weathering processes that remove carbon dioxide from the atmosphere.

Once an area cools and an ice sheet begins to grow, there are many feedbacks that encourage its growth. These include local cooling caused by the ice itself—from the higher reflectivity (albedo) of the ice and the increasing altitude of the ice surface. There are also many feedbacks that alter the levels of atmospheric greenhouse gases. For example, marshes and other regions of vegetation can be a source of greenhouse gases; as these regions freeze or are covered in ice, that source of greenhouse gas is removed. As the globe cools and the oceans begin to cool, even more greenhouse gases are removed from the atmosphere, because a cool ocean has more capacity to absorb carbon dioxide. Feedbacks are instrumental in starting and maintaining an ice age or glacial period. In a warming world, these feedbacks occur in reverse, and evidence from ice cores indicate that warming feedbacks contribute to much more rapid changes in global climate than cooling feedbacks.

MODELING LAST GLACIAL MAXIMUM

One way to model ice ages is using a general circulation model (GCM) or Earth System Model of Intermediate Complexity (EMIC) to simulate the global climate representative of a particular time in history. Many early modeling studies attempted to simulate the most recent glacial, the Last Glacial Maximum (LGM). Since those early studies, a major project was established called the Paleoclimate Modelling Intercomparison Project (PMIP), providing a rich source of modeling studies of the LGM.

The PMIP is designed much like the Atmospheric Model Intercomparison Project (AMIP) or the Coupled Model Intercomparison Project (CMIP), with a range of modeling groups running their GCMs and EMICs with a set suite of forcing factors. Key epochs simulated as part of PMIP were the climatic optimum at 6,000 years ago and the Last Glacial Maximum (LGM), about 20,000 years ago. These times were chosen as end-members of the range of global climate in the recent geological past. They were compared with a present climate with pre-industrial greenhouse gas levels. The project has several aims. It aims to test the ability of models to simulate climates quite distinct from today, and the differences between models. Modeling extreme climates will help to understand the drivers of climate change and the climate's response to different forcing. Finally, the PMIP will provide many results to help fill in the gaps in knowledge of past climates and understand proxy evidence.

The first phase of PMIP included GCMs where full ocean dynamics were not considered, and which used low resolution EMICs. In most models, the ocean surface temperatures were prescribed from a map derived from proxy evidence. Some models also included interaction with the ocean surface. The main step to the second phase of PMIP was the inclusion of full ocean models. Some models also included interactive vegetation.

BOUNDARY CONDITIONS

Some consider changes in solar radiation pattern and timing associated with Milankovitch cycles an important factor in maintaining a glacial climate. These changes are routinely included in GCM simulations of the LGM, however, they have minimal impact, as they were actually very similar to today. The continental configuration was also very similar to today, and changes need not be considered. The conditions at the LGM were the culmination of 100,000 years of cooling, thus models of the LGM must include an estimate of certain features in the climate system that hold memory of that cooling. These features include massive continental ice sheets, cooler oceans, lower sea levels, and lowered levels of atmospheric greenhouse gases.

The massive ice sheets that spread across the polar reaches of the continents during the 100,000 years of cooling prior to the LGM were imposed when modeling the LGM. Antarctica was glaciated, as it is today. The other major ice sheets are called the Fennoscandian, which covered much of Europe, and the Laurentide, which covered much of North America. Both the change in surface type (to ice) and the increase in elevation are included. The bright white surface of the ice will reflect more sunlight, encouraging cool conditions. The height of the ice sheets (up to 2.5 mi., or 4 km.) also alters the track of weather systems, particularly in the Northern Hemisphere.

With so much water locked up in the extensive continental ice sheets, the sea level is estimated to have been 393 ft. (120 m.) lower at the LGM. This exposes more land and alters the pattern of land-sea contrast. This is particularly important in regions where landmasses are surrounded by shallow seas. One such place is to the north of Australia, where a land bridge connected Australia to Papua New Guinea and Indonesia to its north, limiting the oceanic warm pool, which is of great importance to the monsoon and rainfall in the region. The exposure of this land bridge also had consequences for human migration.

Oceans circulate on timescales much longer than the atmosphere. Conditions at the surface are slowly transferred to the deeper ocean, thus the ocean would have a memory of the cool conditions that were experienced for thousands of years prior to the LGM. The ocean could also be seen as forcing glacial conditions. As in the first phase of PMIP, sea-surface temperatures can be prescribed, which provides a strong constraint on the global climate. Models forced by prescribed sea-surface temperatures provide a test-ground for a range of experiments, including the consistency between proxy evidence from the land and ocean. They also require reasonably low levels of computing power. However, prescribing sea-surface temperatures neglects interactions between the atmosphere and the ocean, which are important to the climate and variability of both.

More recent efforts at modeling the extreme climate of the LGM include full models of the ocean. The LGM ocean has a temperature structure that has been exposed to thousands of years of cool atmospheric conditions during the preceding glacial cycle, and would be expected to be much cooler than the modern ocean, thus modeling the LGM ocean requires an appropriate initial state. There are a variety of methods used to achieve an appropriately cool ocean. Due to the high computational expense, approximations or accelerations are required. One method is to run the ocean model alone, intermittently inputting atmospheric information.

Variations in sea-ice extent alter the ocean-atmosphere interactions that can occur. If open ocean is exposed to the atmosphere, the relatively warm water has the opportunity to impart heat, moisture, and energy. However, a cover of sea-ice cuts off this interaction. There is evidence that sea-ice was more extensive at the LGM. Models with prescribed sea-surface temperatures also prescribe sea-ice, while models that include full oceans usually also include models that determine the extent of sea-ice from the oceanic conditions.

Levels of atmospheric greenhouse gases are very important to the climate, and these are generally imposed in models of the LGM. For well-mixed gases such as carbon dioxide, levels are reasonably well known from the LGM air bubbles trapped in polar ice. Some EMICs include a module of interactive atmospheric chemistry as part of the carbon cycle. For PMIP GCMs, the level of atmospheric carbon dioxide is set at 280 parts per million by volume (ppmv) for the present day (pre-industrial) and 185 ppmv for the LGM. This change is estimated to reduce the radiative forcing of the troposphere by 2.8 Wm-2.

Vegetation changes and atmospheric particulates are believed to have influenced the global and regional climate of the LGM. EMICs have generally included a crude estimate of vegetation; some of the most recent attempts to simulate the LGM include vegetation, its changes and feedbacks. At the LGM, the generally drier environment meant that there was more potential for dust from drier, less-vegetated surfaces to enter the atmosphere. The result of increased particulate levels in the atmosphere is to cool the surface—it is estimated that the increased dust at the LGM reduced the radiative forcing of the troposphere by about 1 Wm-2. Particulates and dust are not currently included in the GCMs in PMIP, but it has been flagged as an important component to be considered in the future.

RESULTS

The modeled LGM surface temperature is cooler compared to the modeled pre-industrial temperatures. The global cooling ranges from 5.9–8.4 degrees F (3.3–4.7 degrees C) when the temperature of the sea surface is prescribed. When the LGM ocean is also modeled the cooling is generally greater, ranging from 6.5–10.2 degrees F (3.6–5.7 degrees C) cooler. The Northern Hemisphere has greater cooling than the Southern Hemisphere due to the massive ice sheets, with temperatures up to 54 degrees F (30 degrees C cooler). The height of the ice-sheets also modifies weather systems, contributing to greater cooling right across Eurasia. In the tropics, the cooling is generally less pronounced, while over the ocean there is a large range, with cooling ranging from only 3.6–9 degrees F (2–5 degrees C).

The U.S. Geological Survey National Ice Core Lab in Denver, Colorado, stores and studies ice cores from all over the world.

A major shift in the LGM climate compared to the present was the reduction in atmospheric water vapor, leading to a much drier environment. This drying has implications for the energy of weather systems across the globe. The greatest drying is over the ice sheets and sea ice. Water vapor is also a strong greenhouse gas, and the reduction of water vapor, carbon dioxide, and methane in the atmosphere is the main driver of the cooling poleward of 54 degrees F (30 degrees C) in these modeled glacial climates. In the Northern Hemisphere, reflection off the massive continental ice-sheets and extensive sea ice were also important to the cooling at high latitudes. This effect was particularly important in summer, when the sun is higher in the sky, contributing to about half of the modeled cooling.

The westerly winds in the Southern Hemisphere impact the southern reaches of the three mid-latitude continents. The prescribed ocean-surface temperatures in the first phase of PMIP drove a southward shift of the westerlies at the LGM, particularly in the Australian region. The results from models that include full oceans are not in agreement. The models generally show no latitudinal shift in the westerlies, with most showing a reduction in the intensity of the winter winds, particularly in the Pacific Ocean sector. In the Northern Hemisphere, there was an equatorward shift in the winter jet-stream in most models.

The models involved in PMIP can clearly simulate a cooler climate for the LGM, although the prescribed ocean temperatures used in phase one have known errors that lead to erroneously warm conditions in some regions. Results are similar across models in those regions, where the models are strongly-constrained by boundary conditions such as ice sheets. However, away from these regions, such as in the Southern Ocean, there is great variability.

MODELING GLACIAL INCEPTION

Understanding the drivers and feedbacks of the climate system is important for a proper understanding of the world. Modeling the conditions required to drive the globe into an ice age is a great way to better understand the climate system. There are three major periods of glacial inception: the beginning of the current glacial cycle, about 115,000 years ago; the beginning of the current ice age, about 34 million years ago; and the Cryogenian period, when the Earth was believed to be nearly covered in ice.

The Milankovitch theory dictates that glacial conditions could be instigated when the Earth's orbit is more elliptical and the Earth is furthest from the sun in the Northern Hemisphere summer. These orbital conditions were in place 115,000 years ago, at the beginning of the glaciation that culminated in the LGM. Early modeling studies with simplified GCMs could not capture the appropriate initiation of glacier growth, however, there was more success with recent models that have more accurate representation of mountains. This suggests that it is on high peaks where snow will first persist year-round; then, as feedbacks come into play, the area of glaciation will expand. Experiments using differing levels of atmospheric carbon dioxide revealed that there were thresholds of carbon dioxide, below which shifts in orbital parameters became much more important.

It is believed that the growth of the Antarctic Ice Sheet about 34 million years ago, at the Eocene/Oligocene boundary, was instigated when the Drake Passage (the strait between Antarctica and South America) opened as South America moved north away from Antarctica. Modeling studies show that when the Drake Passage is closed, the southward ocean heat transport is increased by 15–20 percent over all southern latitudes. When the Drake Passage opened, it allowed the circumpolar current to develop, effectively thermally isolating the Antarctic continent. Thus, warm tropical waters could not make their way to the shores of Antarctica any more. Further modeling studies, using a dynamic ice-sheet model asynchronously coupled to a simplified GCM, indicate that carbon dioxide needed to fall below critical levels before ice-sheets would form, even if the Drake Passage was closed. Once ice growth began, feedbacks then aided ice-sheet growth and ice eventually covered most of the continent, as it does today.

Geological evidence of the continental configuration during the Cryogenian period suggests that the continents were centered on the equator, and ice covered much of the globe. Conceptual models of how this ice age came about suggest that the strong tropical rainfall weathered these continents, drawing carbon dioxide out of the atmosphere and reducing the greenhouse effect. Continents on the equator would also limit the oceanic transfer of solar input in the tropics to the poles, allowing the poles to cool. These conditions, combined with a weaker sun, are suggested as adequate climate drivers to lead to an Earth that was almost completely ice-covered.

Modeling of Ocean Circulation

OCEAN WATERS MOVE in a global circulation system, transporting huge amounts of heat around the globe. The thermal capacity of the ocean is very large compared to that of the atmosphere, and through its circulation patterns, it can absorb heat in one region and return it to the atmosphere (often decades or centuries later) at an entirely different place. Ocean circulation is, thus, a key determinant of regional and global climate.

Ignoring tidal forces, the long-term mean oceanic circulation is driven by three external influences: wind stress, heating and cooling, and evaporation and precipitation; all of which, in turn, are ultimately driven by solar radiation. Ocean currents are either wind-driven (surface currents) or due to changes in the density of sea water (deep currents). The circulation of the atmosphere is, in turn, influenced by the distribution of oceanic properties, such as sea-surface temperature and the distribution of sea ice. In particular, the amount of evaporation from the ocean depends strongly on the sea-surface temperature; and when the evaporated water is returned as rain, it releases its latent heat into the surrounding air. This heating is probably the strongest driving force for atmospheric winds.

To understand the oceanic and atmospheric circulation fully, they are now treated as a single system of two interacting components, coupled at the air-sea interface through the fluxes of momentum, heat, and mass. However, early ideas on the nature of oceanic circulation pictured the motion in equilibrium or perpetual steady state. This view was formed from limited observations, often based on tracking floating objects released into the ocean. The classic picture of steady-state circulation was laid out in Harald Sverdrup's definitive textbook of 1942, *The Oceans: Their Physics, Chemistry and General Biology,* and although it included a description of the deep thermohaline circulation (now recognized as critical for climate), Sverdrup paid most attention to surface currents like the Gulf Stream. Through the 1950s, oceanographers concentrated on surface winds and currents, far easier to measure and far more important for mariners than the slow, deep circulation. How much of the overall general circulation was driven by the winds, and how much by density changes related to temperature and salinity, was still unknown.

Seminal efforts to numerically-model oceanic circulation began in the late 1960s, led by Kirk Bryan, a Woods Hole oceanographer, who with his collaborator Michael Cox built a model for a highly-simplified ocean basin with five depth levels. Their model produced a picture that looked roughly like the North Atlantic Ocean's Gulf Stream and equatorial flow. Despite deep skepticism from empirical oceanographers who were still mapping the basic patterns of motion in the ocean, Bryan extended his work, motivated by "the pressing need for a more quantitative understanding of climate." Recognizing that surface winds helped drive the ocean currents that transported heat from the tropics poleward, Bryan coupled his ocean basin model to Syukuro Manabe's model of atmospheric circulation. Published in 1969, this coupled ocean-atmosphere circulation model developed by Bryan and Manabe was a forerunner of modern general circulation models (GCMs).

Paralleling the increase in available computing power, the first global ocean model was developed by Cox in 1975, using nine depth levels and a horizontal grid resolution of 2 degrees latitude by 2 degrees longitude. Cox found he could simulate the ocean circulation for only a few years in its centuries-long progress, but overall the "in silico" ocean behaved somewhat like the real one. In 1988, S. Manabe and R. Stouffer developed a coupled atmosphere-ocean model that incorporated a realistic land and ocean topography. Starting from two different initial conditions, asynchronous time integrations of the coupled model, under identical boundary conditions, led to two stable equilibria. In one equilibrium, the North Atlantic has a vigorous thermohaline circulation and relatively saline and warm surface water. In the other equilibrium, there was no thermohaline circulation, with an intense halocline in the surface layer at high latitudes. These results suggested that the real ocean system might have at least two equilibria, echoing the result obtained by Henry Stommel 25 years previously, with a very simple pen-and-paper box model. The simulation raised the "intriguing possibility," as Manabe and Stouffer put it, that global warming might shut down the North Atlantic thermohaline circulation within the next century or so. Halting the steady flow of warm water into the North Atlantic would bring devastating climate changes in Europe and perhaps beyond.

With the advent of high-performance super-computers, coupled ocean-atmosphere models improved rapidly through the 1990s, and a number of studies confirmed the possibility that changes in ocean climate from global warming could eventually shut down the North Atlantic thermohaline circulation, however, the timescale of such a change is still far from certain. In the last decade, the availability of several polar orbiting satellites, that measure winds, waves, sea-surface temperatures, and ocean color, at high spatial and temporal resolution, means much more data are now available for the calibration and validation of numerical circulation models. Also recently launched is the Argo program—an international program to seed the global ocean with an armada of some 3,000 free-floating buoys that measure vertical profiles of ocean temperature and salinity, thus complimenting the surface data from satellites.

Modeling of Paleoclimates

PALEOCLIMATE MODELING INCLUDES the development and application of numerical climate models to simulate climates through Earth's 4.6 billion-year history. Paleoclimate modeling is a theoretical branch of the natural science fields of paleoclimatology and paleoceanography, which seek to document and understand Earth's climate and ocean history. A fundamental goal of paleoclimate modeling is to determine the causes of past global climate change as a guide to modern and future climate change.

Numerical climate models are mathematical expressions of the theoretical laws and physical processes that govern the climate system, approximated and written in computer code for efficient computation. Climate models can vary tremendously in their complexity, capability, domain, and spatial resolution. Climate models used for paleo-applications range from relatively simple one-dimensional models that are based on the conservation of energy (energy balance models), to models that solve the primitive equations to predict the general circulation of the atmosphere and ocean in three dimensions (general circulation models). The capabilities of these models may be limited to one component of the Earth system, the atmosphere, for example; or may include interactions between several components, such as the atmosphere, biosphere, ocean, and cryosphere.

The model domain may be global in extent, or limited to a region, such as the western United States, and is discretized into grid cells. The horizontal (usually latitude by longitude) and vertical (usually altitude, depth, or thickness) resolution of the models can vary substantially between models. Regional models of limited domain may have a horizontal grid spacing of approximately 12 mi. (20 km.), while most global models have grid spacing on the order of hundreds of miles (kilometers). The decision to use a particular model at a specific resolution is based on the scientific problem to be addressed and consideration of the computational cost of running the model.

Paleoclimate models are nearly always initially developed and fine-tuned for the modern climate as a check on the performance of the model. If the model can successfully simulate important aspects of the modern climate, then the model may be modified for paleoclimate applications. It is often assumed that modern climate dynamics and physics are representative of past climates, and thus these aspects do not change for paleoclimate applications. The modifications for paleo-applications are frequently limited to the model's boundary conditions. In mathematics, boundary conditions define the limits of a set of partial differential equations. Similarly, in paleoclimate modeling, the boundary conditions define the limits of the numerical model. Modifications to the boundary conditions are made to represent processes that occur on geological timescales, such as continental drift and seafloor spreading, mountain building and erosion, sea-level change, evolution, and geochemical cycling.

Common boundary conditions required for global paleoclimate modeling include continental positions and topography, ocean bathymetry, vegetation distribution, soil type, solar luminosity, river drainage, atmospheric trace gases (such as carbon dioxide, methane, nitrous oxide, and ozone), and Earth's orbital characteristics (such as obliquity, precession, and eccentricity). The accurate reconstruction of these boundary conditions is a critical aspect, and one of the largest uncertainties, of paleoclimate modeling. For very ancient time periods, geological evidence of past boundary conditions may not exist or may be known only crudely. Numerous paleoclimate-modeling studies have demonstrated that differences within the uncertainty of a boundary condition can have regional or global climatic consequences, as shown by Poulsen, et al.

Paleoclimate studies often simulate a specific interval or time slice. In this case, the boundary conditions remain constant throughout the experiment, and the model is run until a steady-state climate is achieved. The length of the integration varies, depending on the residence time of the system that is modeled. An atmosphere-only model may be run for as little as 30 years, while models that include ocean and ice-sheet components require thousands of years of model integration. The simulation of time slices is prevalent in studies that predict climate on geological timescales, since it is impractical with modern computational capabilities to run most numerical models for millions of years. Transient runs, in which the time-varying response to a forcing is of interest, have been used in studies of Quaternary climate change where the time interval of interest may be hundreds to thousands of years, as shown by Ganopolski and Rahmstorf.

Two approaches are frequently used in the application of paleoclimate models. Many paleoclimate modeling studies fall within the category of sensitivity experiments: modeling experiments in which one parameter is varied at a time and compared to a control case. Sensitivity experiments quantify the model's climate response to a single factor, such as carbon dioxide. This methodology can be used to evaluate how uncertainties in boundary conditions influence the climate prediction. Alternatively, some researchers have attempted to simulate a particular time interval by specifying the best boundary conditions, and then comparing the simulation to climate proxy reconstructions. In practice, many studies mix these two approaches.

The validation of paleoclimate models is made through comparison with climate proxies, paleo-oceanographic and geologic evidence used to infer past climate. Climate proxies differ tremendously in type, spatial and temporal distribution, and accuracy. In general, climate proxy uncertainties increase with age, while the sampling density decreases with age. Types of paleoclimate proxies include: lithologic indicators (such as tillites, evaporites, and coals), geochemical indicators (such as foraminiferal and ice $\delta^{18}O$, foraminiferal Mg/Ca ratios), and paleo-floral indicators (such as tree-ring dendrochronology, distribution of plant types, and leaf-margin analysis). The comparison of paleoclimate models and proxies is often not direct because climate models are not usually capable of simulating geologic processes, for example, the deposition of evaporites or the incorporation of O^{18} in the tests of marine invertebrates. Rather, climate models produce output, such as surface temperature, rates of precipitation and evaporation, winds and currents, snow and sea ice, which are indirectly compared with climate proxies.

APPLICATIONS OF PALEOCLIMATE MODELING

The applications of paleoclimate modeling include: identifying mechanisms of climate change, quantifying the climate response to specific forcing factors, recognizing climatic feedbacks and processes that amplify/damp climatic forcings, identifying limitations of climate proxies from the geological record, and demonstrating strengths/shortcomings in numerical climate models. Paleoclimate modeling studies have contributed to many of the outstanding problems in paleoclimatology.

A few of the most significant advances have been made in: evaluating the plausibility of global glaciation and deglaciation in the Neoproterozoic; demonstrating the effect of super-continentality on Paleozoic climate; delineating the conditions required for glaciation in the Ordovician and Late Paleozoic; understanding the role of greenhouse gases during the Cretaceous, Eocene, and Pliocene periods of global warmth; demonstrating the influences of Cenozoic mountain uplift and ocean gateways on regional and global climate; simulating the conditions of the Last Glacial Maximum and Holocene; quantifying the influence of Earth's orbital variations on climate variability and ice volume in the Pleistocene and Holocene; and simulating the ocean's thermohaline variability and its influence on global climate. These paleoclimate modeling studies have provided insights into the causes and dynamics of past climate change, revealed the major climate forcings through Earth history, and identified shortcomings in our understanding of climate.

With regard to modern and future climate change, paleoclimate modeling has made several notable contributions. By investigating extreme climates outside of the range of modern climate variability, paleoclimate modeling has provided a critical test of climate models, and has shown that they adequately simulate many, but not all, aspects of past climate on a global scale. Importantly, outstanding issues remain including the simulation of abrupt climate change and past warm climates. Paleoclimate modeling has also established greenhouse gases as one of the most important factors in past climates, and demonstrated that other factors (solar variability and volcanic outgassing) could not account for the global warming since the pre-Industrial Revolution, as discussed by Crowley.

Moldova

LOCATED IN EASTERN Europe, the Republic of Moldova, formerly a constituent republic of the Soviet Union, has a land area of 13,067 sq. mi. (33,843 sq. km.), with a population of 3,794,000 (2006 est.), and a population density of 339 people per sq. mi. (111 people per sq. km.). Approximately 46.7 percent of the population lives in urban areas. Fifty-three percent of the land is arable, a further 13 percent is used as meadows and pasture, and 8 percent is forested.

In 1990, Moldova had a per capita carbon dioxide rate of emission of 4.8 metric tons, which fell steadily to 1.7 metric tons in 2003. Because of the cold winter climate in Moldova and its heavy industry, electricity and heat production accounts for 44 percent of carbon dioxide emissions, other energy industries account for 12 percent, another 12 percent is from manufacturing, and 8 percent from transportation. In terms of the source of emissions, 68 percent come from gaseous fuels, 10 percent from solid fuels, and 22 percent from liquid fuels—the latter from heavy use of automobiles.

Moldova has seen a rise in temperatures that has resulted in some water shortages, and heat waves such as those in the summers of 2006 and 2007 that badly affected Moldova and its southern neighbor Romania. This has added to the demand on water supplies, and a gradual reduction of available, arable land. Further complications are caused by the formation of Transdniestra, a breakaway part of Moldova, where there are even more problems enforcing environmental controls.

The Moldovan government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention in 1996. The government has not signed the Kyoto Protocol to the UN Framework Convention on Climate Change.

Monaco

LOCATED AROUND THE city of Monte Carlo, the Principality of Monaco has a land area of 0.75 sq. mi. (1.9 sq. km.). With a population of 33,000 (2006 est.), and a population density of 47,358 people per sq. mi. (18,285 people per sq. km.), it is the most densely populated country in the world.

With a very high standard of living, carbon dioxide emissions from the principality are high, although its statistics are usually included in those of France, which encompasses the land borders of the country. This is because France supplies all electricity used in Monaco, and the country is serviced by Nice Airport, also in France. Monaco has an effective urban bus transport system operated by the Compagnie des Autobus de Monaco, going some way to alleviate the use of cars, although the Grand Prix there each year helps encourage the fascination with Formula 1 cars, adding to carbon dioxide and carbon monoxide emissions.

The Monégasque government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and signed the Kyoto Protocol to the UN Framework Convention on Climate Change on April 29, 1998, ratifying it on February 27, 2006, with it taking effect on May 28, 2006.

Mongolia

THE LANDLOCKED COUNTRY of Mongolia, bordered by China and Russia, has a land area of 603,909 sq. mi. (1,565,000 sq. km.). With a population of 2,629,000 (2006 est.), and a population density of 4.4 people per sq. mi. (1.7 people per sq. km.), the country has the lowest population density in the world. Six percent of the land is arable, 10 percent is forested, and 81 percent of the country is officially registered as meadows and pasture, mostly for low-intensity grazing for cattle, sheep, and goats.

The country's electricity production comes entirely from fossil fuels; the country had a per capita emission rate of carbon dioxide in 1990 of 4.5 metric tons, rising to 5.4 metric tons in the following year, and then slowly falling to 3.1 metric tons per person in 2003. With a relatively low level of private automobile ownership, 83 percent of carbon dioxide emissions come from solid fuels, with many people using wood or coal for heating in the cold winters, and 16 percent from liquid fuels, reflecting the use of buses and automobiles to cover the large distances when traveling in the country.

Evidence of global warming in Mongolia was discovered in 2000 with the examination of some trees in the remote alpine forests located in the Tarvagatay Mountains, which are on the north side of the Hungai Mountains, in west-central Mongolia. A study of the tree-rings showed that 1980–99 had the highest temperatures of any 20-year period on record, and eight of the 10 highest growth years were since 1950.

The Mongolian government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, ratified it in the following year, and in 1996 the government ratified the Vienna Convention. On December 15, 1999, the government accepted the Kyoto Protocol to the UN Framework Convention on Climate Change, which took effect on February 16, 2005.

Monsoons

A MONSOON IS any wind that reverses direction seasonally. These occur in many parts of the globe, but the most famous is the Indian monsoon wind. The name monsoon is an adoption of the Arabic word *mausim,* which means season. For centuries, Arab sailors took the seasonal *mausim* as a wind that would carry them to India and beyond. The term was originally applied to the Indian monsoon. However, as the phenomenon came to be studied more thoroughly, the term *monsoon* has been applied to other annual weather cycles in both tropical and subtropical regions. It has also been applied to evidence of weather patterns in the geologic past, such as a monsoon system over the prehistoric super-continent of Pangaea, and to some extreme continental climate patterns.

Monsoons can occur in summer months or in winter months. Those that occur in summer months usually blow as a prevailing wind from a westerly direction. The westerly monsoons usually bring great amounts of rain as the rising air comes from the ocean and brings moisture that falls as rain. In the winter months, monsoon winds usually blow in an easterly direction. Because easterly winds usually blow from the land, they generally bring dry weather. They may also bring drought as the easterlies diverge or shift about. The intensity of monsoons varies annually. Some years they are stronger than in others. The strength of the annual monsoons is affected by the Earth's total climate system. As the amount of energy available varies, the system has different outputs, such as the strength of the monsoons, which results in variable amounts of annual rainfall.

INDIAN MONSOON

The Indian monsoon is a wind that blows seasonally over India and the land areas surrounding India. The winds blow in different directions at different times of the year. The monsoon winds blow from the southeast from April to October. From November to March they blow from the northeast. The monsoon brings rains when it blows from the southwest across the warm waters of the Indian Ocean. Hundreds of millions of people depend upon the rains it brings. When it blows from the northeast, dry air prevails to create the dry season. Monsoons also occur in northern Australia, the northern and eastern coasts of Asia, some of the Pacific Coast of North America, South America, and Sub-Saharan Africa. In addition, the Indian Ocean has monsoon areas that include parts of the east coast of the African continent.

Differences in the temperatures on land and sea cause the monsoon winds. The temperature differences occur because the heat transfers in the ocean happen in a different manner than the heat transfers on land. In the ocean, sunlight heats the water to a depth of about 64 ft. (50 m.). Winds and wave action churns the ocean waters and as it heats and cools with annual seasonal changes energize or slow wind action. The heating and cooling of the land and waters of the Indian Ocean cause the temperature differences. Sunlight striking the surface of the Earth heats it to much higher temperatures than it does ocean water. As the heated air rises, a large area of low pressure caused by the rising air is formed. The relatively cooler and denser air that blows across the Indian Ocean flows in to fill the low-pressure areas with its heavier air. At the same time, the relatively cooler air is laden with moisture, but is heated over the land so that the moisture rises is cooled at high elevations, condenses, and falls as rain over the land. During the winter, the land is cooler than the Indian Ocean, so as the air over it rises to form low-pressure areas the denser land airflow from the land into the low pressure over the waters of the Indian Ocean.

SOUTHWEST MONSOON

The southwesterly monsoon is a prevailing wind that blows during the wet seasons of April to October. Very heavy rains are brought to India and to countries surrounding the Indian Ocean. These include Pakistan, Bangladesh, Burma, Thailand, the Arabian Peninsula (Oman, Saudi Arabia, the United Arab Republic, and Yemen) and neighboring African countries that border the Indian Ocean and the Arabian Sea. The rains are very heavy and bring the majority of the rainfall to the region each year. There are places in India that receive over 200 in. of rain per year (over 500 cm.). The warm moisture in the southwesterly monsoon falls as rain over the foothills of the Himalaya Mountains. The southwest Indian monsoon is the source of water for most agriculture in the region. If the monsoon fails, or is not strong, there will be drought with the starvation of millions.

The Tibetan Plateau affects the Indian monsoon. The vast Himalayan Mountain system has reached great heights because the India plate is elevating it. Theorists argue that the land's formation and the development of the Indian monsoon began about 8 million years ago. However, other scientists have hypothesized that an older monsoon existed that also was tied to the Tibetan plateau.

From June through September, the southwestern monsoon wind prevails in India. In the Great Indian

Monsoons that occur in summer months usually blow as a prevailing wind from a westerly direction. These westerly monsoons usually bring great amounts of rain, as the rising air comes from the ocean and brings moisture that falls as rain.

Thar Desert, and the areas to the north and south of it, the Indian subcontinent develops very hot temperatures during the long days of the summer months. The hot air causes lower pressure to prevail in the area. Moisture laden air flows into the Indian subcontinent from the Indian Ocean. When the warm moist air reaches the Himalayas, storm clouds form, because the great height of the Tibetan plateau blocks the moist air. The warm air rises to heights where it cools enough that rain falls in varying amounts. When the oceanic southwest monsoon reaches the Indian subcontinent, it splits into two parts. The eastern part becomes the Bay of Bengal branch; the western part becomes the Arabian Sea Branch of the Southwest Monsoon.

The Bay of Bengal branch of the Southwest Monsoon flows over the Bay of Bengal and northward toward Calcutta and then meets the eastern area of the Himalayan Mountains, where it drops huge quantities of rain over Northeast India, northern Burma, and Bangladesh. Cherrapunji, located on the slopes of the Himalayas in Shillong, is one of the wettest spots on Earth. The remaining portion of the Bengal Branch of the Southwest Monsoon then flows westward over the Grand Trunk Road in the Indo-Gangetic Plain. Great quantities of rain pour down during the height of the seasonal monsoon. The Arabian Sea Branch of the Southwest Monsoon bounces off of the Western Ghats of the Indian subcontinent. The monsoon then moves northward, producing rain along the west coast of the Indian subcontinent. The Ghats are steps, or hills that are shorter steps to the Decca plateau. The eastern Ghats are located on the Bay of Bengal side of the Indian subcontinent. They receive considerably less rain than do the western Ghats, which are on the Arabian Sea side of the Indian subcontinent.

Without the monsoon, India would be much more arid. About 80 percent of the rainfall in India is associated with the monsoon. The huge agricultural population in India is totally dependent upon the monsoon rains for growing rice and other crops. In the 1990s, a few days delay affected the future crops. On the other hand, the Bengal Bay Branch of the

Indian monsoon has regularly brought floods. The monsoon is also a great benefit to Indian city-dwellers because it brings relief from the heat and rains that wash away debris from the cities. The first day of June is considered the normal date for the beginning of the Southwest Monsoon. However, in September, the northern part of the Indian subcontinent begins to cool rapidly. The denser air now blocks the flow of the Southwest Monsoon and, instead, reverses in the direction of the retreating monsoon (Northeast Monsoon) that flows from the Indian subcontinent into the Indian Ocean.

NORTHEAST MONSOON

This retreating monsoon also brings rain to areas that received less during the time of the advancing monsoon. The cooler and drier air flowing from the high Himalayas across the Bay of Bengal bring rain to areas of the eastern part of the Indian peninsula. The Northeast Monsoon brings less rain than falls during the Southwest Monsoon, but it bring vital moisture to areas that were missed earlier in the summer.

In southern Asia, the northeastern monsoon appears in December and lasts until early March. In Central Asia, wintertime temperatures are cold so that a dome of high-pressure air develops. As the jet stream passes over the area, it splits into the polar jet and the subtropical jet stream. The subtropical flow passes over southern Asia, creating clear skies over India. At the same time, warm water from the Philippines eastward develops into a low pressure system. The system spreads over Southeast Asia, Indonesia, and northern Australia. The winds then flow in a monsoon trough into the swamp wet areas of northern Australia and into the interior of the continent, bringing much-needed summertime rains.

SUB-SAHARAN MONSOON

The African monsoon in sub-Saharan Africa is different from the monsoon rains that water the vast Serengeti Plains or the areas of East Africa that adjoin the Indian Ocean. The sub-Saharan monsoon is caused by seasonal shifts in the Intertropical Convergence Zone. The Sahara Desert reaches great temperatures in the summertime and creates hot air low-pressure centers. As they move off of the African continent from June to December, they cross the Atlantic Ocean and have the potential to develop into hurricanes. However, in the winter, the dry northeastern trade winds and the extreme harmattan winds shift and bring dry weather to the regions to the south. In the summer, they act to bring moisture to the savannah regions and to the Sahel as far east as the Sudan.

AMERICAN MONSOONS

The South American Monsoon is a key factor in Brazil's weather patterns. Seasonal winds from the Atlantic bring summertime rains that feed the Amazon basin. They also frequently bring flooding to Rio de Janeiro.

The North American monsoon begins in late June and ends in September. It blows from the Pacific Ocean onto Mexico is a relatively weaker version of the Indian monsoon. It is an invasion of humid air that brings thunderstorms. The North American monsoon is sometime called the Summer Monsoon, Mexican Monsoon, Southwest Monsoon, Desert Monsoon, or the Arizona Monsoon. It begins in the south off of the coast of Mexico. It soon affects areas such as the region of Guadalajara. As the Mexican Monsoon spreads, it affects the Sierra Madre Occidental, Arizona, New Mexico, Utah, Colorado, West Texas, and California. In California, it brings moisture-laden winds to the Peninsular Ranges and the Transverse Ranges in Southern California.

As the Desert Monsoon, it brings up to 70 percent of the rain that falls in the Mohave and Sonoran Deserts. Compared to the Sahara, these deserts appear wet. In the upper elevations, the rains also bring moisture that mitigates the summer temperatures with its natural drying effects. Oddly, while reducing drought conditions, the monsoon rains can increase wintertime plant growth, which, in turn, provides fuel for wildfires. The thunderstorms over the Grand Canyon or in the high mountains can create hazards from flash floods. Or, lightening can strike to begin fires or to injure or kill the unwary.

Montana

MONTANA'S AVERAGE ELEVATION is 3,400 ft. (1,036 m.) above sea level. The border of western Montana is formed by the Rocky Mountains and includes a section of the Continental Divide, the separation mark of the Pacific and Atlantic watersheds begins in Glacier National Park and runs south at one point, forming part of the southern boundary between Montana and Idaho. While western Montana is mountainous with highlands and the location of most of Montana's natural lakes, eastern Montana is Great Plains with grassland prairie and scattered small mountains. Fort Peck Dam on the Missouri River in northeastern Montana creates Fort Peck Lake, the world's third largest reservoir. According to the 1972 state constitution, all water in the state, even water on private land, is under state control.

The average annual precipitation is 15 in. (38 cm.), with the higher mountain areas receiving more than 50 in. (127 cm.) with winter snow. To the west of the Rocky Mountains, mild air currents from the Pacific give cooler summers and warmer winters than the area east of the Rocky Mountains, which receives Canadian and Arctic air currents in winter, and warm moist air flows from the Gulf of Mexico, in summer. Average July temperatures vary from 72 degrees F (22 degrees C) in the southern plains, to 60 degrees F (16 degrees C) in the mountains, and average January temperatures are below freezing. The highest temperature recorded in the state was 117 degrees F (47 degrees C) on July 5, 1937, and the lowest temperature recorded in the state was minus 70 degrees F (minus 57 degrees C) on January 20, 1954.

The state supports a population of approximately one million people. Coal, petroleum, and natural gas are mined in Montana. Forests cover 22 million acres, providing opportunities for commercial logging. The eastern part of Montana is perfect for agriculture, including beef, wheat, barley, and sheep. Western Montana's milder climate is suitable for fruits (berries, cherries, and apples). Electricity is generated by coal-burning plants and by hydroelectric plants.

IMPACT OF CLIMATE CHANGE

Climate models vary on the amount of temperature increase possible; however, potential risks include having decreased water supplies; increased risk for wildfires; population displacement; changes in food production with agriculture improving in cooler climates and decreasing in warmer climates; and change in rain pattern to downpours with the potential for flash flooding and health risks from certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents; and heat-related illnesses.

Park officials at Glacier National Park show glaciers are melting with warmer temperatures. Snow pack in Montana holds about 75 percent of the state's water supply and acts as a reservoir that keeps streams flowing in the summer months. Warmer temperatures resulting in decreased snow pack could mean less water in Montana's lake and streams during the summer months. Montana may benefit from changing climate. Shorter, milder winters could mean longer growing seasons and increasing crop yields, though higher temperatures may mean changing crops produced for those more adapted to a warmer climate and more drought-resistant. The milder climate could attract more tourists. Taking advantage of sun and wind to produce electricity could provide economic benefits.

ADDRESSING HUMAN-INDUCED CONTRIBUTIONS

Based on energy consumption data from the Energy Information Administration, Montana's total CO_2 emissions from fossil fuel combustion in million metric tons for 2004 was 35.10, made up of contributions by source from: commercial, 1.08; industrial, 5.87; residential, 1.58; transportation, 7.73; and electric power, 18.84.

The Montana Climate Change Advisory Council (MCCAC) formed in 2005, with members appointed in Aril 2006, by the Department of Environmental Quality, includes representatives from industry, environment, local and tribal governments, transportation, and agriculture. It was given the task of inventorying and developing policy options for reducing greenhouse gas emissions. One of their recommendations is to design a mandatory reporting program, as carbon emission-reporting is not yet required.

Montana holds observer status with the Western Regional Climate Action Initiative, in which the partners will set an overall regional goal for reducing greenhouse gas emissions and will design a market-based mechanism to help achieve that reduction goal. Montana joined the Climate Registry, a voluntary national initiative to track, verify, and report greenhouse gas emissions, with acceptance of data from state agencies, corporations, and educational institutions, beginning in January of 2008.

During the 2007 Legislative session, lawmakers debated several greenhouse gas and climate change-related bills. Those approved include legislation to provide permanent property tax rate reductions for new investments in transmission lines for renewable-source electricity, liquid, and carbon sequestration pipelines, in addition to those available for new investments in biodiesel, biomass, and other defined technologies; prohibiting approval of new electric generating units primarily fueled by coal unless a minimum of 50 percent of the CO_2 produced by the facility is captured and sequestered. Natural gas plants also must include cost-effective carbon offsets. The bill applies only to electric generating units constructed after January 1, 2007.

In addition to activities at the state level, the mayors of Billings, Bozeman, and Missoula have signed the U.S. Mayors Climate Protection Agreement, in which mayors commit to reduce emissions in their cities to 7 percent below 1990 levels by 2012. Missoula, Montana is the base for GlobalWarmingSolution.Org, a network of 35 member organizations representing 320 groups in the United States and individual supporters. Founded in 2003, the group's mission is to advocate global greenhouse gas emissions reduction. Other conservation organizations active in Montana include the Montana Environmental Information Center, Montanans for a Healthy Climate, and Montana Trout Unlimited.

Montreal Protocol

THE MONTREAL PROTOCOL is an international treaty designed to protect the ozone layer by phasing out the production of a number substance (such as CFCs—Chlorofluoro compounds) believed to be responsible for ozone depletion. In the late 1920s, chemicals called chloroflourocarbons (cloro-floro-carbons) or CFCs, were invented. These chemicals were not poisonous and did not harm fabrics, plants, or people. Companies thought they were great products and used them in refrigerators, air conditioners, styrofoam packaging, and spray cans. From the 1920s to the 1970s, billions of CFC molecules were released into the air.

In the 1970s, scientists began to wonder what happened to all the CFCs after they had been in the air for a while. Scientists eventually learned that CFCs could float past the troposphere (troposphere is a layer of atmosphere that is closest to the Earth. It extends to about 3.7–10.5 mi. (6–17 km.) above the Earth's surface and is thickest at the equator. Temperatures in the troposphere decrease as altitude increases. They are warmer nearest the Earth, in part because gases in the troposphere are warmed by heat radiated from the earth.) up into the stratosphere (stratosphere is the second layer of atmosphere, and extends out beyond the troposphere, to about 31 mi. (50 km.) above the earth. Gases in the stratosphere are heated mainly by incoming radiation from the Sun; temperature in the stratosphere gradually increases as altitude increases. As a consequence of temperature differences between the troposphere and stratosphere, and the resulting circulation patterns, exchange of air between the two layers is slow. The stratosphere is also known as the ozone layer. The distribution of ozone is closely linked to the vertical structure of the atmosphere. Approximately 90 percent of all ozone molecules are found in a broad band within the stratosphere. This layer of ozone-rich air acts as an invisible filter to protect all life forms from over-exposure to the Sun's harmful ultraviolet (UV) rays. Long-term ozone depletion is result of human-activity.) where UV rays would break them down. The chemicals that make up CFCs, mainly chlorine and fluorine, float around the stratosphere, breaking up ozone molecules.

Although CFCs were invented in 1920s, and research in the impact of CFCs on the ozone layer began as early as the 1930s, it received attention mainly in 1970s. During the 1970s, concerns arose that stratospheric transport aircraft might damage the ozone layer. This concern started in 1973, when the American Chemists (Frank Sherwood and Mario Molina) decide to study the impact of CFCs on the Earth's atmosphere. They discovered that CFC molecules were stable enough to remain in the atmosphere until they got into the stratosphere where they would finally be broken down by ultraviolet radiation releasing a chlorine atom, after an average of 50–100 years for the two common CFCs.

In 1974, Sherwood Rowland and Mario Molina discovered a dramatic change in the chemical composition of our atmosphere, an enormous increase in concentration of chlorine throughout the world. This increase in chlorine is attributed to widespread use of CFCs. It was at this time that the theory was proposed that CFCs were depleting the ozone layer. At the time, CFCs were used in refrigeration, aerosol cans, and some industrial processes. Initially greeted with a great deal of skepticism, further research and monitoring began to convince the scientific community that the CFC hypothesis might be valid. In the late 1970s and early 1980s, some national governments imposed bans on CFCs as aerosol and other propellants in non-essential uses for antiperspirants, hairsprays, and deodorants. In 1977, the United Nations Environment Program (UNEP) established the Coordinating Committee on the Ozone Layer.

In 1981, UNEP acted on a proposal submitted by a meeting of legal experts and decided to develop a global convention. In 1985, the Vienna Convention on the Protection of the Ozone Layer was signed. The period between the Vienna Convention (March 1985), and the Montreal Protocol (September 1987), was characterized by incredible progress in negotiations. In 1987 a hole in the ozone layer was found over Antarctica, the size of the United States. This discovery transformed politics and international negotiations. In 1987, over 60 countries met in Montreal (more than half of them were developing countries) to discuss the treaty. The global scientific community reached consensus, while meetings were held in Rome to clarify and quantify the current global emissions of ozone-depleting substances and future trends, and new mechanisms for control were discussed. By September 1987, the disagreements and lack of understanding on CFCs and its role on ozone depletion had given way to trust. In turn, the trust offered the prospect of consensus on control measures. Thus, on September 16, 1987, the Montreal Protocol on Substances that Deplete the Ozone Layer was signed by 24 countries. The treaty was opened for signature on September 16, 1987, and took effect on January 1, 1989. It has undergone five different revisions since: in 1990 (London), 1992 (Copenhagen), 1995 (Vienna), 1997 (Montreal), and 1999 (Beijing).

All Parties agreed to meet near-term targets of freezing consumption of key CFCs and halons at 1986 levels, and reducing consumption by 50 percent within next 10 years. While the Protocol is complex, its most important feature was the dynamic process for controlling ozone-depleting substances, in addition to those initially identified in the Protocol. One of the major steps was the amendment to the Montreal Protocol in Copenhagen, in 1992, which resulted in a further acceleration of the phase-out of several

The status of ratification as of October 10, 2007.

ozone-depleting substances. In addition to CFCs, hydrochlorofluorocarbons, and methyl bromide were added to the list of substances subject to control.

The Montreal Protocol was the first treaty to protect the atmosphere from human impacts on the ozone layer. The agreement and the way it was developed are unique. For instance, research findings were a vital part of the decision-making process, and scientific assessments are stipulated in the Protocol every four years as a basis for further decisions on ozone-depleting substances.

In 1979, many countries, including the United States, banned CFCs from manufacture or use. This was a big step toward fixing the problem. Today, no spray cans contain CFCs. Other chemicals are gradually replacing the CFCs in air conditioners. Scientists originally predicted that the ozone layer would be the thinnest around 2008, but then start recovering. But new research shows that other air pollution problems are not only worsening the general situation, but also slowing down the ozone layer's ability to rebound. There are products that still contain CFCs and need to be treated with care. One example of this is car air-conditioners. When the air-conditioner breaks, or the car is taken to a junkyard, the CFCs need to be carefully taken out and recycled or stored so that they do not leak into the air. This can be best achieved by educating people that they should have their car air conditioners fixed by mechanics who are certified to work with CFCs; it is essential in protecting human health (skin and eyes) from the harmful effects of UV rays.

The Montreal Protocol has been a success story and it owes a great deal of this success to the actions of the U.S. government, which played a very aggressive role in producing the protocol. American companies also played a large role in the protocol's success, because they stood at the forefront of technological innovation in creating substitutes for the chemicals that were causing ozone-depletion. All of these countries are complying with their obligations for it has been shown that the ozone-depleting chemicals' global emissions have decreased by over 95 percent since the Protocol was put into action. Atmospheric concentrations of all of these chemicals have also been declining since 1994. By 2050, it is expected that the ozone layer will return to its natural level. Since the Montreal Protocol, 15 of the worst CFCs were phased-out worldwide, with the United States, Europe, and Canada completely phasing-out all use of CFCs. As a result of all of these restrictions, new damage to the ozone layer has greatly decreased and the hole in shrinking.

Due to widespread adaptation and implementation, the Montreal Protocol is hailed as an example of exceptional international cooperation, which prompted Kofi Annan, the former Secretary General of the United Nations, to state that the Protocol is "Perhaps the single most successful international agreement to date.…"

Morocco

LOCATED IN NORTHWEST Africa, the Kingdom of Morocco covers an area of 172,414 sq. mi. (446,550 sq. km.), with a population of 31,224,000, 49 percent of which lives in urban areas. The country has a population density of 181 people per sq. mi. (69.8 people per sq. km.), although few people live in the Western Sahara region.

Twenty-one percent of the land in Morocco is arable, with another 47 percent used for meadows and pasture. The agricultural sector, including fishing, accounts for nearly a third of all export earnings; main crops include wheat and fruit, especially oranges. With 91.3 percent of Morocco's electricity production coming from fossil fuels, and only 8.7 percent from hydropower, and increased industrialization in the country, the per capita rate of emissions of carbon dioxide still remains relatively low at one metric ton in 1990, rising to 1.2 metric tons per person in 2004. Sixty percent of the country's total carbon dioxide emissions come from liquid fuels, 29 percent from fossil fuels, and 11 percent from the manufacture of cement. The high use of liquid fuels comes from the heavy use of oil, a quarter of which comes from Saudi Arabia, and a fifth from the United Arab Emirates, supplemented by some local production of oil and gas, with Morocco having to import electricity from Algeria. In addition to use in automobiles, liquid fuels is used to run generators on isolated properties and farms, and as a reliable source of electricity in many urban areas.

Since the 1980s, the government has tried to develop a program for the generation of hydroelectric power, but hydroelectric plants have failed to generate anywhere near the planned output. One of the problems has been that the hydroelectric facility at Ammogguez in the Atlas Mountains has experienced cave-ins in the hydro tunnels because of gypsum. The possibility of oil in the Western Sahara is expected to generate new wealth for the country, along with a probabile rise in greenhouse gas emissions. In terms of the carbon dioxide emissions by sector, 35 percent comes from electricity and heat production, 18 percent from manufacturing and construction, and 11 percent from residential use, with only 6 percent from transportation, a figure kept low by the extensive public transport network, with a bus service covering much of the country.

Global warming and climate change will affect the agricultural base of Morocco, leading to less land available for farming and declining crop production. This will come about through longer droughts that have been affecting Morocco for many centuries, but which have rarely lasted longer than two years. The Moroccan government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention in 1995. They accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on January 25, 2002, which took effect on February 16, 2005. The Moroccan government has also signaled its support for the Clean Development Mechanism as part of its National Sustainable Development Strategy.

Movements, Environmental

ENVIRONMENTAL MOVEMENTS ARE groups collectively trying to improve the conditions of the environment for human health, biodiversity, and ecosystem integrity. Environmental movements can have a diverse set of political perspectives and ethical orientations and engage in tactics that vary from social protest and direct action to litigation and policy reform. Environmental movements promote one or more dimensions of environmentalism, which seek social change based on a commitment to resource sustainability and ecosystem preservation.

Some of the earliest environmental movements were organized around concerns about hunting and conservation of wildlife. By the 20th century, urban environmental issues with sanitation, clean water, clean air, and public health became another key focus for environmental movements. Environmental movements emerged at the same time as the women's liberation, the anti-Vietnam War, and other leftist counterculture movements. The counterculture of the 1960s connected environmentalism to the critique of capitalist consumer society. Some note the image of a fragile Earth from the early space missions as a key moment for environmental movements. Widespread support for environmental movements emerged with attention to the story of Love Canal, where children were exposed to toxins in the soil below a school on a site that previously was a toxic dump. Environmental movements began to emphasize local and household issues, where families took up concerns about children's exposure to toxins.

The ethical orientations of environmental movements range from the conservation-oriented utilitarians who look to preserve resources for human use, to those with preservation-oriented perspectives who attribute intrinsic value to ecological systems, biodiversity, and charismatic species. Utilitarian perspectives are often characterized as anthropocentric because they ascribe rights only to present and future generations of humans. The eco-centric and bio-centric perspectives extend the domain of ethical consideration to living species and assemblages of species. The eco-centric and bio-centric perspectives have their origins in the Romanticism of Thoreau and other 19th century nature writing. These ethical views come into conflict in questions about the human use of natural resource and wilderness.

Given the diversity of environmental problems, environmental movements are quite diverse in their foci, although the political power of these groups often varies with the political power of the opponents they encounter. Environmental movements shape environmental outcomes in various ways, some using the political system, some focusing on the promotion of green consumerism and stewardship, and ecological modernization, while others use more violent tactics, like ecotage. As of 1995, there were over 10,000 environmental organizations in the United States, with 44 million members, income of $2.7 billion, and assets of over $5.8 billion. Environmental organizations come from a variety of perspectives, raising a diverse set of concerns ranging from those that focus on local, not-in-my-back-yard issues; mainstream Washington-based lobby and policy-oriented nongovernmental organizations, such as the Union Concerned Scientists and the World Watch Institute; political parties like the U.S. and German Green Parties; legal-action groups, like Friends of the Earth, the Center for Foods Safety, and the Defenders of Wildlife; donor and member-driven groups such as the Sierra Club, The Nature Conservancy, GreenPeace, the Wilderness Society, and World Wildlife Fund; and radical direct-action groups ranging from Greenpeace to Earth First!

RADICAL MOVEMENTS AND GREEN POLITICS

The Earth Liberation Front (ELF) is probably the most controversial group that could be characterized as a green movement, as the Unabomber's lone actions probably do not qualify as a movement. ELF is a radical environmental group that approves of destructive tactics to achieve their aims. Listed as a terrorist organization by the Federal Bureau of Investigation, the decentralized organization has claimed responsibility for a handful of actions, including arsons committed in new suburban housing developments in Long Island, and the destruction of new Hummers at a dealership in southern California, which gained widespread media attention. Those acts of ecotage are inspired by the Edward Abbey classic, the *Monkey Wrench Gang*, where a group of friends who gain inspiration from the wild, clandestinely sabotage equipment used to extract natural resources.

Radical environmentalists are often depicted as adherents to deep ecology, an environmental worldview that advocates a duty to preserve nature. Deep ecology was coined by Arne Naess, a Norwegian philosopher and mountaineer who has written extensively on the moral philosophy of environmentalism. Deep ecologists have been criticized for holding onto pristine myths about nature and for pressing for U.S.-style national parks and wilderness areas in developing countries.

Green movement popularity has also lent itself to the mainstream programs of political parties. Political parties from all persuasions now seek to claim the environment for themselves. Political parties, such as the German Greens, *Die Grünen*, have gained a populist following. The German Greens have led a strong critique of industrial society and colonialism, and have brought questions about the environment, public health, and military spending into their platform. Ralph Nader's appearance as a Green Party candidate in the U.S. presidential elections of 2000 is often cited as the reason Al Gore lost to George W. Bush. Former Vice President Al Gore is often described as an environmental movement leader, a claim buttressed by his film *An Inconvenient Truth*.

AGRICULTURE

The question about what to eat is perhaps one of the most controversial topics among environmental movement activists. Animal-rights activists and sustainable food system activists have many clashing opinions, but also many overlapping agreements. While they differ on the question of local animals in food systems for example, they agree that modern industrial animal production is cruel and wasteful.

The sustainable agriculture movement is also considered an environmental movement. It shares issues in common with the appropriate technology movement, which advocates a new economy based on a reflection on the social consequences of technological change. They share similar concerns with the "back to the land" movement. The influence of books such as E.F. Schumaker's *Small is Beautiful*; Wendell Berry's *Unsettling of America*; Rachel Carson's *Silent Spring*, an attack on DDT that was serialized in the *New Yorker* in the early 1960s; and Murray Bookchin's *Our Synthetic Environment* demonstrate a significant overlap between environmental and agricultural concerns. Today, the sustainable agriculture movement overlaps with anti-genetic engineering activists who critique technological change in agriculture, drawing on the environmental implications of the Green Revolution and agricultural development.

Some environmental movements see the roots of environmental problems as stemming from globalization. These groups focus efforts on remaking communities based on the ideals of more local production-consumption linkages. The promotion of green or ethical consumption is directed at getting consumers to shorten commodity chains through more direct purchasing, such as farmer's markets, to establish connections between producers and consumers of locally-grown food as opposed to industrial and fast food. Perhaps the most widely-recognizable form of ethical consumerism is vegetarianism, which is motivated by the ethical consequences of eating meat. Epitomizing ethical consumerism and the role of environmental movements is the international coffee situation, where a transition to large plantation, full-sun coffee has led to declines in migratory birds that over-winter in the tropics where coffee has been traditionally grown in shade coffee systems. Environmental groups have promoted the consumption of bird-friendly coffee because small-scale, shade-grown coffee plantations have demonstrated higher levels of biodiversity in birds, trees, and many other species. Ethical labeling has become a popular tactic for environmental movements from organic agriculture to fisheries conservation to timber certifications.

The sustainable agriculture movement shares similar concerns with the appropriate technology movement.

THE GREEN STATE

Environmental movements have played a significant role discursively, as well as materially, in transforming the state to a green one. The heyday of the environmental movement is often described as the time period that saw formation of the Environmental Protection Agency (EPA) and the passage of the Water Pollution Control Act, the Clean Air Act, the National Environmental Policy Act, and the Endangered Species Act during the early 1970s. However, the codification of environmental problems through the state took the environmental movement's momentum away from the left, and took up environmentalism as a cause for the right.

The Richard M. Nixon Administration sought a consensus approach to environmental problems, and his creation of a policy apparatus for environmental problems served to take away the political momentum of the left. While the EPA regulated the harms from production practices, the failure to include the Department of Agriculture, Department of Energy, and Department of Transportation in the planning and regulatory sphere left their interventions more at the whims of market forces and political cronyism. The critique entitled the *Death of Environmentalism* blamed the failure of the environmental movement on a narrowly-defined policy reform that failed to maintain political coalitions and win-win scenarios that could promote jobs and environmental concern.

Some have questioned whether or not the institutionalization of mainstream environmental movement organizations qualifies them as a social movement, which, to some, is a contradiction: you cannot have a movement that is institutionalized. The institutionalization of environmental movements through nongovernmental organizations has seen an increase in passive members who simply write checks in the name of some environmental organization, many of which must maintain large overheads to stay fiscally afloat. Another concern is mainstream environmental organizations' move away from protest tactics and critiques of multinational corporations to a more collaborative approach. Yet, it is unclear if collaborative environmental movements makes them more or less effective in dealing with environmental problems. There is also a concern that the institutionalization of environmental movements has led to the scientization of environmental problems. This has narrowed the focus to the science of environmental problems, often neglecting their social origins.

Environmental movement concerns merge with concerns about development in the developing world. Successful environmental movements—so called red/green movements—in developing countries include the Chipko Andolan Movement, a group that protected trees in Northern India through acts of civil disobedience against transnational logging companies. Often, these campaigns link concerns about livelihoods with concerns about the environment. Chico Mendez led a group of rubber tappers in Brazil on a crusade to link their practices to the preservation of biodiversity in the Amazon. However, not all developing-country environmental campaigns have been successful. The Three Gorges Dam project in China is one glaring example of mass relocation and devastating environmental impact that environmental movements have found difficulty in challenging.

More recently, environmental justice movements have refocused attention to environmental concerns in urban areas and cities. An executive order by President William J. Clinton, in the 1990s, required federal agencies in the United States to evaluate the consequences of agency actions on the distribution of environmental burdens. Many urban environmental movements draw attention to the problem of environmental racism, where communities are disproportionately exposed to negative environmental consequences. With the rapid rise of urban populations around the world, the promotion of sustainable cities has been cited as a high priority for environmentalists.

Mozambique

THE REPUBLIC OF Mozambique, formerly a Portuguese colony, located in southeast Africa, has a land area of 309,496 sq. mi. (799,400 sq. km.), with a population of 21,397,000 (2006 est.), and a population density of 65 people per sq. mi. (25 people per sq. km.). With less than a quarter of the population employed in agriculture, 4 percent of the land is arable, and 56 percent officially classed as meadows or pasture, and 20 percent of the country remains forested, although there is a large timber industry in the country.

As for Mozambique's electricity production, 96.4 percent of it comes from hydropower, and only 3.6 percent comes from fossil fuels. The Portuguese built some of the hydroelectric power plants, the major one at Cabora Bassa. During the war between the Portuguese and FRELIMO (Mozambican Liberation Front) in the 1960s and early 1970s, the Portuguese guarded the dam heavily, but FRELIMO did not attack, realizing its importance to power generation after independence in 1975. After independence, some other hydroelectric plants were built, with the Chinese helping to fund a new plant for Maputo.

As a result of the extensive use of hydropower, Mozambique's per capita carbon dioxide emissions were previously 0.1 metric tons, and fell to 0.08 metric tons by 2003. Another effect from the heavy use of hydropower is that electricity is responsible for only 1 percent of the country's total carbon dioxide emissions, with the use of solid fuels making up only 7 percent of carbon dioxide emissions. About 82 percent of carbon dioxide emissions come from liquid fuels, with transportation making up 67 percent of all emissions by source. Another important factor is the manufacture of cement, which is responsible for 11 percent of carbon dioxide emissions.

Mozambique experienced flooding in many parts of the country in February and March 2000, causing the death of about 800 people, the loss of 20,000 cattle, and the inundation of 540 sq. mi. (1,400 sq. km.) of arable land. There was another flood in December 2006, when the water overflowed the Cahora Bassa Dam, leading to the deaths of 29 people and the displacement of 121,000 more.

The Mozambique government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, which it ratified in 1995. It also ratified the Vienna Convention in 1994, and accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on January 18, 2005, which took effect on April 18, 2005.

Munk, Walter (1917–)

INFLUENTIAL PHYSICAL oceanographer and geophysicist, Professor Emeritus of Geophysics and Secretary of the Navy/Chief of Naval Operations Oceanography Chair at Scripps Institution of Oceanography in La Jolla, California. He made fundamental discoveries in different fields such as the effect of the moon on tides and the circulation of the deep sea. Munk also had a leading role in devising a method for calculating the course of long-term climatic changes related to global warming. In 1999, he became the first in his field to be awarded the Kyoto Prize by the Inamori Foundation.

Born in Vienna, Austria, on October 19, 1917, Munk was sent to preparatory school in New York in 1932. He applied for American citizenship in 1939, after the annexation of Austria by Nazi Germany. His family chose New York as they wanted Walter to follow his relatives' vocation for business and finance. Yet, Munk disliked banking and, after three years, left Columbia University to study physics at the California Institute of Technology, from where he graduated in 1939. Munk then applied for a summer job at the Scripps Institution of Oceanography. The next year, the director of Scripps, the distinguished Norwegian oceanographer Harald Ulrik Sverdrup, accepted him as a doctoral student, although he warned Munk that there might not be many jobs in oceanography. During the war, Munk was excused from active service in exchange of defense-related research at Scripps. Together with several of his colleagues from Scripps, he developed methods related to amphibious warfare, which were used successfully to predict surf conditions for Allied landings in North Africa, the Pacific theater of war, and, on D-Day during the Normandy invasion. During the testing of nuclear weapons at

Bikini Atoll in the southern Pacific Ocean in 1946, Munk contributed to the analysis of the currents and diffusion in the lagoon and the water exchange with the open seas.

Munk graduated with a Ph.D. in oceanography in 1947. Since then he has spent his whole career at Scripps Institution. In 1947, he became an assistant professor. In 1953 he married Judith Horton and the following year he became a professor of geophysics and also was named a member of the UC's Institute of Geophysics. In 1960, he established a branch of the institute on the Scripps campus in La Jolla. Until 1982, he served as director of the Scripps branch and as an associate director of the Institute of Geophysics and Planetary Physics (IGPP). Munk also served as a member of JASON, a prestigious panel of scientists who advised the U.S. government on military strategies.

In the 1960s, Munk focused his research on the attenuation in ocean swells generated in Antarctica. The project measured variations with pressure-sensing devices lowered to the ocean floor. Measurements were also taken at six different Pacific Ocean locations and from FLIP, the Floating Instrument Platform, developed at Scripps. During this decade, Munk began measuring tides in the deep sea, using extremely sophisticated pressure-sensing devices that were dropped to the ocean floor and retrieved by acoustic release.

A NEW MODEL

Munk's relevance for the field of global warming lies in his work on the acoustic tomography of the ocean that he developed from the 1970s through to the 1990s. Munk had a leading role in the development of a new method for tracing long-term changes in climate linked with global warming. Munk came to the conclusion that important information about the ocean's large-scale structure could be gathered by studying the sound propagation patterns and the time it takes for sound to travel through the oceans. He conceived the Heard Island Experiment, where acoustic signals were sent out by instruments lowered 492 ft. (150 m.) underwater near the remote island in the southern Indian Ocean. During four days in January 1991, "the sound heard around the world" experiment took place. Signals were sent from Heard Island, on the east and west coasts of the United States, as well as at many other stations around the world. These researches led to the Acoustic Thermometry of Ocean Climate (ATOC) project. ATOC was based on the idea to send sound signals from underwater speakers and determine how long it takes them to reach receivers anchored to the floor of the Pacific thousands of miles away. Since sound travels faster in warmer than in cooler water, a long-term series of tests that showed increasingly faster travel periods would be the evidence that the ocean is warming.

AWARDS AND ACCOLADES

Throughout his long career, Munk has received numerous awards. He was elected to the National Academy of Sciences in 1956, and to the Royal Society of London in 1976. He has been the recipient of a Guggenheim Fellowship three times. In 1965 he received the Arthur L. Day Medal from the Geological Society of America, and, in 1966, he was awarded the Sverdrup Gold Medal of the American Meteorological Society. The Royal Astronomical Society of London gave him the Gold Medal in 1968. In 1976, he obtained the first Maurice Ewing Medal sponsored by the American Geophysical Union and the U.S. Navy. In 1977, he was given the Alexander Agassiz Gold Medal of the National Academy of Sciences. Munk was honored with the 1999 Kyoto Prize in Basic Sciences for his fundamental contributions to the field of oceanography. The Navy League of the United States honored Munk with the 2001 Albert A. Michelson Award for research that has significantly improved the nation's maritime forces or the U.S. industrial technology base. In the same year, the scientist was awarded the inaugural Prince Albert I Medal from the International Association for the Physical Sciences of the Oceans (IAPSO).

Myanmar

LOCATED IN SOUTHEAST Asia, the Union of Myanmar has a land area of 261,227 sq. mi. (676,577 sq. km.), a population of 48,798,000 (2006 est.), and a population density of 193 people per sq. mi. (75 people per sq. km.). Yangon (formerly Rangoon), the largest city and the former capital, has a population of 4,668,775, making it the 29th largest city in the world. The new capital, Naypyidaw, dates from 2005, and, internationally, little is known about it. About 15 percent of the country is arable, an additional 1 percent used for pasture, and 34 percent of Myanmar remains forested, although there has been an increase in logging in recent years, with teak now the major export of the country.

Relatively underdeveloped, and with large parts of the country having only irregular use of electricity, if at all, Myanmar has a very low rate of carbon dioxide emissions per capita, at 0.1 metric tons per person in 1990, and rising gradually to 0.21 metric tons per person in 2004. This is in spite of the tropical climate, and the heavy use of air conditioners in the cities. Myanmar has its own oil industry, with petrol and gas used to generate electricity. Approximately 83.3 percent of the country's electricity comes from fossil fuels, with the remainder from hydropower. As a result, liquid fuels make up 57 percent of carbon dioxide emissions, and gaseous fuels make up another 39 percent. The remainder comes from solid fuels and from the manufacture of cement. About 36 percent of the carbon dioxide emissions in the country come from transportation, 30 percent from the generation of electricity, and 15 percent from manufacturing and construction.

The main effect of global warming and climate change on Myanmar has been the increased risk of flooding, especially at the mouth of the Irrawaddy. The Boxing Day Tsunami in 2004 led to serious flooding of this region. Although the Myanmar government officially stated that the death toll was only 61, with 200 missing, most commentators felt that many more human casualties occurred. The flooding washed away topsoil and destroyed arable land, and will also cause a rise in insect-borne diseases, such as malaria and dengue fever.

The Myanmar government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. They accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on August 13, 2003, and it took effect on February 16, 2005.

Namibia

THE REPUBLIC OF Namibia has a land area of 318,696 sq. mi. (824,290 square km.), a population of 2,074,000 (2006 est.), and a population density of 6.5 people per sq. mi. (2.5 people per square km.). Namibia has the lowest population density of any African country. Much of Namibia is arid, with only 1 percent of the land arable and 46 percent used for pasture, mainly low intensity grazing of cattle, sheep, and goats. The country has an extremely low rate of carbon dioxide emissions, at 1 metric ton per person in 1995, rising to 1.24 metric tons by 2004. This is largely because there is relatively low electricity use in the country; of the 603 million kWh used in 2001, some 578 million kWh was imported from South Africa, and 98 percent of local production came from hydropower.

Since independence in 1990, there have been a number of attempts to increase hydropower production. There was a projected water shortage in the late 1990s, which stopped plans to build a hydroelectric plant on the Kumene River, in the Kaokoveld region, which, as well as power, would also be able to provide water to Windhoek, the capital. However, in 2000 and 2001, there were heavy rains, resulting in extensive flooding, which provided far more water than was needed. The distances in Namibia are vast, with transportation accounting for 85 percent of the carbon dioxide emissions in the country. Thirteen percent of emissions come from manufacturing and construction.

Although it contributes very little to greenhouse gas emissions, the effects of global warming and climate change on Namibia have been significant. The rising temperatures have reduced the already limited amount of arable land in the country. The coastline of Namibia, nicknamed the Skeleton Coast because of the remains of whales from the whaling industry of the 19th century, and the shipwrecks of the 19th and 20th centuries, has also been badly affected by the Benguela El Niño. This has come about from the temperature of the Benguela Current, off the coast of Namibia, reducing fish stocks and impacting the coastline.

The Namibian government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. The government accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on September 4, 2003, and took effect on February 16, 2005.

National Academy of Sciences, U.S.

THE NATIONAL ACADEMY of Sciences (NAS) is an honorific society incorporated by the U.S. Congress and signed into law on March 3, 1863, with the mandate to "investigate, examine, experiment, and report upon any subject of science or art" when requested to do so by the government. The NAS advises policymakers and its private sponsors on technical matters, and promotes the advancement of science and its use for the public welfare. The NAS is one of four organizations that comprise the National Academies, which also include the National Academy of Engineering (NAE), the Institute of Medicine, and the National Research Council. The NAS organized the National Research Council in 1916, as its operational arm. The National Research Council is now the primary operating agency of the National Academy of Engineering and is administered by the NAS, the NAE, and the Institute of Medicine. Committee activities by the National Academy of Science in 2007 covered more than 20 focus areas, including Agriculture, Behavioral & Social Sciences, Chemistry, Computer & Technology, Earth Science, Energy & Energy Conservation, Environmental Issues, Health & Medicine, International Issues, Policy & Research, and Space.

MEMBERS

Current members elect new members of the NAS, like those of the NAE and the Institute of Medicine. Membership in the NAS is regarded as one of the highest tributes conferred in American science. More than 200 members have won the Nobel Prize. Annually, up to 72 members and 18 foreign associates may be elected to membership. With the election in 2007, the number of active members, each of whom is associated with one of 31 disciplines, stood at 2,025. The NAS also has approximately 350 foreign associates. In 2007, the NAS garnered attention for electing the lowest number of women elected to membership since 2001. Only nine women were inducted as new members, raising the total number of members who are women to approximately 10 percent.

The NAS espouses an ongoing commitment to the inclusion of women in leadership and decision-making and in access to grant-funding opportunities and fellowships. In 1994, NAS and the Royal Society of London issued a joint resolution in support of this commitment. According to the leadership of the NAS, the pace at which women are joining the institute may be attributed to the time needed for scientists to build credentials noteworthy enough for consideration for membership. In an effort to inspire an interest in science in middle-school-aged girls, the NAS actively supports the publication of Women's Adventures in Science, a biography series about contemporary women working in diverse scientific fields, and the series' companion website.

AWARDS

In addition to recognizing distinguished accomplishments by electing members to its own ranks, the NAS recognizes the work of other accomplished scientists by bestowing annual awards, currently 30 in number, in nine fields: Astronomy/Astrophysics, Behavioral/Social Sciences, Biology and Medicine, Chemistry, Earth and Environmental Sciences, Engineering and Applied Sciences, Mathematics and Computer Sciences, Physics, and a General category. Awards include the John J. Carty Award for the Advancement of Science, with an emphasis in ecology; the Arthur L. Day Prize and Lectureship, focusing on the physics of the Earth; the Public Welfare Medal, and the NAS Award for Scientific Reviewing, in the fields of social and political sciences; and the Public Welfare Medal. The Public Welfare Medal is awarded in honor of distinguished service in the application of science to the public good. Noted recipients include Gilbert White, in 2000, for educating members of the academic community and government institutions on water resource management, hazard mitigation, and environmental assessment; Carl Sagan, in 1994 for his ability to describe complex scientific theories in graspable language; and Herbert Hoover, in 1920 for the utilization of science in food conservation and distribution.

PUBLICATIONS

The NAS also publishes *Proceedings of the National Academies of Sciences*, founded in 1914, which is published weekly and includes research reports, reviews, and papers, and *Issues in Science and Technology*, which is published quarterly and available in print by subscription. Articles from back issues of both of these publications are available online at no charge. *Biographical Memoirs,* published since 1877, highlights the life histories and accomplishments of deceased members of the NAS. Monographs printed from 1995 to date can be accessed online free of charge. The National Academies Press also publishes books and reports for the NAS, many of which are available in their entirety, or by chapter, online.

PROGRAMS AND ACTIVITIES

Among the many activities of the National Academies and its member organizations is the Keck Futures Initiative, a 15-year undertaking to stimulate interdisciplinary research, particularly cutting-edge research, and to increase interaction among researchers, universities, funding institutions, and the general public. The National Academies Keck Futures Initiative incorporates the following annual activities: Futures Conferences, Futures Grants, and National Academies Communication Awards. As of 2003, the National Academies annually bestow three $20,000 Communication Awards recognizing writers, journalists, and producers who have demonstrated excellence in communicating about science, engineering, and/or medicine to the general public through different media formats. In 2006, Elizabeth Kolbert, staff writer for the *New Yorker*, won the Newspaper/Magazine/Internet award for her three-part series "The Climate of Man." Additional 2006 finalists in the category, writing about climate change, included writer Michelle Nijhuis, "Hot Times: Global Warming in the West," *High Country News*, and Clayton Sandell, producer, and Bill Blakemore and Jay Lamonica, co-producers, for "Global Warming & Extinction," *ABC News*.

Since 1991, the NAS has addressed a broad range of contemporary scientific issues across disciplinary boundaries through the annual Arthur M. Sackler Colloquia, named in honor of the well-known scientist, philanthropist, editor of *Journal of Clinical and Experimental Psychobiology*, and founder of the *Medical Tribune*. An average of four to six such colloquia are held, each generally two days long, global in scope, and featuring presentations by leading scientists and discussions with at least 100 researchers interested in the field. The colloquium, "Early Cities: New Perspectives on Pre-Industrial Urbanism," was held in Washington, D.C., in 2005; "Auditory Neuroscience: Development, Transduction, and Integration," in 2000 in Irvine, California; and "Carbon Dioxide and Climate Change," organized by Charles Keeling, of the Scripps Institution of Oceanography, in Irvine in 1995.

The NAS also supports the Marian Koshland Science Museum, which features interactive displays about the role of science in people's daily lives and in national policymaking. The exhibit, "Global Warming Facts & Our Future," delved into issues related to global warming and its global impact on the quality of life. Questions addressed by the exhibit include: Is the Climate Warming, Are Humans Causing Climate Warming, What Effects Might Climate Warming Have, and What Should Be Done About Climate Warming. In 2004, the museum received the Bronze Galaxy Award for the exhibit, one of more than 400 entries from 14 countries to the 15th annual competition. In addition to exhibits, many of which are not permanent, the museum offers public and educational programs to stimulate discussion about science.

GLOBAL WARMING AND POLITICIZING SCIENCE

The NAS's reputation in research and the dissemination of information about global warming and climate change precedes its accolades for its museum exhibits about climate change. In 1991, the NAS released a report, *Policy Implications of Greenhouse Warming,* calling for a decrease in the dependence on fossil fuel, the advancement of nuclear and solar energy technologies, and the promotion of energy conservation, all aimed at a reduction in greenhouse gas emissions. The NAS asserted that the United States could reduce emissions by up to 40 percent cost-effectively and that a potential ecological disaster because of global warming was reason enough to implement changes immediately.

The NAS's report was met with general approval by environmental groups, most of which supported the recommendation for increased funding to develop renewable technologies, but opposed the NAS's call for the development of nuclear power. Although the White House maintained that the administration's National Energy Strategy was consistent with the recommendations by the NAS, then-Senator Albert Gore, Jr., a Democrat from Tennessee and future U.S. Vice President and author of *An Inconvenient Truth: The Planetary Emergency of Global Warming and What We Can Do About It* (2006), charged that many of the administration's policies actually conflicted with the recommendations of the NAS. Gore also predicted that history would judge President George H.W. Bush harshly if global warming continued.

In 1998, the NAS distanced itself from a confusing mass mailing that urged scientists to apply pressure to sway public policy and opinion against the Kyoto Protocol to the United Nations Framework Convention on Climate Change to assign mandatory carbon dioxide emissions limitations. The mailing, which appeared in a format similar to that of a NAS journal reprint, challenged the prevailing climate change research and included a cover letter from former NAS President Frederick Seitz urging scientists to lobby against the Kyoto treaty to reduce carbon dioxide emissions. The NAS did not take a position on the Kyoto treaty, although it had long-since recommended a prompt response to global warming, but opposed only the mailing, which generated more than 15,000 signatures because of its misleading design.

Although the NAS conducts research at the request of the government and advises policymakers on technical matters, the academy itself is not a political body. Nonetheless, the alleged distortions of the academy's research by members of presidential administrations to meet political agendas have been the subject of debate, during the William J. Clinton White House and increasingly during the George W. Bush administration. The head of the NAS stated in an interview, however, that he does not think that a deliberate scheme of misrepresentation exists, but that the extent of the problem in the George W. Bush White House is greater and that scientists agreed with policies of the Clinton administration more than those of the Bush administration, under which their independence may be more constrained.

The NAS found itself in the center of discussions about global warming in 2001, following a report commissioned by President George W. Bush, who had rejected the Kyoto Protocol and had hoped the report's findings would alleviate the pressure to find another option to the Kyoto treaty and limits on carbon emissions. The report, however, reached the conclusion that human activity had most likely brought about the increase in global temperature in the 20th century. Accounts issued by a Democratic Congressman in 2003 and 2004 claimed that the Bush administration had, in fact, misused scientific findings to support its own policy agenda. More than 5,000 scientists, including over 100 members of the NAS, signed a letter accompanying the reports that concurred with criticism of the White House.

Among the claims of impropriety were those by an associate director from 1998 to 2003 within a part of the National Institutes of Health, who charged that the Clinton administration was quick to approve suggested appointees to his scientific advisory committees, but the Bush administration rejected over 70 percent of his appointees, in some cases taking months to do so, and apparently in opposition to scientific independence. The Union of Concerned Scientists claimed that the EPA eliminated a chapter about global warming from a 2003 report about the nation's environment after the Bush administration's revisions might have led readers to believe that doubts persisted about global warming when, in fact, none did. Republicans maintained that reports and claims critical of the White House were simply politically-motivated. Democratic staff issued a memorandum that documents obtained from the White House Council on Environmental Quality (CEQ) indicated that additional changes were made in a fiscal year 2003 report to Congress from the administration on the status of the U.S. Climate Change Program. In 2007, the chief of staff for the White House Council on Environmental Quality, however, defended alterations to scientific climate change findings as an acceptable practice to synchronize reports of the executive branch with policies of the administration.

The NAS issued a report by the Nuclear Regulatory Commission (NRC) to the U.S. Climate Change Program in early 2007 that identified for the U.S. Climate Change Science Program, 11 critical components of global change assessments. This is the process through which experts reach agreement about issues related to the environment, including the loss of biodiversity and climate change. Among the essential elements identified were strategic framing of the assessment process, sufficient funding to support an effective assessment process, strong leadership, and the commitment and involvement of stakeholders with clear, unambiguous interactions and exchanges among policymakers and scientists. The NAS, in spite of the charged political environment that surrounds it, continues to support research and programs to effectively inform policymakers.

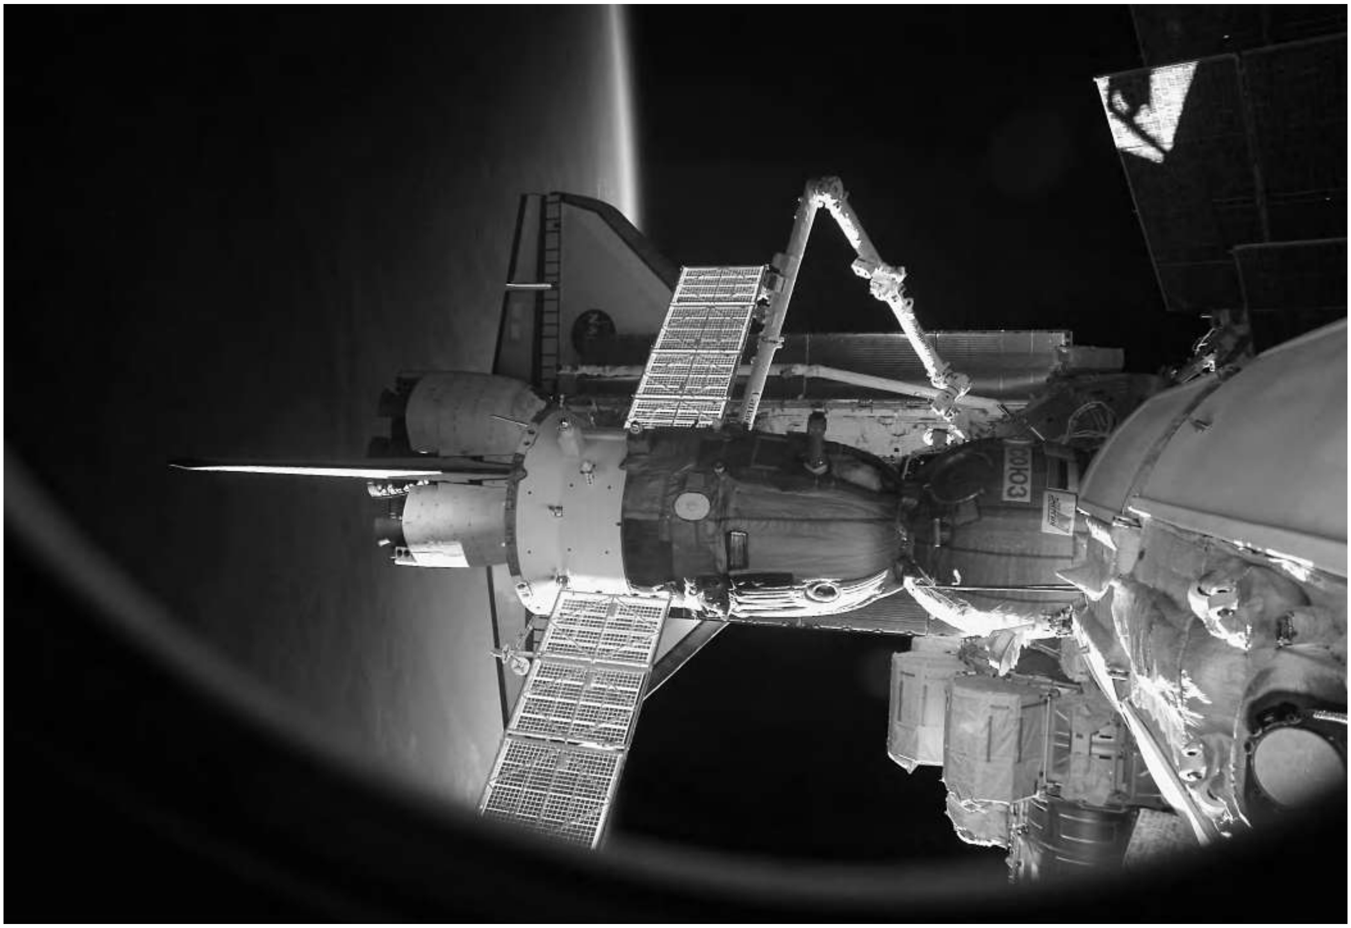
National Aeronautics and Space Administration (NASA)

THE NATIONAL AERONAUTICS and Space Administration (NASA) is an independent U.S. governmental agency, established in 1958, for the research and development of vehicles and activities for the exploration of space within and outside of Earth's atmosphere. Within NASA, the Goddard Institute for Space Studies (GISS) at Columbia University in New York carries out research related to climate change and global warming. NASA is structured around five program offices. Aeronautics and Space Technology is responsible for the development of equipment. Space Science and Applications deals with programs for understanding the origin, structure, and evolution of the universe, the solar system, and the Earth. Space Flight is concerned with manned and unmanned space transportation and all matters related to the space shuttle. Space Tracking and Data involves tracking and data acquisition. Space Station has the long-term goal of establishing a manned space station. A number of additional research centers are affiliated, including the Goddard Space Flight Center in Greenbelt, Maryland, within which the Goddard Institute for Space Studies operates; the Jet Propulsion Laboratory in Pasadena, California; the Lyndon B. Johnson Space Center in Houston, Texas; and the Langley Research Center in Hampton, Virginia. NASA headquarters are in Washington, D.C.

NASA was created largely in response to the Soviet launching of Sputnik in 1957. It was organized around the National Advisory Committee for Aeronautics (NACA), which had been created by Congress in 1915. NASA's organization was already underway by the early years of President John F. Kennedy's administration, when the President proposed that the United States sent a man to the Moon by the end of the 1960s. To that end, the Apollo program was designed, and, in 1969, the U.S. astronaut Neil Armstrong became the first man on the Moon. Later unmanned programs, such as Viking, Mariner, Voyager, and Galileo, explored other bodies of the solar system. When NASA began its operation on October 1, 1958, the agency consisted of only about 8,000 employees and had an annual budget of $100 million. In addition to a small headquarters staff in Washington, D.C., that conducted operations, NASA had three major research laboratories inherited from the National Advisory Committee for Aeronautics: the Langley Aeronautical Laboratory established in 1918, the Ames Aeronautical Laboratory activated near San Francisco in 1940, and the Lewis Flight Propulsion Laboratory built at Cleveland, Ohio, in 1941. It also had two small test facilities, one for high-speed flight research at Muroc Dry Lake in the high desert of California, and one for sounding rockets at Wallops Island, Virginia. It soon added several other government research organizations.

The Apollo program was designed to land humans on the Moon and bring them safely back to Earth. *Apollo 8* and *Apollo 10* tested various components while orbiting the Moon, and returned photographs of the lunar surface. On July 20, 1969, *Apollo 11* landed the first man on the moon, Neil Armstrong.



The International Space Station, with the docked Soyuz spacecraft (foreground) and the Space Shuttle Discovery *(background), orbiting the earth. The onboard lab is ideal for earth observation and all manner of experiments.*

The Apollo program included six missions that landed on the Moon and returned a wealth of scientific data and almost 882 lbs. (400 kg) of lunar samples. Experiments addressed topics such as soil mechanics, meteoroids, seismic, heat flow, lunar ranging, magnetic fields, and solar wind experiments. NASA was also in charge of the development and launch of a number of satellites with Earth applications, such as Landsat, a series of satellites designed to collect information on natural resources and other Earth features; communications satellites; and weather satellites. It also planned and developed the space shuttle, a reusable vehicle capable of carrying out missions that cannot be conducted with conventional spacecraft. The spectacular successes of the agency is tempered by the controversies and tragic disasters that marked its space shuttle program. The flights of the shuttle turned out to be much more expensive than initially expected. On January 28, 1986, the Space Shuttle *Challenger* was destroyed during its launch from the Kennedy Space Center. The explosion occurred 73 seconds into the flight as a result of a leak in one of two Solid Rocket Boosters that ignited the main liquid fuel tank. On February 1, 2003, the Space Shuttle *Columbia* broke up about 15 minutes before the scheduled landing. In both cases, all the astronauts on board lost their lives. The Space Shuttle *Columbia* disaster, in 2003, caused a 29-month interruption in space shuttle flights and led to a serious re-examination of NASA's priorities. The U.S. government, various scientists, and the public all reconsidered the future of the space program.

The shuttle, however, was also used to launch milestone projects like the Hubble Space Telescope (HST) in 1990, which has proved popular with both scientists and the public. Some of the images it has returned have attained an almost legendary status, such as the groundbreaking Hubble Deep Field images. The shuttle was also instrumental in the creation of the International Space Station (ISS), a cooperative project that mainly involves the United States and Russia for the construction of the biggest space station ever built. Costing over $100 billion, it has been difficult at times for NASA to justify the ISS. During much of the 1990s, NASA also faced shrinking annual budgets because of Congressional belt-tightening. This caused NASA administrators to adopt the "faster, better, cheaper" approach that enabled the agency to cut costs, while still delivering a wide variety of aerospace programs. Yet, that method was criticized and re-evaluated following the twin losses of the Mars Climate Orbiter and the Mars Polar Lander in 1999.

NASA's ongoing investigations include in-depth surveys of Mars and Saturn and studies of the Earth and Sun. Other NASA spacecraft are presently en route to Mercury and Pluto. With its spacecraft and satellites, the agency covers over half the solar system. In 2004, President George W. Bush launched the Vision for Space Exploration, which contemplates another human landing on the Moon by 2020, and the establishment of outposts in preparation for human exploration of Mars and other destinations.

From 2002 to 2006, the mission statement of the agency included understanding and protecting "our home planet." Since February 2006, however, the statement has been reworded and the portion pertaining to understanding and protecting our home planet has been deleted. This has been read by some as a result of the controversy concerning some NASA scientists such as James Hansen and the U.S. governments over the issue of global warming. Hansen, the director of the GISS, bitterly criticized the Bush Administration for what he thought were its ineffective environmental policies. In 2005 and 2006, Hansen also claimed that NASA officials were closely monitoring his participation in public events where he was invited to speak about global warming. This was part of an attempt to influence his statements on global warming. NASA officials have denied that the mission statement has been altered because of the controversy on global warming, but simply reflects the priority of space exploration for the agency in the coming years. They have also denied trying to manipulate Hansen and monitoring his scientific activities. Yet, Hansen has restated his accusations in the Al Gore-hosted documentary *An Inconvenient Truth* (2006).

The NASA sector that deals with research on climate change and global warming is the GISS, located at Columbia University's Armstrong Hall, in New York City. GISS is a component laboratory of Goddard Space Flight Center's Earth Sciences Division, which is part of GSFC's Sciences and Exploration Directorate. The institute was originally established, in May 1961, by Dr. Robert Jastrow to do basic research in space sciences in support of Goddard programs. The initial research at the Institute focused on planetary atmospheres using data collected by telescopes and space probes; in time that led to GISS becoming a leading center of atmospheric modeling and of climate change. The Institute currently encompasses a broad study of Global Change, treating it as an interdisciplinary initiative addressing natural and anthropogenic changes in our environment. These can occur on various timescales (from one-time forcings, such as volcanic explosions, to seasonal/annual effects, such as El Niño, and on up to the millennia of ice ages) and have a different impact on the habitability of the planet. Program areas at GISS may be roughly divided into the categories of climate forcings, climate impacts, model development, Earth observations, planetary atmospheres, paleoclimate, radiation, atmospheric chemistry, astrophysics and other disciplines. However, due to the interconnections among these topics and the interdisciplinary approach, most GISS personnel are engaged in research in several of these areas.

The main aim of GISS researchers is the prediction of atmospheric and climate changes in the 21st century. Their research combines analysis of comprehensive global datasets, derived mainly from spacecraft observations, with global models of atmospheric, land surface, and oceanic processes. GISS studies past climate change on Earth, and of other planetary atmospheres, as a useful tool in assessing our general understanding of the atmosphere and its evolution. The perspective provided by space observations is crucial for monitoring global change and for providing data needed to develop an understanding of the Earth system. As the principal NASA center for Earth observations, Goddard Space Flight Center plays a leading role in global change research. Global change studies at GISS are coordinated with research of other groups within the Earth Sciences Division, including the Laboratory for Atmospheres, Laboratory for Hydrospheric and Biospheric Sciences, and Earth Observing System science office.

The Climate Modeling Program at GISS attempts to develop three-dimensional general circulation models (GCMs) and coupled atmosphere-ocean models for simulating the Earth's climate system. Some research efforts may also include the use and development of two-dimensional energy balance models (EBMs), and one-dimensional radiative-convective models (RCMs). Primary emphasis in the use of the GCMs is placed on investigation of climate sensitivity, including the climate system's response to such forcings as solar variability, and anthropogenic and natural emissions of greenhouse gases and aerosols. GISS GCM simulations study the potential for humans to impact the climate, as well as the impact of a changing climate on society and the environment. GCM research focuses on sensitivity to parameterizations of clouds and moist convection, ground hydrology, and ocean-atmosphere-ice interactions, as well as explorations of more accurate numerical methods. The program also involves the advance of techniques to understand global cloud properties from satellite radiance measurements of the International Satellite Cloud Climatology Project. Ongoing field and laboratory programs in palynology, paleoclimate reconstruction, and other geophysical sciences offer fundamental climate data for evaluating and validating model predictions.

Research in the area of Earth Observation builds on the assumption that satellites provide the potential for observing changes of the Earth system on a global scale. GISS attempts to define which satellite observations are needed for the advancement of research, and to study how satellite data relates to and supports data acquired using more conventional techniques. Satellite observations are analyzed to obtain information on the Earth's surface, atmosphere, and, especially, global cloud systems. GISS is particularly interested in clouds, because they represent a great source of uncertainty in predicting future climate. Clouds are potentially the most powerful feedback mechanism in the climate system. Thus, further research is needed to decide if they are a positive feedback, which will enhance future greenhouse warming, or a negative feedback.

As far as climate impacts are concerned, GISS aims to develop a complex framework of analysis for interactions among biophysical and socioeconomic processes. GISS research in this area investigates the sequence of causes and effects linking climate and its impacts, utilizing the GISS global climate model (GCM), physically based impact models, chemical tracer models, and interdisciplinary teams. Distinctive features of research methods in this field include regional disaggregation, high spatial and temporal resolution, and theoretical improvement in the treatment of uncertainty. GISS climate impacts study addresses the impacts of current climate variability, such as El Niño Southern Oscillation (ENSO) events, and potential impacts of climate change resulting from greenhouse gas emissions. Observed climate data and climate model outputs (temperature, precipitation, solar radiation) are used as inputs for impact models to produce regional changes in variables such as crop yields, water availability, and forests. These changes are then measured in terms of economic and social costs, including the number of people threatened by hunger, drought, or coastal storm surges.

Studies in Planetary Atmosphere, a long-standing tenet of NASA, enables testing of basic understanding of atmospheric processes, including the greenhouse effect, aerosol and cloud physics, and atmospheric chemistry and dynamics. Aware of the difficulty interpreting observational data without comparing them to the results of an atmospheric model, GISS researchers use a variety of models, from relatively simple simulations of radiative transfer to full-fledged general circulation models (GCMs). The more complex models, developed through the conversion of Earth GCMs, allow the study of dynamical atmospheric processes, including the role of eddy, diabatic, and dissipative processes in the context of comparative planetary meteorology.

GISS Paleoclimate research is based upon the use of global climate models (GCMs) to generate simulations of past climates. GCMs are employed, in combination with geophysical, geochemical and sedimentological data analyses, to reconstruct various time periods and events in the Earth's climate history. Paleoclimate simulations are also used to test the ability of GISS digital representations of climates that differ significantly from the present. The ability to simulate climate changes that occurred in the past strengthens confidence in the conclusions drawn from simulations of future climate.

Several warm time periods are also of particular interest, because they provide insights regarding processes and impacts related to global warming scenarios.

Radiation studies at GISS cover three main areas: the construction of accurate radiative transfer models, which allow the interpretation of remote sensing data of Earth and other planets obtained from ground-based and satellite sensors; the accurate and efficient calculations of radiative transfer to determine heating and cooling rates in computer models of climate; and the theoretical modeling required to improve the methods and approximations used in radiative models. Theoretical modeling can also provide fundamental understanding of the physical processes involved in the absorption, scattering, and emission of electromagnetic energy. The study of radiation at GISS follows an interdisciplinary pattern, interacting with other fields, such as atmospheric chemistry, climate modeling, Earth observations, and planetary atmospheres. Projects in radiation studies include understanding the water vapor continuum absorption, modeling the effect of aerosols, as well as trying to retrieve their microphysical properties, analysis of aircraft and ground-based data, and understanding the difference between broadband and narrowband flux retrievals.

Research in atmospheric chemistry at GISS includes both near-term issues, such as air quality and ozone depletion, and the longer-term linkages between atmospheric chemistry and global climate.

GISS works cooperatively with area universities and research organizations, most especially with Columbia University. Almost half of GISS personnel are members of Columbia's Center for Climate Systems Research (CCSR) and also work with researchers at Columbia's Earth Institute and Lamont-Doherty Earth Observatory. Systems and programming support for GISS is provided by Sigma Space Partners, a joint venture of Sigma Space Corp. and SGT, Inc.

National Association of Energy Service Companies (NAESCO)

ESTABLISHED OVER 20 years ago, the National Association of Energy Service Companies (NAESCO) is a trade organization that encourages the widespread use of energy efficiency. On behalf of its members, NAESCO, based in Washington, D.C., attempts to open new markets for energy services. To reach this aim, the association promotes the importance of demand reduction to customers through seminars, workshops, training programs, and publication of case studies and guidebooks. As its chairm Buddy Hahs put it, "NAESCO's mission [is] to build market opportunities by encouraging customers and policy makers to rely on energy efficiency as the first energy priority. NAESCO has taken a leading role in establishing industry best practices and supporting its membership in the creation of tangible economic value." As an association interested in promoting energy efficiency, NAESCO is committed to fight against global warming and strongly supports the implementation of legislation limiting greenhouse gas emissions. Its representatives have been heard as witnesses in Senate committees dealing with the impact of global warming on the U.S. economy.

NAESCO wants to play a major role in devising innovative policies for a changing marketplace. It represents the various parts of the energy services industry and advocates for the cost-effective supply of inclusive energy services to all types of customers. In order to promote industry quality, NAESCO has organized a meticulous endorsement program for ESCOs (Energy Service Providers and Energy Efficiency Contractors) to identify capabilities and experience. The Association has the ambition to gather the broadest spectrum of market participants in the energy industry. Its membership includes about 75 companies that deliver over $4 billion of energy efficiency, renewable energy, and distributed generation projects across the United States every year. NAESCO also tries to go beyond American national boundaries, acting as a forum for energy service-providers from around the world on how to facilitate market opportunities. The association has members in Israel, China, and Mexico.

Far from believing that legislation on energy efficiency and greenhouse gas limitation will cause the U.S.

economy to slow down, NAESCO holds that energy efficiency can contribute to industrial competitiveness and employment growth. It believes that investments in energy-efficiency schemes will result in the creation of new job opportunities. In addition, institutions, such as schools, will be able to hire new staff thanks to the energetic savings. NAESCO also counters the line of reasoning claiming that the new jobs in energy efficiency will simply be replacements for jobs lost in energy production and distribution. According to the testimony of Donald D. Gilligan, NAESCO's President, before the Senate Committee on Environment and Public Works, in September 2007, the marginal job losses caused by energy-efficiency programs are largely going to be overseas. Gilligan argued that the United States is dependent on foreign sources for oil supply and for Liquefied Natural Gas for fuel used for heating and electrical generation.

He identified this dependency as a drain on American economy and a threat to national security. So reducing this dependency would benefit the whole country. Citing the National Action Plan for Energy Efficiency, Gilligan found that a national effort by utilities to invest about $7 billion a year in energy efficiency would leverage an additional $20-30 million of nonutility investment, which, in turn, would yield annual savings to consumers of about $22 billion in 2017, or a net present value of about $344 billion. Based on three different studies of job creation effects, Gilligan made a mid-point estimate, identifying the jobs created under the investment levels envisioned by the National Action Plan at about 298,000. The adoption of a large-scale energy-efficiency program would not entail a drastic reduction of energy-producing plants. In addition, the adoption of such scheme does not mean the discharge of skilled trade workers who are employed to build and maintain electric power plants and transmission and distribution systems. Finally, new job opportunities can be created by the research needs of the new energy production and generation technologies (widespread renewables, clean coal, nuclear fuel, oil from shale or tar sands). In conclusion, NAESCO believes that a major national commitment to energy efficiency and to greenhouse gas limitation, the cornerstones of all green initiatives, will create hundreds of thousands of high-skill, high-wage jobs, providing a substantial boost to the American national economy.

National Center for Atmospheric Research (NCAR)

BASED IN BOULDER, Colorado, the National Center for Atmospheric Research (NCAR) provides the university community with the tools, facilities, and support required to perform innovate research. Through NCAR, scientists have access to high-performance computational and observational facilities, such as supercomputers, aircraft, and radar. These resources can be used to improve human understanding of atmospheric and Earth system processes. NCAR and university scientists collaborate on issues such as atmospheric chemistry, climate, cloud physics and storms, weather hazards to aviation, and interactions between the Sun and Earth. In all of these areas, scientists are looking closely at the role of humans in both creating climate change and responding to severe weather occurrences.

The core research of NCAR is based on the assumption that human activities are causing large-scale changes in the Earth system. The advances in scientific understanding, Earth system modeling, and computational and observational technology can shed new light on how the Earth system works. NCAR's activities contribute to the development of a predictive Earth system science that can help sustain Earth's habitability, improve environmental quality, safeguard human health, reduce the impacts of natural disasters, and increase economic productivity. This predictive Earth system becomes of particular importance in the face of global warming. The Climate and Global Dynamics Division of the Earth and Sun Systems Laboratory conducts broad-ranging research on all aspects of climate. The center explicitly connects global climate change, "whether it involves more heat or more cold, more precipitation or more drought," with "planetary warming." NCAR estimates that, since 1900, the Earth has warmed about 1 degrees F (about 0.6 degrees C). This warming of temperatures has various effects regionally. The center points out that scientists contributing to the 2007 International Panel on Climate Change predict changing precipitation patterns and retreating glaciers in Latin America, higher crop productivity in high-latitude regions, and sea-level rise along coastal regions. To lessen the insecurities about future climates, NCAR employs various tools and techniques, including climate models, radar and weather-balloon observations, satellite data, and so on, to understand the impacts of global and regional climate change.

NCAR has taken a clear stance on global warming, arguing that the data collected for more than 100 years on the Earth's surface temperature through a global network of land-based weather stations, supplemented by readings taken across the oceans, have shown a global rise in temperatures since the late 1800s. The center identifies human activities that amplify the natural greenhouse effect as "a major culprit." The NACR report on the topic states that "this warming of the average temperature around the globe has been especially sharp since the 1970s." The global models at NCAR have simulated 20th century climate and found three main factors at work. Solar activity contributed to a warming tendency in global average temperature in the first three decades of the last century. However, climate simulations at NCAR have shown that solar changes are accountable for less than a third of the warm-up during the last century. As industrial activity increased after World War II, Sun-blocking sulfates and other aerosol emissions helped lead to a slight global cooling up until the 1970s. Since 1980, the rise in greenhouse gas emissions from human activity has overwhelmed the aerosol effect to produce overall global warming. Thus, the most straightforward explanation for a warming Earth, NCAR states, is the greenhouse gases emitted when fossil fuels are burned in homes, gas and coal-fired power plants, vehicles, and factories. One of the objections of global warming skeptics is that some urban areas warm up due to the heat-island effect, because buildings and pavement retain more heat than undeveloped areas. NCAR scientists and researchers have made their estimates on global warming with particular attention to this heat-island effect. They have worked to remove and other potential biases from the global record. Even after these adjustments, they claim that the rise in global temperature remains clear.

NCAR lists other signs of a warming planet, such as retreating glaciers. Modeling by NCAR scientists has shown that, in the Arctic, the thickness and extent of summer sea-ice have decreased at a fast pace over the last 50 years. In addition, NCAR modeling has predicted that the Arctic's summer ice may virtually disappear by 2040. The increasing snowfall over Antarctica is, to NCAR scientists, a paradoxical sign of warming temperatures in this frozen land. The annual cycle of plants and migrating animals points to a expansion of the warm season over much of the Northern Hemisphere.

Reporting on the temperature in the troposphere several miles above Earth, NCAR states that satellites initially showed a smaller temperature rise at these heights than at ground level. Yet, it now seems that most of the disagreement was due to errors in the satellite data and how they was interpreted. There are still differences between tropospheric and surface warming in some regions, but NCAR researchers point out that a 2006 U.S. Climate Change Program report has cancelled the discrepancy on a global scale. NCAR is committed to the improvement of data-gathering, computer modeling, and analysis for studies of past, present, and future climate. For example, research at NCAR has focused on a re-examination of the role of decades-long cycles of solar variation in explaining the observed warming in the first half of the 20th century. NCAR researchers have identified another impact of humanity's increasing consumption of fossil fuels: the alterations in seawater chemistry as the oceans absorb more carbon dioxide. These alterations create a real danger to marine organisms, including those that build coral reefs around the world.

Many NCAR scientists are part of a global team studying global warming and its meaning for the Earth's future. In 2001, NCAR scientists estimated that increasing levels of greenhouse gases will warm the globe by a significant amount. They came up with a 90 percent likelihood that the range will fall between 3 and 9 degrees F (1.7–4.9 degrees C) over 1990 levels by the year 2100. NCAR researchers have concluded that the effects will be far more varied than a simple, uniform warming over the entire planet, because heating also alters the water cycle, among other changes. As a result, some regions will become considerably hotter or cooler, or wetter or drier, than others. NCAR scientists are working to improve understanding of potential regional changes in climate, such as the change in U.S. rainfall and snowfall patterns. Researchers are also working to translate temperature changes from a model into consequences that affect people's everyday lives. A 2004 NCAR study estimated that, by the period 2080–99, American and European heat waves will be more severe, frequent, and will last longer. A related study found that days in which temperatures dip to 32 degrees F (0 degrees C) will decrease in many parts of the globe by 2080–99. The biggest reductions are foreseen for the northwest parts of Europe and North America.

New research, in 2006, by NCAR scientists considered more specifically the possibility of an increase in weather extremes in a warmed climate. Employing simulations from nine different climate models, the researchers demonstrated the risk of dangerous heat waves, intense rains, and other kinds of extreme weather in the next century. NCAR studies have been used in preparing the 2007 Intergovernmental Panel on Climate Change assessment.

National Oceanic and Atmospheric Administration (NOAA)

THE NATIONAL OCEANIC and Atmospheric Administration (NOAA) is a scientific agency of the U.S. Department of Commerce, which studies the conditions of the oceans and the atmosphere. NOAA issues warnings of dangerous weather, charts seas and skies, guides the use and protection of ocean and coastal resources, and conducts research to improve understanding and preservation of the environment. NOAA is particularly active in the fields of climate change and global warming. In addition to its civilian employees, the NOAA Corps, staffed by 300 uniformed service members, support NOAA research and operations. The Undersecretary of Commerce for Oceans and Atmosphere at the Department of Commerce, retired Navy Vice Admiral Conrad C. Lautenbacher, serves as the director for NOAA.

NOAA's main aim is to contribute to the creation of "an informed society that uses a comprehensive understanding of the role of the oceans, coasts, and atmosphere in the global ecosystem to make the best social and economic decisions." The agency's mission is "to understand and predict changes in the Earth's environment and conserve and manage coastal and marine resources to meet our nation's economic, social, and environmental needs." NOAA supports its mission through the pursuit of four targets that form the

A tornado photographed in Oklahoma by the National Severe Storms Laboratory, part of the scientific agency NOAA.

guiding principles of its operations. Each of them corresponds to activities focusing on ecosystems, climate, weather and water, and commerce and transportation. NOAA encourages the sustainable use of resources and the balance among competing uses of coastal and marine ecosystems, which recognize both their human and natural components. NOAA works to understand changes in climate, including global climate change and the El Niño phenomenon, to ensure that societies can respond and adapt properly to climate change. It provides data and forecasts for weather and water-cycle events, including storms, droughts, and floods. Finally, NOAA gives weather, climate, and ecosystem information to make sure individual and commercial transportation is safe, efficient, and environmentally sound.

NOAA was created in February 1970, within the Department of Commerce, combining the Bureau of Commercial Fisheries, Weather Bureau, Coast and Geodetic Survey, Environmental Data Service, National Oceanographic Data Center, National Satellite Center, Research Libraries, and other components. Although NOAA was officially created in 1970, the different bureaus that merged into it were among the oldest in the Federal Government: the Coast and Geodetic Survey was formed in 1807, the Weather Bureau in 1870, and the Bureau of Commercial Fisheries in 1871. President Richard Nixon proposed creating a new department to serve a national need "for better protection of life and property from natural hazards … for a better understanding of the total environment … [and] for exploration and development leading to the intelligent use of our marine resources…."

NOAA's offices and divisions play an important part in various aspects of American national life. The National Ocean Service (NOS) has been a leading institution in the introduction of electronic nautical charts that, together with GPS, have enhanced the safety and efficiency of navigation. NOS has also played a leading role in advocating coastal and ocean stewardship. As the trustee for 12 marine protected areas, NOAA protects National Marine Sanctuaries, which are akin to national underwater parks. Each sanctuary has a unique goal, from protecting the breeding ground of humpback whales, to preserving the remains of historical shipwrecks, or coral reef colonies. Through the sanctuary program, a growing number of partners and volunteers embrace NOAA's ocean mission to preserve, protect, and respect our nation's marine environment.

Thanks to NOAA's cooperative weather observers, including a network of more than 10,000 National Weather Service (NWS) volunteers across the country, the agency can continue to take daily weather measurements that become part of U.S. climate records. This is a tradition that goes back to Thomas Jefferson and the times before the American revolution. These records, along with other records from the NWS, U.S. Navy, U.S. Air Force, the Federal Aviation Administration, and meteorological services around the world, are housed at the National Climatic Data Center in Asheville, North Carolina. The center is the largest active archive of climate data in the world, and is part of NOAA's National Environmental Satellite, Data, and Information Service (NESDIS). In addition to the climate center, NESDIS also manages the National Geophysical Data Center in Boulder, Colorado, and the National Oceanographic Data Center in Silver Spring, Maryland. National and international users access these data to study how climate and environment are changing.

NOAA's satellite operations grew out of the space program and the desire to study our earth from a vantage point. NOAA's satellites have evolved from weather satellites to environmental satellites. Data are used for applications related to the oceans, coastal regions, agriculture, detection of forest fires, detection of volcanic ash, monitoring the ozone hole over the South Pole, and the space environment.

The NWS uses complex technologies such as Doppler radar, automated surface-observing systems, sophisticated computer models, high-speed communications systems, flying meteorological platforms, and a highly-trained and skilled workforce to issue more than 734,000 weather, and 850,000 river and flood forecasts, and between 45,000 and 50,000 potentially life-saving severe weather warnings annually. The Weather Service has also developed the Advanced Weather Interactive Processing System, the final piece of technology in a $4.5 billion modernization program to improve climate, water, and weather products and services that help protect life and property, and increase economic growth. It was estimated that the NWS's accurate, long-range predictions for the 1997–98 El Niño episode, helped California prevent about $1 billion in losses.

NOAA's National Marine Fisheries Service takes a rational, scientific approach to the difficult, contentious issues of living marine resource management. NOAA

Fisheries Service advocates the sustainable use of living marine resources, seeking to balance competing public needs and interests in the use of those resources, while protecting their biological integrity. Two recent examples are represented by international and domestic actions to rebuild swordfish stocks, working with both industry and conservationists; and developing an innovative, long-term strategy for restoring threatened and endangered salmon in the Pacific Northwest.

NOAA's Office of Oceanic and Atmospheric Research (OAR) establishes cooperative projects between its scientists and their university partners to better understand the Earth. OAR is the theoretical base that allows better weather forecasts, longer warning lead-times for natural disasters, new products from the sea, and a greater understanding of our climate, atmosphere, and oceans. NOAA research is done both in traditional laboratories, and also aboard ships, on planes, and beneath the sea. NOAA research tools can be as high-tech as supercomputers or as basic as rain gauges. Officers of the NOAA Corps, the smallest of the seven uniformed services of the United States, operate NOAA's fleet of research vessels and aircraft.

As the ultimate goal of all NOAA's activities is to predict environmental changes on a wide range of time and space-scales, to protect life and property, and provide industry and government decision-makers with a reliable base of scientific information, most of the agency's researches and programs are increasingly focusing on global warming and climate change. NESDIS data centers are extremely important in answering some of the most pressing global change questions that remain unresolved. The National Climatic Data Center contains the instrumental records that can measures the nature of climatic fluctuations at timescales of a up to a century. The National Oceanographic Data Center provides the subsurface data, which portray the ways heat is distributed and redistributed over the planet. Knowing how these systems are changing, and how they have changed in the past, is crucial to allow predictions of how they will change in the future. And, for climate information that extends from hundreds to thousands of years, the paleoclimatology program, also at the National Climatic Data Center, helps to provide longer-term perspectives.

The most significant effort in the research on global warming and climate change is NOAA's international Tropical Ocean-Global Atmosphere (TOGA) program, which officially began in 1984. This program aims to understand the role that the tropical Pacific Ocean plays in producing climate changes over North America. The principal focus of the program is the El Nino-Southern Oscillation, two phenomena that when coupled can cause dramatic changes in climate pattern amd result in major damage. NOAA has established a monitoring network and computer-modeling capability, which will allow scientists to recognize the early signals of the phenomenon so they can be predicted. This predictive capability is a priority for the agency as it will avert economic damages and will also be one of the most significant contemporary scientific achievements.

NOAA's research, since the 1980s, has also played a key role in the area of longer-term climate changes and air quality. Building on a strong tradition of research in atmospheric chemistry, in 1985, NOAA started the Radiatively Important Trace Species (RITS) research program. NOAA had already been researching the causes and potential effects of carbon dioxide on the Earth's climate, the so-called "greenhouse warming. In the early 1980s, however, NOAA provided the scientific community with a fuller picture by identifying other so-called "greenhouse gases," such as methane and the chlorofluorocarbons which are becoming increasingly central in debates over stratospheric ozone depletion. NOAA scientists have calculated that the global greenhouse warming from these gases could be as great as that expected from carbon dioxide. NOAA was among the first institutions to investigate the reasons for the increasing levels of these gases and predict the potential climatic and chemical consequences of such changes. The RITS program remains the principal coordinated agency response to this scientific challenge and environmental problem.

In 1986, NOAA led an Antarctic Ozone Expedition to McMurdo Base to investigate the Antarctic ozone hole. The results showed highly-elevated abundances of reactive chlorine compounds, reduced levels of nitrogen oxides, and 40 percent depletion of ozone at 7–12 mi. (12-20 km.) altitude. Because the cause of the ozone hole had not been defined with certainty, NOAA also led a second expedition in 1987, and a NOAA scientist was also selected as mission scientist for an interagency aircraft observation program to fly through the ozone hole in 1987. More recently, the Paleoclimatology Program has provided the paleoclimate data and information needed to contruct interannual to centennial-scale environmental change. This research proved the importance of understanding past climates to understand global warming, and, through paleoclimate data, provided a long baseline of past change. This long baseline revealed the natural variability of Earth climate, and illustrated how climate and greenhouse gases have changed in the past. The Paleoclimatology Program also began to shed some light on several disputed global warming issues, such as the extent of anthropogenic responsibility for greenhouse gases emissions, the future levels of warming, and the other changes that will occur with future warming. The Program's estimate is that about 50 percent of the observed global warming is due to greenhouse gas increases. The paleoclimatic record shows how much temperature change occurred in the past when carbon dioxide levels were different. Studies explain that the 100 parts per million (ppm) reduction in carbon dioxide during the last glacial era was followed by a 5.4 degree F (3 degrees C) cooling in the western tropical oceans. This amount of temperature change is consistent with the change predicted by numerical climate model simulations. Changes at higher latitudes were much larger, and included the formation of large ice sheets. Studies of the glacial world demonstrate that many aspects of climate were different when carbon dioxide was reduced, including lower sea level, lower snowlines, and altered patterns of circulation. Starting from these studies, NOAA scientists predict that other aspects of the climate, in addition to temperature, will change with future warming.

NOAA plays a crucial role as the Federal Government's principal operational climate observing, prediction and information management center. These activities characterize NOAA's unique role and contribution to an evolving national and international scientific program to understand and predict natural and anthropogenic changes in the global environment. Together with the other principal U.S. participants in these efforts, the National Aeronautics and Space Administration and National Scientific Foundation, NOAA has recognized the importance of focusing on the global climate system, because changing climate has far-reaching economic, health and safety, and national security consequences. NOAA programs in oceanic and atmospheric observations, monitoring, data processing, research, predictive modeling, and information management contribute to advancing our understanding of phenomena related to global warming and climate change.

National Science Foundation

THE NATIONAL SCIENCE Foundation (NSF) is a U.S. government agency that supports research and education in science and engineering. The agency was created by Congress in 1950 "to promote the progress of science; to advance the national health, prosperity, and welfare; to secure the national defense." With an annual budget of about $5.91 billion, the NSF funds approximately 20 percent of all federally-supported research conducted by U. S. colleges and universities. In some fields, such as mathematics, computer science, economics, and other social sciences, NSF is the major source of federal funding. NSF has funded several important studies in the area of global warming.

The President of the United States appoints the NSF's director, its deputy director, and the 24 members of the National Science Board (NSB), who are then confirmed by the Senate. The director and deputy director are responsible for administration, planning, budgeting and day-to-day operations of the foundation, while the NSB holds six meetings per year to establish its overall policies. The NSF is unlike other U.S. government agencies, in that it does not operate its own laboratories, but seeks to fulfill its mission mainly through competitive, limited-term grants, in response to specific proposals from the research community. NSF receives about 40,000 proposals each year, and funds about 10,000 of them. The projects that receive funding are selected in a merit review process carried out by panels of independent scientists, engineers, and educators who are experts in the relevant fields of study. These are selected by NSF with particular attention to avoid conflicts of interest;

for example, no-one of the reviewers can work for the institutions whose project is under examination.

NSF grants typically go to individuals or small groups of investigators who carry out research at their academic institutions. Other grants provide funding for mid-scale research centers, as well as instruments and facilities that are useful to researchers from different bodies. Finally, there are grants that fund national-scale facilities shared by the research community as a whole. Examples of national facilities include NSF's national observatories, with their giant optical and radio telescopes; its Antarctic research sites; its computer facilities and ultra-high-speed network connections; the ships and submersibles used for ocean research; and its gravitational wave observatories. In addition to research and research facilities, the NSF supports sciences through education grants from pre-Kindergarten through to post-graduate work.

NSF's workforce is made up of about 1,700 employees, nearly all working at its Arlington, Virginia, headquarters. That includes about 1,200 career employees, 150 scientists from research institutions on temporary duty, 200 contract workers, and the staff of the National Science Board office and the Office of the Inspector General, which examines the foundation's work and reports to the NSB and Congress. NSF is divided into seven directorates that fund science and engineering research and education: Biological Sciences; Computer and Information Science and Engineering; Engineering; Geosciences; Mathematics and Physical Sciences; Social, Behavioral and Economic Sciences; and Education and Human Resources. An assistant director heads each section which is further divided into smaller units such as materials research, ocean sciences and behavioral and cognitive sciences. Some of the divisions within the NSF's Office of the Director are also involved in supporting research and researchers. These include the Office of Polar Programs, the Office of Integrative Activities (covering a wide-range of activities), the Office of International Science and Engineering, and the Office of Cyberinfrastructure. The NSF also has offices charged with financial management, award processing and monitoring, legal affairs, outreach and other functions.

According to David M. Hart, the NSF was the result of an unsatisfactory compromise among too many contrasting visions of the purpose and scope of the federal government. In the years following its foundation, the agency was superseded in importance by the more-specialized agencies established because of the postwar anxieties in the fields of medical research (National Institutes of Health), nuclear energy (U.S. Atomic Energy Commission), space science (National Aeronautics and Space Administration) and defense-related research (Defense Advanced Research Projects Agency). With the end of the Cold War, however, NSF gained importance and acquired new fields of research that were not included in its original mission. Now the Foundation is the federal agency with the largest mandate, acting as a support for all scientific fields, except for medical research. The technological boom of the 1980s was another important factor in increasing the NSF's prestige. The awareness that scientific and technological research was necessary to keep the United States a safe and competitive nation ensured strong bipartisan support in Congress for the NSF. Its growing prestige is mirrored in its budget, which has increased from $1 billion in 1983, to the current $5.91 billion.

The grants and projects provided by the NSF have contributed significantly to technological advancement. For example, NSF-funded research helped to develop the internet as well as Mosaic, the first freely-available internet browser that allowed users to view World Wide Web pages with both texts and images. It has also launched the Digital Library Project to extend and develop digital library methods and technologies.

Several important projects funded by the NSF have dealt with issues related to global warming. It's interest in ozone depletion dates back to the mid-1980s when it supplied researchers at the South Pole with ozone sensors, along with balloons and helium, to measure stratospheric ozone loss. The action was taken due to data forecasts of a steep drop in ozone over a period of several years. In 1996, NSF-funded research led to the conclusion that the chemistry of the atmosphere above Antarctica is apparently abnormal, and that levels of key chlorine compounds are extremely high. NSF researchers contributed to further understanding and awareness about the ozone hole. In 2004, researches focused on the potential impact of global warming on high-altitude plants and animals. NSF researchers concluded that large-scale climate change (warming temperatures, receding glaciers, and the loss of permanent snowfields) could lead to a loss of many species of birds and plants. In the same year, researchers also assessed the potential of dissolved carbon in the Arctic ocean for the process of global warming. The international team of scientists concluded that most of that carbon was fairly young and not likely to affect the balance of global climate. Yet, they still cautioned that a well-documented Arctic warming trend could result in ancient carbon, a reservoir of the gas currently locked into peat bogs, being released and added to the mix contributing to the warming trend. Researchers stressed that, under the current warming trends in the Arctic, more of the old carbon would enter the carbon cycle as carbon dioxide. This would increase the greenhouse effect and accelerate global warming. This was the first time that gases trapped in the bogs were accounted for in climate change models.

In 2006, a joint research of NSF and Scripps Institution of Oceanography found out that global climate change may have quickly disrupted ocean processes and led to drastic shifts in environments around the world. Although the researchers were concerned mainly with a warming trend that took place over 55 million years ago, known as the Paleocene/Eocene Thermal Maximum (PETM), their data were relevant to the contemporary warming trend. The results of the research indicated that deep-ocean circulation in the Southern Hemisphere abruptly stopped the conveyor belt-like process known as overturning, in which cold and salty water in the depths exchanges with warm water on the surface. This process became active in the Northern Hemisphere, causing a shift of unusually warm water to the deep sea, likely releasing stores of methane gas that led to further global warming and a massive die-off of deep-sea marine life. The researchers further stated that modern carbon dioxide input from fossil fuel sources to the Earth's surface was approaching the same levels estimated for the PETM period, and they claimed that this should raise concerns about future climate and changes in ocean circulation. Thus, the Paleocene/Eocene example suggests that human-produced changes may have lasting effects not only on global climate, but on deep ocean circulation. Richard Norris, one of the leading researchers on the team, went as far as stating that "the case described here may be one of the best examples of global warming triggered by the massive release of greenhouse gases. It gives us a perspective on what the long-term impact is likely to be of today's human-caused warming."

One of the most recent NSF-sponsored research studies carried out by climate modelers at the National Center for Atmospheric Research found out that, despite efforts to reduce greenhouse gas emissions, global warming and a greater increase in sea level are inevitable during the 21st century.

Natsource

NATSOURCE-TULLET (NATSOURCE) IS an international company based in Alberta, Canada. It is one of many international companies that respond to the needs of governments and corporations for assistance in meeting the demands of global greenhouse gas (GHG) emissions reduction policies. There are three major branches of Natsource business: Advisory Services, Transaction Services, and Asset Management Services. Advisory Services assist in developing policies whereby markets are created for GHGs and air pollutants. Additionally, the company advises clients on the impact of potential policies. Transaction Services assist interested parties in establishing a route for transactions for trading environmental goods and renewable energy. Finally, Natsource Asset Management (NAM) services manages the Greenhouse Gas Credit and Aggregation Pool (GG-CAP), which closed in 2007, holding commitments from 26 parties valued at greater than $550 million. Additionally, NAM oversees Aeolus, which is a series of on-shore and offshore funds.

NAM's GG-CAP is the first private sector plan to assist global nations in meeting GHG emissions standards. The European Union Emissions Trading Scheme and the Kyoto Protocol have set the major emissions-reduction standards. While meeting these reductions will ultimately protect the environment and industry for a longer period of time than current standards would. Meeting them requires great financial commitment, which may be a burden to some developing countries. Therefore, the GG-CAP established a pool of capital that will be used to buy and trade emissions-reductions credits. Thus, a company with emissions under the standards can sell its extra credits to another company that is struggling to meet standards. These extra credits would be at a lower cost to the purchasing company than the restructuring needed to meet the standards. The principle behind this trade is that the selling company is rewarded for exceeding standards, and the purchasing company is given extra time to meet those standards, without penalty. Overall, the same net amount of emissions is effectively released, as if the two companies had both met standard allowances.

The Natsource Asset Management Services (NAM) is based in the Calgary office; other offices around the globe are located in La Paz, Bolivia; London; New York; Ottowa; Tokyo; and Washington, D.C. Each office is situated to address specific regional concerns in an international context. For example, the La Paz office manages Latin American interests and monitors carbon dioxide emissions reductions in this region, while the London office manages the interests of the United Kingdom and in Europe.

The New York office focuses on international efforts; the Washington, D.C., office works to engage all levels, such as corporations, governments, and other institutions, in policymaking. The Ottowa office houses Natsource's Global Change Strategies International (GCSI). The purpose of GCSI is to provide consultation regarding climate change and other broad environmental issues. Finally, the Tokyo office serves Japanese corporations.

Natural Gas

NATURAL GAS IS a fossil fuel existing in deposits in the Earth over wide regions of the globe. It is composed of hydrocarbons, which are molecules of hydrogen and carbon of up to five different combustible gases, and traces of other gases such as nitrogen, hydrogen sulfide, carbon dioxide, and helium. The type of hydrocarbon gas depends on the number of carbon atoms in the molecule. Methane is the primary gas of natural gas, having just one carbon atom per molecule. As a result, it is the cleanest burning fossil fuel, with less carbon than the equivalent amount of oil or coal. The greenhouse gases of natural gas are methane, carbon dioxide (CO_2), and minor amounts of nitrous oxide.

The combustion of natural gas releases CO_2 and nitrous oxide. Combustion is a rapid form of oxidation in which carbon will bond with oxygen as carbon dioxide or carbon monoxide. Gasoline is not natural gas, but is instead refined from oil. By contrast, gasoline has 8–11 carbon atoms, so produces more CO_2 per unit of energy. Therefore, using natural gas as a fuel, from a greenhouse gas point of view, is better than other fossil fuels. However, this does not take into account cost and practicality. CO_2 by volume is not considered as significant a greenhouse gas as methane. Methane is reported as 21 times stronger in its entrapment of heat in the atmosphere. Methane in the atmosphere has other sources besides natural gas. Living organisms, such as livestock, are considered major sources of methane in the atmosphere.

Natural gas exists in large portions of the globe. In many regions, it is trapped as large deposits in rocks deep beneath the Earth's surface. It is also found in deposits of crude oil and coal, and in ice crystals in permafrost regions. Natural gas is found at shallow depths, less than 100 ft. (30 m.), to depths of over 20,000 ft. (6,096 m.) Shallow depth gas is typically biogenic gas, meaning generated by the bacterial decay of organic matter. It is generated over a relatively short period of time. Methane from landfills and swamps are examples of biogenic gas. Another type of shallow depth natural gas is hydrates—gas trapped in ice crystals in permafrost.

THE INCREASING VALUE OF NATURAL GAS

Most of the natural gas produced is trapped in rock formations that are millions of years old and at depths much deeper than the shallow-biogenic type. The market for natural gas has developed recently, relative to the history of the oil industry. For many years, it was regarded as a nuisance because necessary pipelines did not exist and could not be justified financially. Therefore, discoveries of gas in the search for oil were abandoned, and when gas was produced as a co-product from oil wells, it was ignited and flared for safety reasons. Natural gas is now regarded as a valuable commodity and only minor amounts are flared or lost to the atmosphere. Markets have developed and demand is strong and growing. The primary transportation of natural gas is by pipeline, and because of higher prices, smaller deposits of gas can justify drilling and laying a pipeline. In addition, a rapidly-developing transportation mode for natural gas is by tanker in liquefied form. Large volumes can be pressurized and moved on the high seas to coastal terminals where pipelines then move the gas to consumers. Natural gas is now a global commodity.

The increased value also spurs exploration for new deposits at depths of 4 mi. (6.4 km.), and the development of nontraditional sources, such as from landfills and coal seams. The production of natural gas from coal beds, known as coal bed methane, is through wells drilled into the coal. This same gas has been the source of coalmine explosions when not properly ventilated. The production of coal bed methane can reduce the eventual release of methane to the atmosphere through mining operations. The production of natural gas from hydrates is not a reality yet, for technical and economic reasons. Ironically, the methane in gas hydrates of tundra regions may be released by global warming. The permafrost is thawing in some areas. This will release the gas trapped in ice crystals to the atmosphere. In this instance, global warming becomes the culprit in creating greenhouse gas.

Most of the methane in the atmosphere is the result of living organisms such as livestock, and not natural gas. Natural gas is sequestered in the Earth until released through production into a pipeline or other vessel. It enters the atmosphere in raw form or as CO_2 and nitrous oxide from combustion. While the greenhouse gases released are in lesser amounts than from burning other hydrocarbons, the concern is for the enormous volumes of natural gas being produced and, therefore, the enormous amount of CO_2emitted. Natural gas has been forming for millions of years; the first organisms on Earth are thought to be more than 600 million years old. These organisms, if buried before decay, can generate natural gas through a maturation process in the absence of oxygen. If not buried, they oxidize in the atmosphere and release gases at that time. The natural gas produced today literally represents a deposit of greenhouse gas that was not spent at the time the organism died. So, millions of years of saved deposits of greenhouse gas are now being released at a rapid and accelerating rate with the popularity of natural gas as a clean, efficient burning fuel.

Based on trapped gases in ice cores in Antarctica, there has been a dramatic increase in greenhouse gases in the global atmosphere since the beginning of the Industrial Revolution. Samples indicate that in the last 200 years, CO_2 has increased by 35 percent, methane by 600 percent, and nitrous oxide by 18 percent. Data for CO_2 suggest that about 100 years ago there was an increase in the growth rate of atmospheric concentration, followed by another rate increase beginning about 50 years ago, when the world consumption of hydrocarbons, combined oil and gas, surpassed coal in energy content.

Natural Resources Defense Council (NRDC)

THE NATURAL RESOURCES Defense Council (NRDC) describes itself as "the nation's most effective environmental action organization," and indicates that the world's foremost environmental problem is global warming. In 2007, the NRDC was a founder and organizer of the U.S. Climate Action Partnership, a coalition of environmental organizations and corporations advocating legislative action to address global warming. Incorporated in New York in 1970, the NRDC also has offices in Los Angeles, San Francisco, Washington, D.C., Chicago, and Beijing. Frances Beinecke was named president in January 2007.

According to its mission statement, the NRDC strives "to protect nature in ways that advance the long-term welfare of present and future generations." In addition to affirming the "integral place of human beings in the environment," and decrying the "pattern of disproportionate environmental burdens borne by people of color and others who face social or economic inequities," it emphasizes a way of life "that can be sustained indefinitely without fouling or depleting the resources that support all life on Earth." The group began as a public interest lobbying organization funded by the Ford Foundation, and now focuses on litigation and legislation involving protection of the environment. Its program foci include Health, Nuclear, Land and Forests, Urban, Climate, Air and Energy, Water and Oceans, International, Market Transformation, Advocacy Campaigns, and Legislation and Litigation.

NRDC has frequently appeared before the U.S. Supreme Court, and has been involved in federal, state, and local litigation. NRDC was partially responsible for passage of the Clean Water Act, which allowed citizens to sue water polluters directly. Removal of lead from gasoline and the increase of energy efficiency in home appliances have also resulted from NRDC's actions. A 1976 court battle resulted in limitations on water pollution for 24 major industries, and, in 1978, a successful lawsuit cut sulfur dioxide emissions by a million tons annually. Legal action, in 1984, forced the U.S. Department of Energy's nuclear weapons facilities to comply with environmental laws. Two other lawsuits forced major corporations, Bethlehem Steel in 1987, and ARCO and Texaco in 1993, to pay stiff fines for water pollution.

In October 2007, 11 of its 160 program staff members worked in its Climate Center. Invited by the U.S. House to testify on global warming legislation, the NRDC responded with substantial scientific data and an offer to work with the government on solutions "to prevent the worst global warming impacts, meet other objectives such as reducing our oil dependence, and promote continued strong economic growth." The NRDC helped craft and pass California's landmark Global Warming Solutions Act that requires substantial reduction of greenhouse gas (GHG) emissions. It also was a party to the *Massachusetts vs. EPA* case, in which the Supreme Court, in 2007, affirmed the EPA's ability to regulate GHG emissions. The group also gives attention to the social effects of global warming.

The NRDC funded a 2006 study, by the Institute for Lifecycle Environmental Assessment, which determined that producing and burning ethanol is better for the environment than producing and burning gasoline, and that celluosic ethanol has a substantial advantage over corn ethanol. The NRDC's suggested program for cutting GHG emissions by more than half (with approximate percentages of total reductions) involves boosting energy efficiency (41 percent), building better cars (24 percent), increased use of renewable and biofuels (19 percent), and scrubbing carbon from fossil fuels (16 percent).

The NRDC spends 80.3 percent of its budget on its programs and services, and uses 8.1 percent of its functional expenses on administrative costs. The group uses 11.5 percent of its expenses to raise funds, and spends 9 cents to raise each $1 it receives. NRDC has five top administrators, and over 300 employees. In 2005, its then-president, John Adams, received $297,140 in compensation, which was .51 percent of the group's total expenses. According to the Better Business Bureau, the NRDC meets the Standards for Charity Accountability.

Nauru

THE REPUBLIC OF Nauru, located in the Pacific, has a land area of 8.1 sq. mi. (21.2 sq. km.), a population of 10,000 (2006 est.), and a population density of 1,608 people per sq. mi. (621 people per sq. km.). With very little arable land, Nauru is completely dependent on imported food and water. Nauru makes its money from the sale of phosphate, which has led to the destruction of much of the country, and during the 1970s and 1980s, incredible wealth. Electricity production in Nauru comes from fossil fuels, with Nauru contributing heavily, relative to its size, to global warming and climate change. In 1990, its carbon dioxide emissions were 13.9 metric tons per capita, falling to 10.8 metric tons per capita by 1992, and rising to 14.2 metric tons per capita in the following year.

The effect of global warming and climate change will be dramatic for Nauru. With much of the island physically removed by the phosphate industry, the likelihood of massive water inundation is high. Many of the coral reefs off the coast of Nauru have experienced coral bleaching, and with the money from phosphate significantly reduced during the 1990s and 2000s, the country has faced major environmental problems.

The Nauru government of Bernard Dowiyogo took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. The government of René Harris ratified the Kyoto Protocol to the UN Framework Convention on Climate Change on August 16, 2002, and it took effect on February 16, 2005. However, Nauru added an extensive addendum to its signing of the Kyoto Protocol stating that "in the light of the best available scientific information and assessment of climate change and impacts, it [the government of Nauru] considers the emissions and reduction obligations in Article 3 of the Kyoto Protocol to be inadequate to prevent the dangerous anthropogenic interference with the climate system."

Robin S. Corfield
Independent Scholar

Navy, U.S.

THE U.S. NAVY was established on October 13, 1775, with the Department of the Navy founded on April 30, 1798. While the mission of the U.S. Navy is to "maintain, train and equip combat-ready naval forces capable of winning wars, deterring aggression and maintaining freedom of the seas," it also serves to provide important astronomical information to scientists and analysts. Given its handling of vast quantities of hazardous chemicals and environmentally-dangerous substances, the Navy recognizes its responsibility to the local and greater environments and makes efforts to remain environmentally conscious.

One example of Naval efforts to study the effects of environmentally-hazardous materials took place in 2007. The U.S. Navy participated in a joint research effort to investigate the effect and impact of aerosols on global warming and climate change. The mission was called UAE2 (United Arab Emirates Unified Aerosol Experiment), took place in the Arabian Desert, and joined scientists from the Naval Research Laboratory (NRL), the National Aeronautics and

In addition to the Navy's own research, it delivers supplies annually to research scientists at McMurdo Station, Antarctica.

Space Administration (NASA), and the Scripps Institution of Oceanography. Aerosols are tiny airborne particles, which naturally contribute to cloud formation and, therefore, rainfall. They can be classified as light or dark. Lighter aerosols reflect sunlight and heat; therefore, they have a cooling effect on the atmosphere. Darker aerosols, however, trap sunlight and heat within the atmosphere, causing the temperature to rise.

Additionally, the U.S. Navy maintains equipment that can be used by scientists to study extreme weather conditions. This equipment, while intended for other purposes, has characteristics that can be taken advantage of by researchers. For example, the Navy has two major types of submarines: the TRIDENT ballistic missile submarine, and the Attack submarine that is less encumbered by large, bulky weapons and can travel into most waters, including those of the Arctic Ocean. The Attack submarines have been used for years by researchers, taking scientists to the Arctic waters to collect data regarding global warming. Such data include ice sheet thickness, water temperature at increasing depths, and other variables.

The Navy also has an undersea surveillance that can be used to collect data regarding global warming. This system is called SOSUS, the Sound Surveillance System. It is part of IUSS, the Integrated Underwater Surveillance System, and passively senses acoustic data that can be analyzed to monitor underwater activity of ships, as well as animals and other environmental components.

The U.S. Navy uses many pieces of equipment; each piece requires a significant amount of energy. As a major consumer of energy and fuels, the Navy makes efforts to reduce its fuel and energy consumption and to use cleaner fuel and energy options. For example, in Crane, Indiana, Team Crane consists of the Naval Facilities Engineering Command Midwest and the Public Works Department at the Naval Surface Warfare Center Crane Division. Team Crane uses a fuel that is 80 percent biodiesel and 20 percent soybean oil; the fuel is called B-20 and comes from the Indiana Soybean Board. Plans are under way to convert all the diesel-burning equipment at Crane to B-20 utilizing equipment. The base at Crane is not the only naval station that practices environmental responsibility.

AWARDS

To foster environmental stewardship, the Navy gives annual awards to those who exhibit exemplary environmental responsibility and awareness. For example, the Secretary of the Navy honors ships annually with the Secretary of the Navy Environment Quality Award. This award recognizes a ship's responsibility and leadership in environmental stewardship. The principal factor in this stewardship is the ship's storage, handling, and disposal of environmentally-hazardous material. Examples of systems on ships to handle hazardous material include those for dealing with trash, sewage, and incinerations of these materials. Additionally, a ship may actively avoid interfering with any visible marine life.

The Chief of Naval Operations Environmental Quality Award recognizes naval stations that follow environmental requirements to protect both the local environment and people. In 2003, then Public Works Environmental Division Director Tim Riordan outlined the environmental concerns at naval stations: "... a range of programs, including air emissions, drinking water, hazardous materials, hazardous waste, historic and cultural resources, and natural resources and endangered species, to name a few."

ORGANIZATION OF THE NAVY

The Navy has three main branches: the Navy Department, the operating forces, and the shore establishment. The Navy Department is mostly located in Washington, D.C.. The operating forces include the Coast Guard (in times of war), the Marine Corps, and the naval reserve (during peace, the U.S. Coast Guard is managed by the Department of Homeland Security). The Secretary of the Navy oversees the Chief of Naval Operations and the Commandant of the Marine Corps. The Chief of Naval Operations oversees the shore establishment and the naval operating forces, while the Commandant of the Marine Corps oversees the Marine operating forces. Finally, the two operating forces can work together and provide support to one another. The shore establishment includes all land-based personnel who support the system of naval ships, termed the fleet. These offices include the Naval Facilities Engineering Command, the Naval Meteorology and Oceanography Command, and the U.S. Naval Observatory.

The U.S. Naval Observatory is among the longest-standing scientific institutions in the United States. It has been in operation since 1830, when it was called the Depot of Charts and Instruments. It operates from its Washington, D.C., headquarters, as well as an observatory in Flagstaff, Arizona, and a Master Clock facility for the United States, based in Colorado Springs, Colorado. The Naval Observatory also manages the Lieutenant James Melville Gilliss Library, which houses an impressive astronomical literature selection. The Naval Observatory serves to collect and transmit invaluable astronomical information, such as the orientation of the Earth.

University of Illinois at Urbana–Champaign

Nebraska

NEBRASKA IS MADE up of a combination of mountain rages and high plains. The state has an area of 77,354 sq. mi. (200,346 sq. km.), with inland water making up 481 sq. mi. Elevations range from 840 ft. (1,246 sq. km.) above sea level on the Missouri River, to 4,424 ft. (1,348 m.) at Kimball County in Western Nebraska (the southwest corner of the panhandle). Nebraska can be divided into three geographic zones. Eastern Nebraska has many rivers, salt marshes, and grassland. Central Nebraska is flat in the south with the Platte River and the sand hills in the north with shallow lakes. A dam holds back the North Platte River, forming Lake McConaughy, the largest lake in the state. Western Nebraska, the Panhandle, has the highest in elevation of all of Nebraska, and is windy. Nebraska is drained by the Missouri River system.

Nebraska's climate experiences light snow, low humidity, hot summers, and cold winters. Warm, moist air flows from the Gulf of Mexico, while hot, dry air travels from the southwest, and cool, dry air currents flow from the northern Pacific Ocean and northwest Canada. The Rocky Mountains limit moisture from the west. Annual precipitation in the eastern third of the state averages 27 in. (69 cm.), in the central third 22 in. (56 cm.), and in the western third 18 in (46 cm.). An excessive rate of rainfall is frequent during summer thunderstorms. Floods occur in the eastern third of the state, as do tornadoes. Average snowfall normally ranges from about 20–40 in. (51–102 cm.), with the heaviest snows in late winter. Severe weather is common, from blizzards, to damaging winds, hail, and torrential rain.

Underneath central and western Nebraska is the largest aquifer in the world. Ogallala Aquifer lies underground beneath eight states, including Nebraska. The aquifer was named for the town of Ogallala in 1899. The level of water in the aquifer has been dropping steadily for decades and farmers are now trying to conserve this water by practicing conservation in irrigation. The rate of depletion has not stopped the dropping level of water, but it has slowed. Agriculture is a major economic concern, especially corn, livestock, soybeans, and sugar beets.

IMPACT OF CLIMATE CHANGE

During the Great Flood of 1993, natural disaster rain and snow runoff raised the Missouri river to flood stage and devastated southeastern Nebraska. While climate models vary on the amount of temperature increase possible, potential risks include decreased water supplies; increased risk of wildfires; changes in food production, with agriculture improving in cooler climates and decreasing in warmer climates; change in rain pattern to downpours with the potential for flash flooding; health risks of certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents; and heat-related illnesses.

Nebraska's substantial agricultural resources are sensitive to changes in climate. Increased heat could push temperatures above the tolerance level for crops like corn, causing a decline in yields. Strained water systems could pose a significant problem for state agriculture. Most runoff in Nebraska comes from snowmelts in Colorado and Wyoming that could decline with higher temperatures. The state's substantial groundwater resources could also be impacted by reduced spring and summer recharge. Weather variability would also likely increase with in increase in crop-damaging droughts. Positive impacts could include increasing carbon sequestration for emissions credits. Also, Nebraska farmers could see an increase in demand for corn-based ethanol.

ADDRESSING HUMAN-INDUCED CONTRIBUTIONS TO CLIMATE CHANGE

Based on energy consumption data from the Energy Information Administration, released in 2007, Nebraska's total CO_2 emissions from fossil fuel combustion in million metric tons for 2004 were 42.85, made up of contributions by source: commercial, 1.83; industrial, 6.01; residential, 2.44; transportation, 12.18; and electric power, 20.39.

Nebraska remains innovative in conservation practices. On April 10, 2000, the state became the first to enact legislation linking agricultural policy with greenhouse gas reduction. While agriculture is not a high contributor to greenhouse gas emissions, it has the potential to mitigate climate change. By forming a Carbon Sequestration Advisory Committee, made up of advisors from public and private sources in agriculture, industry, energy, and government and authorizing funding from the Nebraska Environmental Trust Fund, legislators ensured a quality, detailed assessment and recommendations. The benefits to Nebraska would be promoting the continuation and improvement of soil conservation programs, as well as an economics policy on the national or global carbon markets. The major problems with implementing pilot programs are initial and ongoing funding as well as the need for single-source oversight from CSAC or a similar lead organization.

The University of Nebraska is home to the Applied Climate Sciences (ACS) program for researching climate impacts in the Great Plains region. Because the area is sustained by agriculture, the university began an agricultural meteorology program in the 1960s. The program continues today within the university's School of Natural Resources. In addition, Julius Sterling Morton, a Nebraska newspaper editor, began the Arbor Day Foundation, located in Nebraska City, in the 1870s. His vision was to help beautify the state, provide shade, and prevent soil erosion. The nonprofit foundation continues today with a mission to create a world where trees and forests are abundant, healthy, and sustainable. To meet this goal, the Arbor Day Foundation helps protect the global environment by promoting rain forest preservation, urban and community forestry, and tree planting throughout the world. Trees absorb carbon dioxide, thus, the more trees are planted, the more carbon dioxide can be absorbed. Planting shade trees near a home can also reduce annual heating and cooling costs.

Needs and Wants

THE CONCEPT OF needs and wants and the ability to distinguish one from the other plays an important role in society. The issue is explored in philosophy, psychology, ethics, and modern social thought. To assert that something is a need is to argue that it is an essential element that is required for the body or society to exist. Some philosophers call needs real goods, and wants apparent goods. In Western political thought, the goods of having, doing, and being are seen as needs. The good of having refers to physical things like food, water, clothing, and shelter. The good of doing refers to a state of freedom, the ability to determine one's own life. The good of being refers to the ability to choose one's own thoughts and spiritual sensibilities.

In American political philosophy, these three goods are seen as required needs, the required foundation for any good republic. These real goods, or needs, may be seen in the phraseology of "life, liberty and the pursuit of happiness." Basic needs are also defined by humanitarian aid agencies and may include human rights, medicine, freedom from torture, control of reproductive rights, and access to nourishment. Needs are argued to be objective goods, universal and compelling. Sometimes, needs are argued to be self-evident.

Whereas needs are seen as universal and objective, wants are argued to be products of taste, culture, and personal preference. Wants are seen as acquired, pluralistic, contingent, and subjective. Wants are stylish, preferential, dispensable, and luxuries beyond what are needed. Wants may also be insatiable, such as the desire for experience, luxury, and social competition.

Both needs and wants stem from human desire. Needs are in relation to natural desires, and wants come from acquired desires. While human beings may all have the same needs, individuals are different from each other in their wants. The Greeks thought an educated man was one who was trained to desire the right things and distinguish needs from wants, real goods from apparent goods. Their end goal was creating leaders of good character, who were virtuous and had the habit of desiring good things. The classical Greek philosophers recognized that it was possible to have dangerous and misguided wants and that such wants could distort the ability to apprehend what was a needed good.

Needs are sometimes closely related to rights, because they are argued to be essential. If the issue is sharing food or some other essential element, the failure to share such is seen as a social and moral failure. Arguing that something is a need (essential for the functioning of the world) is a powerful social tool, and, thus, has social, moral, and political implications. Many things argued to be needs, however, are not entirely objective, and the arguments occur in a social-historical context.

Food may be necessary to live, and a person may want a hamburger, but that does not mean that a person needs a hamburger. Children are commonly seen to say they need things that they, in fact, do not need, but only want. Parents, government officials, the clergy, scientific experts, and other authorities frequently claim that things are necessary, even though this may not be evident. Experts, or a whole society can argue that there are needs that are not matters of personal choice, but fundamental essentials to all individuals and the whole society. Some needs are socially-created. Social power, social knowledge, and needs are closely related. In a debate about global warming, some nations organize around the perceived need to reduce greenhouse gasses, while other nations focus on the need to increase the size of the economy. A disciplined debate on these issues may lead to the realization that one of these positions is not really a need, but a want.

LIBERALISM

The struggle over if something is a need or a want is formidable in history, and the struggles shape society. When something is agreed to be a want and not a need, it is reduced to a less important issue of debate. It moves from an issue of truth to an issue of taste. Issues of taste and personal preference cannot easily be disputed and are frequently recognized to be questions of subjective value. In liberalism, the individual is sovereign when it comes to issues related to taste, opinion, consumption, and personal choices, as long as they do not infringe on the rights of others.

Critics of liberalism point out that liberalism enables one to describe what people want, but it cannot prescribe what people should want. In liberalism, individual reason is frequently oriented toward self-interest, and need and right is the battle cry of the individual, sometimes enabling acts that hurt social values and solidarity. Liberalism is not well-suited for distinguishing individual from universal values. Conservatives think needs and rights ought to be determined from the organic history and tradition of culture as it transcends individuals and informs current human communities. Critics on the left also critique liberalism and the confusing of needs and wants. They have images of a post-industrial and post-capitalist society focused on equality and a collectively and democratically decided-upon definition of need, where tradition is superimposed by functional democratic politics.

Distinctions between needs and wants are not only made difficult by culture, history, and individuals, but also by the values of particular communities. Researchers in sociology and anthropology have long explored how needs and wants are shaped by the underlying values in different communities. Some argue that each society has underlying needs, but needs are expressed and met in different ways, depending on the culture. Each culture may agree on the need for food, but the food may be very different across cultures. While the differences look arbitrary and may distract the researcher, the differences mask the underlying need. The final question is not about the various social manifestations that attempt to meet needs, but whether or not needs are being met. The problem, however, is that the researchers are tempted to argue that they can identify the real needs of a foreign culture. Both needs and wants are defined and negotiated within each specific culture. Sociologists caution about defining needs and wants from outside a culture, or with abstractions, and are interested in how cultures define needs and wants internally.

As the world becomes more pluralistic, diverse, densely-populated, and in competition with itself, it is crucial to agree on universal needs. As more of the world industrializes and strives for a higher standard of living, there will be more competition over resources and other problems of an increasingly global nature. Developed and developing nations will increasingly be linked on issues of trade, immigration, and greenhouse gas emissions. The affluence of developed nations and poverty in the developing world will increasingly force moral discussions about the relationships between the world's haves and have-nots. Questions about poorer countries bearing the greater costs of climate change have already begun. The anticipated manifestations of climate change will intensify questions about the real needs and costs for industrial emissions and the needs of less-industrialized countries.

Nepal

THE NEPAL HIMALAYAS, along with the mountains to the east, are called the Water Towers of Asia, as they provide water amounting to 2,298 x 28,002 cubic gallons (8.7 x 106 cubic meters) per year. The Nepal Himalayas have 3,252 glaciers covering 2,055 sq. mi. (5,323 sq. km.). Affected by global warming; some of these glaciers have shown signs of retreat, along with a diminution of ice fields, particularly in the Great Himalayan region of Nepal. Nepal, with an area of 55 sq. mi. (142 sq. km.). The population of 27 million (2005 est.) is affected by global warming differently in its four regions.

Warming of the Indian Ocean will accentuate monsoon precipitation-generated erosion activity in all four regions of Nepal. The southernmost narrow Terrai region (average height of 656 ft. or 200 m.) that borders India is a plain land, with extensive rice cultivation. Global warming-generated monsoon rain intensity and drought uncertainty will affect agriculture adversely. Moreover, flooding from excessive snow melting will increase until about 2035 in the Kosi, Gandak, and Karnali river basins; causing extensive damage to rice paddies and settlements. After 2035, fresh water flow in rivers will diminish, lowering the levels of Kosi River reservoir, situated only a few miles north of the Indian border. This will adversely affect agricultural activity.

Another narrow east-west stretching region north of Terai is Churia Hills and Inner Terai. This is known as the Siwalik foothills of the Himalayas. The hills reach an altitude of 4,000 ft. (1,219 m.). Siwaliks consist of deposits susceptible to heavy erosion, which will be further aggravated by heavier rainfall. Heavy silting of riverbeds downstream, both in Nepal and India, will aggravate river overflow. The mid-mountain region north of Siwaliks, in which two important valleys (Kathmandu, the capital, and Pokhra) occur, has a complex mountain system that rises up to 14,000 ft. (4,267 m.). This will also experience heavy erosion caused by greater precipitation. Terraced rice fields of this region will face erosion. Heavy snow-melting at the headwaters of Arun, Dun, Sun Kosi, Irisuli, Gandak, Beheri, and Karnali rivers will increase flood damage until 2035; parts of Kathmandu will also be further threatened. After 2035, the fresh water supplied by the rivers will diminish, affecting rice cultivation.

The Great Himalayas, the northernmost region, consists of the world's tallest permanent snow-clad

The Himalayas, in Nepal, are showing a change in the ice fields and signs of glacial retreat.

mountain ranges, where, apart from Mount Everest, there are eight others with peaks over 26,247 ft. (8,000 m.). A large chunk of this snow cover will diminish; the process has already started. Several glacial lakes are formed in the region as a result of glacial retreat. Overflow of these lakes leads to forest and farmland destruction, known as Glacial Lake Outburst Floods (GLOF). On August 1985, a GLOF originating from Langmorche glacial lake washed away 14 bridges and damaged a hydroelectric plant in Namche.

Netherlands

THE NETHERLANDS IS a wealthy European country with unique vulnerabilities to climate change. The country is creating proactive responses to anticipated rise in sea levels and increased flooding. It is working to meet the Kyoto Protocol, creating new government offices, and spending significant sums of money to make itself climate-proof. The country hopes that, through international agreements and domestic innovation, it will meet the challenges of climate change.

The Netherlands is a prosperous, small, and densely populated river delta country in Northern Europe, with a parliamentary democracy, and a 2007 population of 16.5 million. It has the 16th largest economy in the world. The gross domestic product (GDP) in 2006 was approximately $688 billion. It ranks 10th in the world in GDP per capita. Its economy depends on industry, particularly metal and chemical processing, petroleum refining, and electrical machinery. It is also a region of intensive agricultural and horticultural use. It takes advantage of its water infrastructure and its geographic location at the center of Europe's transportation network.

The Netherlands is one of the countries that may suffer the most from climatic change. In the Netherlands, 26 percent of the land lies below sea level, and two-thirds of the country's population lives below sea level. The Dutch government is deeply concerned about the national and global consequences of climate change. The government faces immediate threats on at least three fronts: rising North Sea levels on its coast line, increased risk of flooding from melting glaciers, and heavy rain and droughts that can cause sea and river dikes to subside and crack. The Agricultural Minister has stated that the effects of global warming are already seen in the form of milder winters, warmer summers, and altered rainfall patterns. Dutch policymakers are planning on sea level rise in the coming century.

Internationally, the Dutch government is a vocal leader on the issue of climate change and wants the European Union to actively contribute to furthering the process leading to more international agreements. The Netherlands is one of over 170 countries that ratified the United Nations Framework Convention on Climate Change (Rio de Janeiro, 1992). The country is a member of the European Union, the North Atlantic Treaty Organization (NATO), the Organisation for Economic Co-operation and Development (OECD), and has signed the Kyoto Protocol. The Netherlands' emissions reduction obligation is 6 percent. The country is committed to meeting this goal and will employ Joint Implementation (JI), Clean Development Mechanism (CDM) and Emissions Trading, in addition to domestic policy.

The National Environmental Policy Plan (NMP) sets Dutch environmental policy. The NMP aims to cut all forms of pollution 80 to 90 percent in one generation. The National Inventory Report, "Greenhouse Gas Emissions in the Netherlands 1990–2003," published in 2005, concluded that total CO_2-equivalent emissions of the six greenhouse gases together increased in 2003 by about one percent relative to 1990. In 2005, emissions equaled 214 billion kg. of carbon dioxide. The Minister of Housing, Spatial Planning, and Environment claims that the country is meeting emission reduction goals, but more work needs to be done to meet the Kyoto goals. Some key Dutch cities and infrastructure facilities are particularly vulnerable to rising seas and flooding, such as The Hague, Schiphol Airport, and the Port of Rotterdam. In 2006, the government approved a new $19 billion increase in spending on water defense systems over the next 20 years. This is in addition to another $4 billion for other special related projects and the $1.36 billion for annual maintenance of water defense systems currently in place.

In July 2007, the Dutch Cabinet earmarked €50 million for a new climate change center over five years. In some locations, giant sea-blocking doors called sluices will be added 2008–13 to fend off rising seas and storms. The National Spatial Planning and Climate Adaptation Programme (ARK) is charged with making the Netherlands climate-proof, starting in 2008. Engineers are discussing the creation of breaker islands off the country's North Sea cost. Pumping sand into strategic locations offshore, where North Sea currents will sweep the sand into place and bulk up the dunes, can create breaker islands. Similar techniques could create a series of small islands off the coast. The Netherlands is also working to develop a hydropole, a city that can live on the rising waters. Discussions in The Hague are also underway about a massive evacuation drill to be held in 2008, should sea defenses fail.

Net Primary Production

PRIMARY PRODUCTION IS the production of organic compounds from atmospheric or aquatic carbon dioxide, principally through the process of photosynthesis, and, to a very limited extent, through chemosynthesis. All life on earth is directly or indirectly reliant on primary production. As the earth is an open system with regard to energy, this is constantly used up and lost as heat as it moves through ecosystems, and new energy is continually added to the earth in the form of solar radiation. The organisms responsible for primary production are known as primary producers or autotrophs (from the Greek *autos*, meaning self and *trophe*, meaning nutrition), and form the basis of the food chain. In contrast, organisms that cannot produce their own energy, but have to feed off other organisms are called consumers or heterotrophs. Organisms able to produce complex organic molecules from simple inorganic compounds (water, CO_2, nutrients) include plants, algae, and some bacteria. Such organisms require sunlight, carbon dioxide, water, and nutrients, and through photosynthesis, they produce reduced carbon compounds and oxygen. Light energy is converted into energy stored in chemical bonds within plant tissue. This energy activates the metabolic process of the organism or system. New compounds and structures are created, cells split, and the plant grows in size over time.

Primary production is distinguished as either net or gross. Net primary production (NPP) accounts for losses through processes such as cellular respiration and maintenance of existing tissues, while gross primary production (GPP) is the total amount of energy produced by primary producers in an specific area or ecosystem. NPP is the remaining amount of CO_2 after we deduct the quantity lost through metabolic activity. Thus, NPP is an important part of the global carbon cycle and is important to monitor. The fact that concentrations of atmospheric CO_2 and tropospheric ozone (O_3) are rising at the same time in the atmosphere produces potentially adverse effects on forest NPP and negative results for terrestrial carbon sequestration. Both gross and net primary production are in units of mass, area, and time. In terrestrial ecosystems, the mass of carbon per unit area per year (g C/m2/yr) is most commonly used. In terms of NPP per unit area, the most productive systems are estuaries, swamps and marshes, tropical rain forests, and temperate rain forests. To calculate the total NPP of the world, these values per unit area should be multiplied by the area that the various ecosystems occupy. The results show that the most productive systems are open oceans, tropical rain forests, savannas, and tropical seasonal forests. Human appropriation of net primary production (HANPP), through the consumption of food, paper, wood, and fiber, modifies the composition of the atmosphere and the levels of biodiversity.

Nevada

NEVADA HAS A unique geography that makes it extremely vulnerable to global warming and climate change. Much of the state is uninhabitable, and the United States government owns 86 percent of the 109,806 sq. mi. (284,396 sq. km.) land area. Nevada has more than 300 mountain ranges. The Great Basin Desert covers the northern part of the state, and southern Nevada contains a section of the Mojave Desert. With some sections of the state averaging only 4 in. (10 cm.) of annual rainfall, Nevada is the driest state in the United States, and meteorologists have noted a dramatic 7 degree F rise (3.8 degree C) in average annual temperatures in Las Vegas, the state's largest city, over the past three decades.

Scientists predict that the southwest will become even drier in the future, in response to global warming and climate change. Evidences of change are already present. The glacier at the Great Basin National Park has lost 90 percent of its ice over the last one and a half centuries, and it now disappears in the summer. The ecosystems within the basin are considered extremely vulnerable to climate changes. Droughts have become more frequent in Nevada, posing increased threats of wildfires. Reaction to global warming and climate change in Nevada is focused in large part on the promotion of renewable energy. The Union of Concerned Scientists has predicted that, by 2012, Nevada will rank third in the United States in the production of green power.

Although Nevada has the 13th lowest ranking of carbon dioxide (CO_2) emissions in the United States, overall pollution levels within Nevada have been on the increase since the 1960s. A 2006 publication of the U.S. Public Interest Research Group, a nonpartisan organization based in Washington, D.C., used data compiled by the U.S. Department of Energy to track pollution in all 50 states 1960–2001. PIRG reported that global warming pollution in Nevada rose 835 percent during the relevant period. Coal-burning power plants were responsible for the 43 percent increase in Nevada's CO_2 emissions, but emissions from oil and natural gas also contributed to the increase. PIRG announced in an updated report in 2007 that 1990–2004, CO_2 emissions in Nevada had increased by 639 percent, placing that state fifth in the nation in increased emissions. State representatives insist that Nevada's increased CO_2 emissions have been a result of the 73 percent increase in population 1990–2001, caused by the industry that precipitated the population explosion. Efforts to control CO_2 emissions led to a 21 percent increase in CO_2 efficiency in Nevada 1990–2001.

In April 2007, Nevada Power was fined $1.1 million to settle a joint lawsuit filed by the U.S. government and Nevada. A total of 70 percent of the settlement was paid to Nevada, and 30 percent to the federal government. Nevada Power also agreed to spend $85 million to install cleaner technology and pledged to donate $4 million over a seven-year period to energy conservation projects for the Clark County School District. The suit was filed in response to 56 violation notices issued by the Bureau of Air Pollution Control to Nevada Power at the Reid Gardner coal-fired electric generating plant, which is located 50 mi. (81 km.) from Las Vegas, the gambling capital of the United States. All plans to open new coal-fired power plants in Nevada are now facing opposition from both the government and environmentalists.

In Nevada, environmental responsibilities are shared between the Department of Agriculture and the Department of Conservation and Natural Resources. The Conservation Commission, the Division of Environmental

Protection, the Bureau of Corrective Actions, and the Division of Water Resources all operate under the auspices of the Department of Conservation and Natural Resources, which issues permits and enforces state and federal laws, monitors the environment, enforces pollution prevention, and remedies conflicts. Specific departmental responsibilities include monitoring air and water quality and overseeing the cleanup of hazardous materials.

PROGRAMS

In the late 1990s, Nevada began working with activists and environment-related industries to develop a statewide plan for renewable energy. By 2001, the legislature had bipartisan support to institute what was then the most aggressive renewable portfolio standard of the time. The standard promoted the use of biomass, geothermal, solar, and wind energy as a means of reducing toxic emissions from fossil fuels. The Nevada Public Utility Commission was ordered to work with individual electric service providers to increase renewable energy to five percent in 2003, seven percent in 2005, nine percent in 2007, 11 percent in 2009, 13 percent in 2011, and 15 percent each year thereafter. Five percent of each renewable energy requirement must be derived from solar sources. Utilities may earn credits for up to 25 percent of the standards by instituting efficiency measures, and the state helps to defray costs involved.

In April 2007, the governor of Nevada established the 13-member Climate Change Advisory Committee and charged them with making recommendations for reducing greenhouse gas emissions throughout the state. A major focus of the committee's work is directed toward identifying methods for developing renewable energy resources that will protect the environment without threatening economic stability. Individuals on the committee represent local governments, state agencies, the academic sector, environmental groups, and the mining and energy industries.

Mining has historically been one of the major industries in Nevada, and mining is generally considered a major threat to the environment. Nevada's Mercury Emissions Testing Program is designed to control toxic emissions in Nevada mines. The first stage of the project began in spring 2007 with testing at the state's largest precious metal mine. As mandated by law, the Division of Environmental Protection conducts annual tests of emissions from the exhaust stacks of all units that potentially produce mercury. One of the purposes of the initial testing is to identify the forms of mercury emitted in order to understand the environmental impact of the emissions and determine acceptable emission levels.

New Hampshire

NEW HAMPSHIRE HAS an area of 9,350 sq. mi. (24,216 sq. km.), with inland water making up 314 sq. mi. (813 sq. km.), and access to territorial water of 68 sq. mi. (176 sq. km.). The White Mountains region in the northern part of New Hampshire has dense forests and deep glacial valleys. The New England Upland in central and southern New Hampshire is hilly and contains many glacial-formed lakes and streams. The Seaboard Lowland covers the southeastern corner of the state and slopes down to sea level. New Hampshire's coastline on the Atlantic is only 13 mi. (21 km.) long, with islands and inlets.

New Hampshire has cool summers and long cold winters, though weather can have extreme variations. New England weather and climate is influenced by latitude (warm, moist air from the south and cold, dry air to the north), coastal orientation (position within the zone of the westerlies), and elevation changes. In winter, these waters remain warm relative to land areas, thereby influencing snow-rain boundaries, which are difficult for forecasters to predict. The highest temperature recorded in the state was 106 degrees F (41 degrees C) on July 4, 1911, and the lowest temperature recorded in the state was minus 47 degrees F (minus 44 degrees C on Mount Washington on January 29, 1934.

Land once used for farming is being returned to forestland. Remaining agricultural production includes dairies, livestock, Christmas trees, apples, and maple sugar products. Most of the commercial forestland is privately owned. Individual holdings are generally small, mostly less than about 80 hectares (about 200 acres). Some of these holdings were formerly unprofitable farmlands. More than two-thirds of the timber consists of softwoods, including pine, spruce, fir, and hemlock. In order to discourage indiscriminate cutting on private land, the state collects no tax on timber until after it is cut.

IMPACT OF CLIMATE CHANGE

New Hampshire is already experiencing the effects of higher temperatures and rising sea levels. During the last decade, 18 ski areas increased snowmaking to ensure good snow conditions. While climate models vary for the northeast on the amount of temperature increase during the 21st century from 5–12 degrees F (2.7–4.2 degrees C) during the winter months, to 3–14 degrees F (1.7–7.8 degrees C) during the summer months. Anticipated rising sea levels (7–14 in., or 17–36 cm., on the low end, and 10–23 in., or 25–58 cm. on the high end), is projected to increase shoreline erosion and wetland loss. Potential risks are more severe under the higher-emissions scenarios, with heat stress in cows decreasing milk production, and a climate no longer suitable for apples. Weeds and pests would proliferate. New Hampshire would lose winter tourism from skiing and snowmobiling. Under the lower-emissions scenario, changes would be less severe.

Among New Hampshire's most serious conservation problems is the destruction of forests by overcutting. This practice eliminates an important source of state revenue, destroys the habitat of many animals, and increases the possibility of erosion and flood damage. For these reasons, the state aids in the preservation of forest areas by encouraging selective forest cutting through special tax provisions. Global climate change may have a positive impact on certain New Hampshire forest areas. Certain trees and forests may flourish due to longer growing seasons, more abundant carbon dioxide (CO_2), and wet summers. White pine and red oak, two very profitable timber species in New Hampshire, could increase in number.

Health risks associated with rising temperatures include a potential increase in certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents and heat-related illnesses. In addition, Portsmouth might expect to issue health advisories during summers to limit outdoor activity.

ADDRESSING HUMAN-INDUCED CONTRIBUTIONS TO CLIMATE CHANGE

Based on energy consumption data from Energy Information Agency released June 1, 2007, New Hampshire's total CO_2 emissions from fossil fuel combustion in million metric tons for 2004 was 21.83, made up of contributions by source from: commercial, 1.81; industrial, 1.14; residential, 3.40; transportation, 7.77; and electric power, 7.71.

New Hampshire's Greenhouse Gas reduction target is to meet 1990 levels of six greenhouse gases by 2010, to be 10 percent below 1990 levels by 2020, and 75 to 85 percent below 2001 levels in the long term. New Hampshire has joined New England and some mid-Atlantic states in the Regional Greenhouse Gas Initiative (RGGI), a mandatory cap-and-trade program. Carbon emissions from power plants will be capped at current levels 2009–15 and they will be incrementally reduced by 10 percent before 2019. New Hampshire joined the Climate Registry, a voluntary national initiative to track, verify and report greenhouse gas emissions, with acceptance of data from state agencies, corporations, and educational institutions beginning in January of 2008.

New Hampshire signed a 2001 compact between New England governors and neighboring Canadian provincial leaders requiring a collective reduction of global warming pollution in the region. In 2002, New Hampshire passed a law to reduce carbon pollution from power plants to their 1990 levels by 2006. The state also has a voluntary greenhouse gas reduction registry. The state's Building Energy Conservation Initiative allows state agencies to contract with a private energy services company to improve energy efficiency in state-owned buildings through retrofits and upgrades. New Hampshire has the potential to meet more than 72 percent of its electricity needs with renewable energy like wind and biomass.

The University of New Hampshire is home to the Climate Change Research Center (CCRC), dedicated to the study of the Earth's atmosphere. The CCRC engages in educational activities ranging from graduate level instruction to informal outreach at science centers. CCRC research focuses on understanding the fundamental properties of the atmosphere and how they have been affected by human activities.

New Jersey

NEW JERSEY IS a densely populated state of almost 9 million on the Atlantic seaboard. It lies between the metropolitan areas of New York City and Philadelphia. It has a long barrier island shoreline exposed to the Atlantic Ocean to the east and is bordered by the Delaware River and Bay to the west and south respectively, the Appalachian Mountains in the northwest, and Hudson River on the northeast. The state has been particularly progressive on state-level greenhouse gas policies and regulations, and is also known as a site of a heavy industry and petrochemical production. It has the largest petroleum containment capacity outside of the Middle East, which is visible along the New Jersey Turnpike.

New Jersey has a long industrial legacy. Tributaries to the Hudson, Passaic, and Hackensack rivers fueled textile industries during the Industrial Revolution. Many large companies were founded in this state. John D. Rockefeller started Standard Oil of New Jersey as a result of the Standard Oil antitrust settlement of 1911. The company later became Exxon and eventually merged with Mobil, formerly Standard Oil of New York. The oil, chemical, and pharmaceutical industries remained the economic lynchpins of the New Jersey economy into the 21st century. The deep ports of Newark, Elizabeth, and Bayonne, and their proximities to dense populations also attracted industries that utilize the extensive transportation infrastructure for moving global commodities. Port Elizabeth is the largest container port in the eastern United States. It was the largest in the world as recently as 1985; today it is the world's fifth largest marine terminal. It moved over $100 billion in goods in 2006. Little of that economic benefit remains in nearby communities, which are some of the poorest urban communities in the New York metropolitan region.

EFFECTS OF CLIMATE CHANGE

The 130 mi. (209 km.) long, densely developed shoreline of New Jersey is particularly vulnerable to significant storm events such as hurricanes and the often more powerful Nor'easters. With rising sea levels, an extensive population will be increasingly vulnerable to these storms in the future. Much of the developed shoreline is built on barrier islands, giant sandbars that occasionally breach into the backside bays during the most intense storms. Although there is a substantial coastal infrastructure of bulkheads and sea walls, much of the valuable coastal real estate, including high-rise casinos and recreational beaches, could be severely damaged in the event of severe storms. In 1962, a Nor'easter, known as the Ash Wednesday Storm, destroyed 45,000 homes. The state is also frequently hit by moderate hurricanes, though they are typically less powerful than those that hit the southern United States.

The federal government heavily subsidizes the protection of the densely developed New Jersey coast. Taxpayers, through the Army Corps of Engineers, pay for shoreline erosion and beach replenishment programs. New Jersey's current plans for beach sand replenishment will cost about $60 million per mile, with a 50-year total of $9 billion. Many property owners also get subsidized insurance through the National Flood Insurance Program. Storms often result in the use of Federal Emergency Management Agency (FEMA) funds to rebuild in the same place, without important property modifications such as sand dunes and other shoreline protection infrastructure. FEMA suggests that a 1 ft. (30 cm.) sea-level rise on the northeast coast could raise flood insurance premiums.

Changes to temperature, sea level, and water regimes in New Jersey could affect its most important and unique ecosystems. Temperature increases and rainfall declines could make the Pine Barrens area on the outer coastal plains and the skylands area of the mountainous northwest more prone to catastrophic fires or biological invasion. This could affect rare and endangered species like the Pine Barrens tree frog. Sea level rise could cause salt water intrusion into freshwater wetlands, significantly affecting marine and avian species. The New Jersey landscape has been shaped by global change in the past, with the devastating unintended introductions of Chestnut Blight and Dutch Elm disease. Some of the most serious invasive species threatening New Jersey ecosystems today are the Asian Long Horn Beetle, Hemlock Woolly Adelgid, Japanese Honeysuckle, and Chinese Bush Clover. Climate change could make New Jersey habitats even more welcoming to these invasive species. The increase in temperatures may be responsible for expanding the habitat for mosquito-borne illnesses such as dengue, West Nile Virus, and malaria into urban areas. With an extensive area paved over and urbanized, New Jersey has many areas that have a blackbody-effect that keeps them warmer at night. Climate change will also likely cause increases in ground-level ozone levels in the congested areas of the state.

A 2007 legislative bill in New Jersey requires that state greenhouse gas emissions be reduced to 1990 levels by 2020, and 80 percent below 2006 levels by 2050. New Jersey is also a participant in the Regional Greenhouse Gas Emission Initiative, a 10-state program that is the first CO_2 cap and trade program in the United States. In addition, leading some of the state universities to adopt groundbreaking greenhouse gas policies, Governor John Corzine has also proposed a Governors' Climate Protection Leadership Council. A large number of New Jersey mayors have signed the U.S. Mayors Climate Protection Agreement. Activists in the state have organized the annual New Jersey Climate March.

New Mexico

NEW MEXICO HAS an area of 121,590 sq. mi. (314,917 sq. km.), with inland water making up 234 sq. mi. (606 sq. km.). New Mexico's average elevation is 5,700 ft. (1,737 m.) above sea level, with a range in elevation from 2,842 ft. (866 m.) above sea level at the Red Bluff Reservoir, to 13,161 ft. (4,011 m.) at Wheeler Peak. New Mexico's topography is varied, including mountains, plateau, basins, and the Great Plains. New Mexico's major river is the Rio Grande, originating in southern Colorado, and flowing southward for through the state (with very low water flow), is used for irrigation. The Continental Divide (the separation mark of the Pacific and Atlantic watersheds) passes north to south through New Mexico. In addition to streams and rivers, small glacial lakes are in the Sangre de Cristo Mountains and several large reservoirs store water for irrigation and recreation.

The climate of New Mexico is generally mild, sunny, and dry. Temperatures vary in the different regions of

Enchanted Mesa: Much of New Mexico consists of desert terrain, however, there are forested plateaus and mountain regions.

the state; the annual average temperatures vary as much as 10 degrees F (minus 12 degrees C) from south to north, with the northern mountains cooler. The highest temperature recorded in the state was 122 degrees F (50 degrees C)on June 27, 1994 and the lowest temperature recorded in the state was minus 50 degrees F (minus 45 degrees C) on February 1, 1951. Most of the state has between 10 and 20 in. (25–51 cm.) of annual rainfall. The mountains also have a higher precipitation. Summer thunderstorms provide the larger portion of annual precipitation. Winter precipitation is in the form of mountain snowfall and rain or snow at lower elevations. Cold air masses from Canada may produce blizzards.

The dry climate does not preclude agriculture; commercial farming is more common along the river valleys for irrigation, and in the driest eastern part of the state, dry farming is common. Crops include corn, hay, sorghum, chili peppers, onions, and wheat. Ranching is important to the economy, and grazing rights are provided on National Forest land. The largest aquifer in the world, the Ogallala Aquifer, lies underground beneath eight states, including New Mexico.

IMPACT OF CLIMATE CHANGE

New Mexico's climate has changed over the centuries. The ancient native peoples began farming the area in approximately 1500 B.C.E. Optimum rainfall brought increased population and arable farmland. A Medieval climate anomaly in the southwest during the 8th and 12th centuries, caused human hardship. In approximately 1250 C.E., the changing weather pattern caused two decades of severe drought and the people moved from places like Chaco Canyon to water sources higher in the Colorado Plateau.

Climate models vary on temperature increase for New Mexico, from 2–7 degrees F (1–4 degrees C) in autumn, from 2–9 degrees F (1–5 degrees C) in summer and winter, and from 1–5 degrees F (0.5–3 degrees C) in spring by the end of the century. Potential risks include decreased summer water supplies. A warmer climate would mean more winter rain and less snowfall in the mountains for snowmelt in the spring to feed New Mexico's streams, the major source of surface water throughout central and southern parts of the state. The levels of reservoirs would drop because of increased evaporation caused by higher temperatures. Water supplies for municipal districts and irrigation in the densely populated Rio Grande Valley, where Albuquerque is located, would become more restricted, increasing reliance on groundwater, although decreasing spring and summer recharge would lower groundwater levels too, impacting the eastern and southeastern areas of the state, which rely on groundwater already.

Hotter, drier summers increase the risk for wildfires as well as droughts, and flooding could be caused by rapid snowmelt in the spring. More severe summer downpours could lead to more frequent flash flooding. Flooding increases the possibility of contamination of water supplies by sediment erosion, and also increases levels of pesticides and fertilizers and runoff from grazing, mining, and urban areas. The yields of some crops like wheat and sorghum would decrease as temperatures rise over the tolerance level for optimal growth. With less water available for irrigation, farming on the whole could decrease as well.

Human health risks include contracting certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents (rodent-borne diseases are prevalent in New Mexico. Increased rodent populations have been associated with El Niño). Warmer temperatures would increase the incidence of heat-related illnesses and lead to higher concentrations of ground-level ozone pollution causing respiratory illnesses (diminished lung function, asthma, and respiratory inflammation).

ADDRESSING HUMAN-INDUCED CONTRIBUTIONS TO CLIMATE CHANGE

Based on energy consumption data from the Energy Information Agency released June 1, 2007, New Mexico's total CO_2 emissions from fossil fuel combustion in million metric tons for 2004 was 58.32, made up of contributions by sector from: commercial, 1.67; industrial, 8.27; residential, 2.31; transportation, 15.64; and electric power, 30.43. New Mexico's Greenhouse Gas reduction target is to lower emissions of greenhouse gases to 2000 levels by 2012. In addition, the legislators approved a state law requiring New Mexico power producers to generate 10 percent of energy from renewable sources by 2011.

By executive order in June 2005, the governor established the New Mexico Climate Change Advisory Group to propose options for reduction of greenhouse gas emissions. The group completed its work and filed a final report in October 2006. The executive order also required reports on possible impacts of climate change on New Mexico and water resources. The governor established the Climate Change Action Council in December 2006 to progress previous work toward implementation. New Mexico holds member status with the Western Regional Climate Action Initiative, in which the partners will set an overall regional goal for reducing greenhouse gas emissions and design a market-based mechanism to help achieve that reduction goal. New Mexico joined the Climate Registry, a voluntary national initiative to track, verify and report greenhouse gas emissions, with acceptance of data from state agencies, corporations and educational institutions beginning in January of 2008.

New Mexico Climate Center

ESTABLISHED DURING THE 1980s, the New Mexico Climate Center is located on the campus of New Mexico State University and is in charge of collecting and disseminating data on the state's weather. The center is the home of the state climatologist, Ted Sammis. It collects its data through electronic data-logger machines, both from its own network of 27 weather stations at its Agricultural Science centers and from station networks from other agencies such as the Bureau of Land Management, the Natural Resource and Conservation Service, and NOAA. In total, the New Mexico Climate Center collects daily climate data from 138 automated climate stations around the state, including irrigation districts and NAPI (Navajo Agricultural Products Industry). These stations monitor air temperature, relative humidity, soil temperature and moisture, precipitation, solar radiation, and wind speed and direction. These data are then disseminated for the benefit of policymakers, administrators and the public. In addition to this electronic collection of data, more than 50 volunteers record their daily local temperature and rainfall across the state and send this information to the National Center for Data Collection. The services of the New Mexico Climate Center can be accessed through the world wide web. The center's web site processes climate data daily and makes it available to the public.

In addition to the state climatologist, the center is staffed by a group of students. The purpose of the center is to assist the state's efforts to understand and respond to natural and human-induced climate processes, including global warming, to cooperate with federal government activities relating to climate studies, and to promote and disseminate a general knowledge of the climatology of the state. Some of the activities carried out at the center are: assessing the impact of climate on the natural environment, agricultural production, land and natural resources, and human health; coordinating studies and schemes to understand more fully natural and human-induced climate changes, and the social and economic implications of climate changes; developing methods and procedures to encourage the participation of interested state agencies and public institutions of higher education in the climate-related programs; and disseminating climate data, information, advice, and assessments to state agencies, local public bodies, and the public.

During its two decades of operation, the State Climate Center has supplied climatic information for the needs of industry, tourism, state agencies, and private individuals. This information has contributed to the economic growth of New Mexico and the bordering regions through applied research and development. The center's web site receives an average of more than 6,000 requests for climate information per day. In addition to these, more than 300 requests are answered by phone and email each year. Besides climate data, the New Mexico Climate Center supplies information on irrigation arrangements for native, landscape, and commercial crops. It provides heat and cooling degree-day calculation, for the construction industry, and economic irrigation software. The center has a variety of teaching material on soil and land use, instrumentation, and irrigation science.

The efficient use of water has been a long-standing interest of the center, given that water is a scarce resource in the state and that droughts are often severe. The New Mexico Climate Center devotes part of its official web site for the New Mexico Drought Task Force with information about current drought status and future climatic conditions. The web site also provides tools to use climate data for determining when to apply pesticides, based on growing degree-day models. Researchers working at the center have developed water production functions (relationships between yield and crop water-use) and crop coefficients (for irrigation scheduling) for many crops. These functions can be used to assist in efficient irrigation management and in making important economic decisions related to water and crop production.

The center has acknowledged that global warming is a stark reality. The state climatologist and his staff have calculated that the temperature in New Mexico was 3.6 degrees F (2 degress C) hotter in the year 2000 than during the 1961–1990 period. Yet, the New Mexico Climate Center has been more cautious in making predictions about local weather. According to State Climatologist Ted Sammis, the global models that look at 50-year scenarios and indicate increased weather chaos are difficult to apply to state weather predictions.

New York

STRETCHING FROM THE Atlantic Ocean to the Great Lakes and the St. Lawrence Valley, New York State presents a wide diversity of climate features. Elevations range from sea level in New York City, to some of the highest peaks on the east coast in the Adirondacks. New York State has a continental humid climate, with the geography causing climate variation. Storms and frontal systems generally move from the west and north, bringing with them masses of cool, dry air. However, storms moving along the Atlantic coast and from the south bring warm, humid air masses. These storms and frontal systems often meet over New York. Average annual mean temperatures range from 40 degrees F (4 degrees C) in the northern Adirondacks, to 55 degrees F (13 degrees C) in the New York City region. Extreme lows can occur in winter months in the Adirondacks and warm conditions generally prevail in the summer months in the New York City area. The highest temperature recorded was 108 degrees F (42 degrees C)in east central New York (Troy) and the coldest temperature recorded was minus 52 degrees F (11 degrees C) in Herkimer County, northwest of Troy.

Precipitation is fairly uniform, without a distinct wet or dry season. Generally, lower precipitation occurs in the winter months in the western Finger Lakes and the eastern Lake Champlain regions (approximately 2.2 in. (6 cm.) per month). The maximum amount of rainfall (approximately 4 in. (10 cm.) per month) falls in the summer in the Hudson Valley. Winter precipitation is usually in the form of snow—especially in the north and west—and snowfall can measure as much as 175 in. (444 cm.) per month in the Adirondacks off of Lake Ontario and off of Lake Erie. The diverse weather patterns support a varied economy that includes agriculture, including grains and corn, grapes, tree fruits, and a dairy industry. The snowfall lends itself to winter recreational endeavors such as skiing, but variable snowfall results in many resorts relying on manmade snow.

EFFECTS OF CLIMATE CHANGE

New York, like the northeast as a whole, is warming. Historical records show that temperature in New York is increasing at a rate of about 0.2 degrees F (0.1 degrees C) per decade, and more recent data suggest even greater warming trends. If these trends, continue, the mean temperature of New York will be more like that of South Carolina by the end of the century. If rates are slowed by reduction of carbon emissions, the temperature will be more like that of Maryland.

Storm tracks of Atlantic storms, including hurricanes, are impacting the coastal regions of New

York, specifically Long Island. While records suggest that about a dozen major storms have hit the Atlantic coast of New York over the last several hundred years, the frequency seems to be increasing. Additionally, many of the areas impacted by such storms in the past were not as developed as they are now. This greatly increases the potential for damage to humans because of both their frequency and of people being put into harm's way, and the danger is not limited to rain storms alone. As there are wider swings in weather, winter storms can likewise impact both coastal and inland regions. Structural failure, incursions of water into transportation and utility systems, and travel are all critical in New York State, and all will be impacted from storms.

Rising mean sea levels are of major concern to the low-lying areas along the coast—most notably Long Island and parts of Manhattan. If current rates of rise continue, much of the lowlands will be under water. The rise of sea level, along with human activity, is already impacting many the salt marshes of Long Island Sound and the Atlantic coast of Long Island. Overall trends of precipitation are down in New York. This has definite impacts on agriculture and recreation. Heat stress has impacted the dairy cow industry and will continue to do so if current trends continue. Grapes are impacted by the change in weather—some varieties do better, others do worse. Skiing, a major recreational industry in New York has been impacted by the reduction of snowfall.

Health is affected by climate change. In New York, increased heat mortality may be expected if trends continue. The longer warm seasons will likely impact insect populations, thereby increasing the risks of mosquito borne diseases such as West Nile Virus (which has already adversely impacted New York). Increased heat can also lead to pollution, increasing an already escalating incidence of asthma and other respiratory problems. Specific events, such as flooding from rising sea levels, can increase mortality and morbidity significantly.

Energy demands go up with extremes of weather and peak load is impacted. Estimates suggest that, in the next decade, given the trend in summer temperature and population, overall demand may double. This will impact an already taxed energy infrastructure, which may not be able to respond. More brown outs or grid failures can be expected throughout the state. While some decrease overall can be expected due to reduced heating, a cooling trend would place the greatest burden on energy delivery systems.

Many of the climate changes are part of global trends impacting the nation as well as New York State. Because of its size and impact on the global economy, New York State has the opportunity to attempt to mitigate climate change where possible, as well as the risk of increased problems from climate change.

New Zealand

NEW ZEALAND IS located in Oceania, southeast of Australia. The islands that make up the nation are mostly mountainous, with a few wide coastal plains. About 80 percent of the population of 4 million lives in urban areas, leaving most of the country free from major human intrusion. It is one of the most beautiful and pristine environments in the world, and its economy, based on tourism, agriculture, and forestry, is largely dependent on the stability of that environment.

As in neighboring Australia, New Zealand is confronting the probability of prolonged droughts in the near future. In the best-case scenario, severe droughts will be twice as frequent by 2080 as they are today, and in some areas, drought could become perpetual even before 2080. Not only will this lead to a decline in agricultural production, it will stress the nation's forests and increase the risk of forest fires. Like any island nation, New Zealand is particularly concerned

Waimangu Valley in Rotorua, New Zealand: New Zealand is one of the most pristine environments in the world.

with the possibilities of sea-level rise. Most of the major urban areas are located on the coasts. Government models indicate a 0.2 meter rise by 2050 and a 0.5 meter rise by 2100, and those figures are now used in planning along the coastline. Losses of structures already built along the coast are probable. Along with general sea level rise is the possibility of higher storm surges as tropical storms grow in intensity.

New Zealand anticipates a few positive outcomes for health, including fewer illnesses during the winter months as average temperatures rise. However, temperature rise also brings the threat of illness and death from heat stroke and vector-borne illnesses. Water contamination is also a possibility in some areas. Warmer temperatures will also increase the need for air conditioning, thus increasing electricity usage. Agriculture will see both benefits and losses from changing climate. While longer growing seasons and increased atmospheric carbon rates are somewhat positive for crops, the increased risk of drought and changing rainfall patterns could lead to significant crop destruction.

New Zealand is working toward sustainability and mitigation on many fronts, both in the public and private sectors. The government is supporting programs to construct energy-efficient housing and retrofit older structures. It also supports the development of more fuel-efficient vehicles, the increased use of biofuels, sustainable land management, healthy forest initiatives, and funding for research into alternative energy. It is also trying to set a good example by making government buildings carbon-neutral and reducing waste.

Nicaragua

NICARAGUA IS BOUNDED on all sides by water: to the east and west lie oceans, and most of the northern and southern borders are large rivers. Although the country has experienced growth in export processing and tourism, Nicaragua remains reliant on agriculture and fishing. The country experiences seasonal climate shifts, with pronounced wet and dry seasons. There is a tendency for flooding in the east and drought in the west. Knowledge about climate change mitigation is poorly developed within the country, in spite of vulnerability to natural disasters due to poverty, low investment in infrastructure, and poor interagency coordination. International nongovernmental organizations provide a large portion of disaster relief.

There has been a recorded increase in temperature of 1.2–1.8 degrees F (0.7–1.0 degrees C) across Central America over the past century. This generates concern over agricultural transition, since warming many increase crop pests and diseases. A drier climate may also increase risk of damage from forest fires. Malaria levels are likely to rise. There has been documentation of annual variation in Nicaragua of dengue/hemorrhagic dengue related to fluctuations in temperature, humidity, solar radiation, and rainfall.

Research suggests that hurricanes and tropical storms originating in the Atlantic Ocean may bring more rain as a result of increasing water temperatures. There is already a loss of more then 1 percent of the gross domestic product (GDP) annually in Nicaragua due to flooding. Regional studies suggest economic losses as a result of natural disasters are eight times greater now, as compared to the 1960s.

Hurricane Mitch struck Nicaragua in 1998. Its impact has been researched as a model for what could occur from extreme weather events. In addition to the loss of 50 percent of GDP, major mudslides on the Las Casitas volcano led to the death of more than 2,000 people. There was also a documented increase in malaria, dengue fever, cholera, and leptospirosis. Conventional farms using chemical intensive monoculture had 60–80 percent more soil erosion, crop damage, and other water-caused losses from the hurricane than farms utilizing conservation practices such as polyculture, crop rotation, water conservation, terracing, and agroforestry.

Biodiversity reduction is a problem across Central America. Nicaragua has lost 50 percent of its forest cover in the last five decades. Research suggests an urgent need to reforest along the floodplains of rivers. Several forest conservation areas receive extensive foreign assistance, but marine reserves remain poorly protected. Mangrove swamps and coral reefs are particularly at risk.

Nicaragua ratified the Convention on Climate Change in 1995 and the Kyoto Protocol in 1999. Geothermal energy production is part of a national plan to combat climate change. New geothermal projects are under construction, with funding from the United Nations's Clean Development Mechanism (CDM). Other CDM projects utilize biodigesters and bagasse cogeneration to transform waste products from sugarcane processing into energy. In addition to rectifying low energy efficiency, Nicaragua needs to improve provision. About 20 percent of annual deforestation comes from fuel wood extraction.

Niger

NIGER IS LOCATED in western Africa, just north of Nigeria. This landlocked country is already one of the hottest and driest places on the planet. It lies within the Sahel region, which has seen increasingly damaging droughts, soil erosion, desertification, deforestation, and overgrazing during the last 30 years. Four-fifths of the terrain is desert, characterized by rolling sand dunes, with the remaining fifth fairly productive savanna. The 13 million residents of Niger are among the world's poorest, with over 60 percent living below the poverty level. Many already face food and water insecurity as a daily fact of life. Climate change is projected to put this already vulnerable people on the brink of collapse.

A study of rainfall patterns for 1965–2000 showed that the climate in Niger has already undergone significant changes, with a steady decrease in both the amount of rain and the number of days of rain per year. This trend is expected to continue in coming decades. The overall decline in precipitation, along with an increase in average temperatures, will strike Nigeriens in their most vulnerable areas: agricultural production and water sources. Modeling indicates declines in vital millet and sorghum crops as early as 2025. The more water that must be diverted from dwindling sources to irrigate crops, the less there is available for humans and livestock. This will naturally lead to conflict over water sources between communities.

Other impacts of climate change in Niger will be deficits in livestock fodder, the drying up and silting of watering holes and ponds, decreased fishing, loss of biodiversity and species extinction, the encroachment of sand dunes into agricultural areas, and increased threat of famine, viral diseases, malaria, and respiratory illness.

Niger is not a major contributor to global carbon emissions, releasing just 1,109,000 metric tons in 1998. About 56 percent of emissions come from liquid fuel sources, with 42 percent from solid fuel sources, wood fires being the primary method of cooking within the country.

Niger's financial resources are limited, and while the government has produced a mitigation plan as part of its participation in the United Nations Framework Convention on Climate Change (UNFCCC), implementation may be difficult. Some options include forming livestock and agricultural cooperatives to increase the efficiency of food distribution and irrigation and encouraging the planting of crops more suited to the Sahel's climate. The government has also indicated a willingness to explore the use of renewable energy sources, including wind and solar power.

Nigeria

NIGERIA, IN WESTERN Africa, has a population of over 144 million. It has an area of 356,669 sq. mi. (923,768 sq. km.). Nigeria is not heavily industrialized; however, it contributes carbon dioxide (CO_2) to the atmosphere through gas flaring and deforestation. These actions have significantly added greenhouse gases to the atmosphere, contributing to global warming, as is apparent in Nigeria's coastal communities that have been threatened by rising sea levels.

Rising sea levels are a prominent consequence of increased surface temperatures, which could cause a submergence of low-lying communities, such as most settlements on Nigeria's Atlantic coastline from Lagos to the Niger Delta. Change in rainfall patterns, sea-level rise, saltwater intrusion, loss of biodiversity, drought, habitat loss, and freshwater depletion and pollution are possible changes Nigeria will face in the near future. In northern Nigeria, recent reports point to increased surface temperatures, which could result in droughts. The release of CO_2 into the atmosphere through uncontrolled gas flaring (especially in the Niger Delta) is capable of exacerbating the fragile climate elements in the country. For instance, the humid, tropical areas of southern Nigeria could witness variation in climate elements (precipitation and temperature), resulting in warming of the region. Increase in rainfall and change in precipitation by 2–3 percent might be expected for the humid zones of Nigeria, and could increase evapotranspiration, leading to droughts.

Nigeria's environmental problems are worsened by excessive cultivation (resulting in loss of soil fertility), deforestation (at a rate of about 2.4 percent), oil spills, the burning of toxic wastes at dump sites, gas flaring, and increasing urban air-pollution due to transportation, use of petrol and diesel generators, and industrial activities. The amount of CO_2 and sulfur IV oxide (SO_2) emissions are growing; Nigeria was listed among 50 nations as one of the world's highest emitters of CO_2 in the early 1990s, totaling about 96.5 million metric tons. Gas flaring has been another major source of anthropogenic emission of greenhouse gases; a report estimated that over 70 percent of the 3.5 billion standard cubic ft. of associated gas produced in 2000 was flared. The World Bank also estimated that, by 2002, flaring in the country had contributed more greenhouse gases to the Earth's atmosphere than all other sources in sub-Saharan Africa combined. These practices continue, and the environmental concerns they create are alarming, leading to extreme weather damage and the risk of further problems such as the increased spread of disease.

Nitrous Oxide

NITROUS OXIDE (N_2O) is a compound of two very abundant elements on Earth, which also compose most of the gases in the Earth's atmosphere—oxygen and nitrogen. It is a colorless gas with a sweetish odor. It is known by the common name of laughing gas. It occurs naturally, and has been implicated as a potentially significant agent in global warming. Joseph Priestly first synthesized it in the 1770s. Dentists and physicians have used it as a mild anesthetic for decades. It was first used in dentistry in 1844, and more commonly after 1860. It is still used in dentistry for minor oral surgery procedures.

Many uses have been found for nitrous oxide. Because it causes people to laugh, it has been used for public and private entertainment, with no lasting physical effects. The psychological effects may last for a few minutes. The physical effects include disorientation and imbalance, vision disturbance, throbbing or pulsating hearing with hallucinations that can be auditory, visual, or both, and a deepening of the voice while the gas is being exhaled. Several dangers associated with breathing nitrous oxide include physical imbalance that can cause injury from falling. If breathed though a bag over the head, death can occur. Frostbite from the rapid expansion of the gas from a compressed state can also occur. It is also used as a propellant in cans of whipped cream, and has other foodservice uses. While not a bactericide, it can act as a bacteriostatic, which prevents the growth of bacteria without leaving an odor. The dairy industry uses it as a foaming agent because it dissolves easily in the fatty cells found in buttery cream.

Deep-sea diving can kill if decompression sickness (the bends) occurs. The cause of decompression sickness is nitrogen in high-pressure environments. Bubbles of nitrogen gas form in the fatty tissue of the body, and if not expelled slowly, can cause terrible pain and death. Nitrous oxide can help prevent the bends in deep-sea divers. Nitrous oxide allows nitrogen in the blood stream to return to the tissues without causing as many bubbles. The sport of car racing uses nitrous oxide as a booster propellant. The compound is injected into the air intake of the car. Nitrous oxide is not flammable, but it does cause more oxygen to enter into the combustion chamber so that a richer and more powerful mixture of fuel is ignited. The firing of the mixture increases the power of the engine. Nitrous oxide is easily obtained and has been abused by some. As a result, many states have attempted to criminalize its abuse.

NITROUS OXIDE AND GLOBAL WARMING

Global warming is believed to be due to the increased use of fossil fuel resources, the production of industrial chemicals, and the use of chemical fertilizers. Among the greenhouse gases that are produced by burning fossil fuels and the use of chemical fertilizers, carbon dioxide is the gas most associated with global warming; however, nitrous oxide is also implicated. It is believed that N_2O is the cause of about 6 percent of current global warming. The amount of nitrous oxide in the atmosphere is of great concern, because a molecule of nitrous oxide can absorb over 300 times the amount of infrared energy absorbed by a carbon dioxide molecule. This means that a much smaller amount of nitrous oxide can contribute immensely more to global warming than carbon dioxide. A small increase in the level of nitrous oxide in the atmosphere can have a major impact upon the global environment.

The amount of nitrous oxide in the Earth's atmosphere is increasing. In the troposphere, it is a long-lived (up to 120 years) inert gas that can be removed by reactions with sunlight. It is removed from the Earth's atmosphere mainly in the stratosphere by photolysis. Nitrous oxide is contributing to global warming because it is increasing in volume. The amount in the atmosphere increased to over 1 percent 1940–2000.

The most important natural sources of nitrous oxide are found in the gaseous emissions of microorganisms and decaying vegetation; rain forests and the oceans naturally emit significant quantities of the gas. If the soil is nearly saturated, it emits nitrous oxide. Different soils emit different amounts of the gas. If the levels were high enough, it would harm crops, but these levels have not been reached. Human sources include nylon, nitric acid production, and adipic acid production. The burning of fossil fuels is another source, but not as significant a source as was first suspected. Probably only one percent of the current levels of nitrous oxide in the Earth's atmosphere are due to burning fossil fuels.

Other sources of nitrous oxide are burning vegetation, gasoline engine exhaust that is reduced with a catalytic converter, lightening activity, and sunspot activity. Regardless of the source, the current trend is for nitrous oxide to continue increasing. With its disproportionate contribution to global warming, it has a very negative consequences. Modern chemical fertilizers are another source of nitrous oxide. Most of them use some kind of nitrate compound(s) to feed plants. Agricultural usage has been growing as the world's population has rapidly increased its demand for food.

Nongovernmental Organizations (NGOs)

NONGOVERNMENTAL ORGANIZATIONS (NGOS), while a comparatively modern phenomenon, have existed in the form of charitable organizations or political associations since the 18th century. During the 18th and 19th centuries, many people formed specific, community-based organizations, designed to meet specific community needs, or to advance particular policies. The issues targeted by these groups were broad in scope and included women's rights, the status of the poor, local government reform issues, alcoholism, and, later, in the 18th century, trade union issues. Many of these groups converged to work together for a common goal. A good example is the anti-slavery movement, founded in England in the late 18th century, which galvanized the establishment of many groups, that worked together to develop the World Anti-Slavery Convention (1840). Other examples include the World Alliance of Young Men's Christian Associations (YMCAs), founded in 1855, and the International Committee for the Red Cross, founded in 1863.

The term was not officially coined until 1945, when the United Nation's Economic and Social Council (ECOSOC) tried to differentiate its relationship with and participation rights for, intergovernmental specialized agencies and international private organizations. Ultimately, ECOSOC decided under Article 71, Chapter 10, resolution 288 (X) of the UN Charter that an international NGO (INGO) was "any international organisation that is not founded by an international treaty." The UN also determined that NGOs should be given suitable arrangements to be consulted on key issues. According to the Organisation for Economic Co-operation and Development (OECD), NGOs also include "profit making organizations, foundations, educational institutions, churches and other religious groups and missions, medical organizations and hospitals, unions and professional organizations, cooperatives and cultural groups as well as voluntary agencies." Colloquial terminology that identifies different types of NGOs includes the terms INGO, International NGO; BINGO, Business NGO; RINGO, Religious NGO; QANGO, Quasi NGO, and ENGO, Environment NGO.

The status of NGOs was confirmed in the three conventions arising from the Rio Summit in 1992, which defined the nature of NGOs as "major groups" and as any organization that subscribes to the conventions' objectives. These major groups include indigenous people, groups representing women, youth, workers, and farmers, local governments, the scientific community, business and industry, grassroots and religious organizations, trade unions, and other NGOs (international, national and local). All three conventions call for active partnerships with NGOs to further implementation of the articles of the convention.

There are thousands of active NGOs operating at local to international scales. According to one estimate, some 25,000 organizations qualify as INGOs (with programs and affiliates in a number of countries), up from less than 400 a century ago. Amnesty International, for example, has more than a million members, affiliates or networks in over 90 countries and territories, and employs over 300 staff in its London office alone. The International Freedom of Expression eXchange (IFEX), which was founded in 1992, is a global network of more than 60 NGOs that promote and defend the right to freedon of expression. According to the 2002 UNDP Human Development Report, nearly one-fifth of the world's 37,000 NGOs were formed in the 1990s. A 1995 UN study on global governance reports that there are nearly 29,000 INGOs. This report also found that the United States has an estimated 2 million NGOs, Russia has

65,000 NGOs, and in countries such as Kenya, up to 240 NGOs come into existence every year.

NGOs have wide scope and appeal. RNGOs include the World Council of Churches, Caritas International, the World Jewish Congress, and the International Muslim Union, while examples of political NGOs include the Inter-parliamentary Union or the work of the Socialist International. Even in the cultural arena, NGOs play an active role, as the International Pen Club and the International Confederation of Authors and Composers highlight. Finally, the activities of Amnesty International in the human rights field as well as those of Greenpeace in the field of environmental protection are well known. Many NGOs such as the World Wildlife Fund (WWF) and Friends of the Earth investigate issues that affect human and environmental welfare, and often the nexus between the two.

NGOs are constituted and operate in diverse ways. Structurally, an NGO can be a global hierarchical organization, single- or multi-issue based, grassroots, or a formally-accredited body. While there are many active international organizations such as the Red Cross, or CARE, most NGOs operate within a single country and frequently function only within a local setting. Some NGOs, such as legal assistance groups, are service-based. Many are essentially neighborhood groups established to promote local issues, such as community improvement, or street safety.

ADVOCACY AND OPERATIONAL NGOS

The World Bank differentiates between operational and advocacy NGOs, where an operational NGO focuses on the design and implementation of development-related projects, such as service delivery, and an advocacy NGO defends or promotes a specific cause.

A good example of an operational NGO is that of the work of the International Medicine Corps (IMC) in Afghanistan. In this case, the IMC instituted a vaccination campaign against measles, a disease that was identified by the World Health Organisation (WHO), to be the leading cause of half of vaccine-preventable diseases in Afghanistan. IMC first trained 170 Afghani nationals in how to vaccinate children and then led a 15-day vaccination campaign, reaching 95 percent of children between 6 and 12 months of age in the capital of Kabul. Similarly, the Green Trust, founded in 1990 as a subsidiary of WWF South Africa, oversees on-the-ground conservation projects. Projects that the trust typically coordinates include species recovery and protection, such as translocation programs for black rhino, advancing indigenous knowledge, such as the Kruger National Park and Traditional Healers Partnership Project; support for subsistence and sustainable fisheries such as the Sustainable Mussel Harvesting by subsistence gatherers along the Northern Natal Coast; development of subsistence Gill Net fisheries in Lake St Lucia; and revegetation and rehabilitation projects, such as the Agulhas Plain Bio-diversity Conservation Project, and the Greening the Cape Flats Program.

Many advocacy NGOs are political or principles based, and campaign actively to achieve broad ideals within the human rights, social justice, and environmental movements. For example, the America's Development Foundation (ADF) works specifically to provide NGOs with advocacy training and technical assistance designed to increase citizen participation in democratic processes. In Croatia, as part of a campaign to return and reintegrate populations, ADF supported Croatian NGOs advocating for democracy and human rights. This support resulted in 100 NGOs forming a coalition that lobbied for change in the Association's Law, the formation of an NGO coalition focusing on the 2000 Croatian Presidential elections, and development of NGO advocacy campaigns aimed to achieve changes in Croatian public policy relating to refugee rights and return issues.

Many NGOs have a primary educational and research focus. For example, Earthwatch promotes community involvement and, therefore, awareness of environmental issues by organizing study and field research trips. In Australia, the Marine and Coastal Community Network, is a nongovernmental project that builds community, industry, and government support for the conservation of marine biodiversity and ecological processes, and the ecologically-sustainable use of marine and coastal environments. Other examples include California's Deadalus Alliance for Environmental Education, the Texas Center for Policy Studies, Santa Fe's North American Institute, and Tijuana's ECO-SOL (Educación y Cultura Ecológica) and Proyecto Fronterizo de Educación Ambiental).

THE DIFFERENCE BETWEEN NGOS AND NOT-FOR-PROFIT AGENCIES

Despite their diversity, it is important to distinguish between NGOs and not-for-profit agencies. Unlike

NGOs which tend to emerge specifically to address certain issues, offer specific services, or advance a cause, nonprofit groups may also include other organizations, such as museums, universities, and hospitals, service-based organizations that are not necessarily independent of government, or campaigning for a cause. An NGO should also not be mistaken for a social movement per se, despite the fact that it may perform an important functional role within such movements.

The term NGO also implies independence from government, which often enables NGOs to promote, or expose activities and events in ways the government cannot. NGOs, then, need to be resourced effectively. For instance, the budget of the American Association of Retired persons (AARP) in 1999, was over $540 million, and, in 2003, Human Rights Watch spent and received $21.7 million. As such, many NGOs rely heavily on membership funds, donations, fundraising, grants, and sponsorships to resource their activities. To some NGOs, it is important to maintain financial independence from government at all times. Greenpeace does not accept donations from governments or corporations, but relies on contributions from individual supporters and foundation grants. Nonetheless, many NGOs depend in part on government funding. For example, the British Government and the European Union (EU) donated a quarter of Oxfam's budget ($162 million) for famine relief in 1998. Medecins Sans Frontieres (MSF) operates with almost 50 percent of its budget coming from government sources.

NGOs also use a wide range of operational mechanisms to achieve their goals. For example, some NGOs will operate independently, while others will form alliances for mutual gain. While convention often constructs NGO activity as occurring in the form of picketing, protests, and demonstrations, many NGOs also focus on extension, education, or diplomatic work to achieve their aspirations. Many NGOs use the media to highlight and progress their campaign objectives. In many cases, an NGO will use a combination of these methods, when and as appropriate to meet their goals. NGO groups are also active on committees, meetings and in undertaking detailed studies that help inform and promote policy debate in different areas.

For example, in Australia, The Wilderness Society (TWS), a community-based environmental advocacy organization, uses many methods to campaign for the protection, promotion, and restoration of wilderness and natural processes across Australia. These include the use of Wilderness Action Groups, volunteering, policy development, political advocacy, committee work, election campaign work, letter-writing, postcard campaigns, protests and actions, and media work. Some NGOs, such as Greenpeace, employ spectacular and unilateral actions to get their message across. A good example is Greenpeace's call for a boycott of the Shell Oil Company, in order to pressure the company to halt its proposed dumping of an oil platform into the North Sea.

Many NGOs are important employers; in 1995, CONCERN worldwide, which is an international NGO campaigning against poverty, employed 174 expatriates and over 5,000 national staff across 10 developing countries in Africa, Asia, and Haiti. NGOs are also powerful players in the international policy arena. The UNCED (UN Conference on Environment and Development) meeting in Rio de Janeiro, Brazil (1992) is a good case in point. Over 22,000 representatives from over 9,000 NGOs of the developed north and the less-developed south gathered at this Earth Summit and in the parallel global forum as major contributors.

NONGOVERNMENTAL ORGANIZATIONS AS LOBBYING FORCES

The NGO movement has also emerged as a powerful lobbying force that can claim many achievements. For example, the NGO-led International Campaign to Ban Landmines (ICBL), first initiated in 1992, laid the groundwork for the UN 1997 International Mine Ban Treaty. In the United States alone, over 500 NGOs participated in the campaign, designed to ensure a global ban on antipersonnel landmines. This campaign illustrates how NGOs can affect international law, and utilize their access to policymakers and ability to leverage resources to good effect. Over 140 countries throughout the world have since ratified the treaty.

Bayne argues that the presence of NGOs were "particularly effective in hardening the EU's position on genetically modified food" and that NGOs had a major influence on the World Trade Organization (WTO) meeting in Seattle, by affecting the negotiating positions of governments. The formation of the Kyoto Protocol on Climate Change (1997) is often credited to the pressure brought to bear on governments by environmental NGOs. Many argue that NGOs have been very successful in ensuring that policy debate is now framed in environmental terms, and are particularly credited for changing the status of environmental issues, from being the domain of a politicized few, to that of the general interest of civil society.

NGOs often work collaboratively to achieve their goals. In Australia, a major conservation campaign effort from a coalition of environmental NGOs, including the Australian Marine Conservation Society (AMCS), the Australian Conservation Foundation (ACF), Cairns and Far North Environment Centre (CAFNEC), and the World Wildlife Fund for Nature (WWF), was a major force in the re-zoning of the Great Barrier Reef World Heritage Area. NGO lobbying helped ensure that the Australian Government rezoned the Great Barrier Reef World Heritage Area to protect 33 percent of the Great Barrier Reef Marine Park (GBRMP) in a network of no-take sea sanctuaries, or green zones. This was a major achievement, as previously, only 4.5 percent of the GBRMP was fully protected from fishing.

In the Americas, an extensive NGO campaign, the environmental right-to-know (RTK) movement has been mounted to ensure that Mexico's Pollution Release and Transfer Register (PRTR) is consistent with those in the United States and Canada. The only consistent lobbying for the PRTR in Mexico has been from the NGO sector, which, supported by funding from the UN Institute for Training and Research (UNITAR) and elsewhere, has undertaken a wide range of activities to further their goals. These included the development of a website, operation of a listserv, the conduct of conferences and workshops, meeting with United States and Canadian counterparts, providing training to corporate executives on inventories, and expanding public outreach through community organizing, as well as through media events. In response to these campaigns, the Mexican government, in 2001, reformed the environmental law to call for the mandatory public register. In this instance, Mexican NGOs operated on the basis of collaboration rather than confrontation, and, today, are seeking alliances with promoters of Mexico's new freedom-of-information act, as part of a broader campaign, in conjunction with Latin America, to further their aspirations.

Some NGOs are developing partnerships with industry, as with the Marine Stewardship Council initiative, which brings together the international NGO, World Wide Fund for Nature (WWF), and the multinational company, Unilever, which is one of the world's biggest buyers of frozen fish. Together, these groups have worked to address global issues of over-fishing, and have developed an eco-certification scheme for major fisheries. Over 40 fisheries are part of the MSC program, which constitutes about 3 million tons of seafood. A total of 14 of these fisheries, such as the Pacific Cod fishery, are now certified by the MSC as having attained a sustainable eco-standard.

NGOs, then, have emerged as significant actors in domestic and international societies. They have done so in both institutionalized and independent ways. In the human rights and environmental field, NGOs have served as agents of change and forces for the public good for the protection of human and environmental welfare. Amnesty International and WWF serve as good examples of human rights and environmental protection NGOs, respectively. While they are international NGOs, they operate by working locally to achieve specific goals in specific regions.

EXAMPLES OF IMPORTANT NGOS

The WWF has been campaigning on environmental issues for over 40 years. It has almost 5 million supporters across five continents, and is active in over 90 countries. Since 1985, this support has enabled it to invest over $1,165 million in more than 11,000 projects in 130 countries. The organization works in three interdependent areas: the preservation of biological diversity, the promotion of sustainable use of resources, and the reduction of wasteful consumption and pollution.

Conversely, Amnesty International is a worldwide NGO focusing on human rights campaigns. Amnesty International conducts its business within its vision of a world "in which every person enjoys all of the human rights enshrined in the Universal Declaration of Human Rights and other international human rights standards." The notion of independence is strongly articulated by Amnesty, which asserts that it is "independent of any government, political ideology, economic interest or religion. It does not support or oppose any government or political system, nor does it support or oppose the views of the victims whose rights it seeks to protect. It is concerned solely with the impartial protection of human rights." Amnesty International has more than 1.8 million members, supporters, and subscribers in over 150 countries and territories across the world. While it is an international NGO, Amnesty operates through national and local volunteer groups who also raise funds for the organization, while an International Council comprised of national representatives takes major policy decisions. Amnesty International runs a wide range of human rights campaigns, including: women's rights, anti-torture, economic globalization and human rights, refugee, and child soldier campaigns. Amnesty's work often achieves results. For example, since Amnesty started highlighting campaigning on specific cases of Guantánamo detainees, 15 of them have been released from U.S. detention.

Friends of The Earth (FoE) is an example of a NGO that works toward both human rights and social justice and environmental issues, recognizing that the two are intertwined and need to be addressed together. FoE operates as a federation of autonomous environmental organizations from all over the world, and has a membership of 1.5 million in 70 countries across the world. FoE members and local groups campaign on urgent environmental and social issues, while advocating a societal shift toward sustainable societies. While FoE campaigns on many issues, it is currently focusing on climate change, which it identifies as the biggest environmental threat to the planet. Campaign foci have included: demanding strong national emissions reductions targets, the initiation of lawsuits against major polluters, such as oil corporations, challenging a number of big oil projects around the world projected to accelerate climate change, and joining forces with climate-affected communities to facilitate a global movement that will redress social and economic equity issues between and within countries.

CRITICISMS OF NGOS

The NGO movement, however, is not without its critics. Many question the accountability of NGOs. For example, the work undertaken by World Vision, in coordinating the relief effort resulting from the Tsunami in South East Asia in 2005, has sustained attacks that the donated monies, millions of dollars in this case, were not reaching the intended victims. Many NGOs working in developing countries are partly funded by their own governments, and have been criticized as being a front for foreign government policy. Critics argue that this makes NGOs accountable to their funders, not the people they work with. This division has often been characterized within a debate about northern (Western) vs. southern (developing world) NGOs.

For example, many African governments see the establishment of NGOs from Western countries as Trojan Horses, designed to promote neo-colonialist agendas. Many developing countries also resent the fact that international NGOs will come into their own countries and establish programs, rather than funding local NGO groups to undertake the same work. As such, the arrival of NGOs can be perceived to actually deny local individuals, councils, and industries of employment, and other opportunities that now flow to and from the foreign NGO, while creating upheaval in local power relations in culturally inappropriate ways. Some countries such as Zimbabwe, Eritrea, and the Sudan have gone so far as to pass laws that effectively limit the operations of foreign-funded NGOs within their borders.

In some cases, NGO focus has been accused of being too narrow, ignoring the effects of their activities on other areas. For example, environmental NGO work can focus on biodiversity imperatives at the expense of cultural heritage or social justice needs. In Australia, the biodiversity work of environmental NGOs has occasionally been critiqued as opposing cultural heritage priorities, and constituting another form of indigenous dispossession. The dependence on donors of many NGOs also lays them open to criticisms that they are not independent, and, thus, may be inappropriately partisan in their approach. For example, CARE International came under attack for not acting to oppose the war in Iraq, with critics claiming this was due to CARE's dependence on U.S. and other funding. Oxfam has been accused of diluting its campaign against poverty in Africa as a result of being too close to the British government.

Finally, NGO effectiveness is often questioned. Again, this is an issue of accountability with which NGOs grapple. Thomas Carroll addresses this by defining an industry standard for the evaluation of NGO performance. These standards include: development services (measured by service delivery and poverty reach), participation and empowerment (measured by responsiveness and accountability), and wider impact (measured by innovation and impact on policy). Michael Edwards and David Hulme (1996) also outline some dimensions for determining the effectiveness of NGOs, including poverty reach, cost effectiveness, sustainability, participation, flexibility, innovation, and democratization.

While NGOs rarely have few formal powers within international or local decision-making structures, they have successfully advanced many human rights, and environmental agendas. These have included the promotion and development of core environmental agreements and policies; strengthening the rights of women, children, and the disabled; advancing indigenous rights and issues; establishing programs to address health, education, and poverty, and significant measures in the area of disarmament and peace negotiations.

North Atlantic Oscillation

THE NORTH ATLANTIC Oscillation (NAO) is quasi-periodic shifts in the relative strength of the quasi-permanent centers of high atmospheric pressure over the Azores and low atmospheric pressure between Greenland and Iceland (the Azores High and Iceland Low). It is a major large-scale mode of the atmospheric circulation over the extratropical ocean in the Northern Hemisphere. The NAO intensity is at a maximum in winter. It governs the large-scale variability of hydrometeorological fields over the North Atlantic, North America, and northern Europe, as became clear after a pioneer paper published by Sir Walker and co-author in 1932. Recently, the NAO has been set in a broader spatial context of hemispheric climatic variations, both at the surface and aloft as follows, for instance, from generalized publications of John Marshal, et al., and Alexander Polonsky, et al.

As a measure of NAO, a special index is often used. This index is the normalized (by standard deviation) difference between sea-level pressure (SLP) in the Azores High and Iceland Low. Difference of absolute values of SLP between Azores High and Iceland Low is a similar measure of NAO. It is sometimes called the Rossby index (in memory of famous meteorologist). The annual mean value of SLP in the Azores High 1890–1990 was about 1024 hPa, while in the Iceland Low it was about 1006 hPa. So, the yearly difference of SLP in the Azores High and the Iceland Low is about 18 hPa. Amplitude of annual harmonic of the Rossby index is about 5 hPa. The amplitude of the semi-annual harmonic is about half the annual one.

The Rossby index value is calculated as the SLP difference between meteorological stations situated in the vicinity of the Azores High and the Iceland Low (for example, Lisbon, Portugal, and Reykjavik, Iceland) is smaller by a few hPa in comparison with the value calculated as difference in centers of atmospheric action defined as positive and negative extremes of SLP in the subtropical and subpolar North Atlantic region. It is as a result of the temporal and space migration of atmospheric centers of action. The study of displacement of the centers of Azores High and Iceland Low using approximately 100-year data sets provided by Hunter Machel et al. and Alexander Polonsky et al. has shown that just the space state of these centers during different NAO phases plays the important role in generating of European climatic anomalies.

The NAO index (NAOI) has two relatively stable states, positive and negative. They are due to high and low NAO phases. The positive NAO phase is characterized by NAOI values exceeding the mean of the NAOI by the standard deviation or more. The negative phase is characterized by the opposite conditions. Long-term series of the NAO index show that it varies at all timescales, from days and weeks, to decades and longer. Typical scales of NAO variations that influence strongly the European climate are the interannual-to-decadal. Spectral and wavelet analyses of fluctuations of the NAO and Rossby indices for more then 100 yeas between the late-19th and early-21st centuries reveals dominant significant peak at the periods of approximately six to nine years. The same scales of variability are typical for different hydrometeorological fields over most of Europe. NAO dominates in winter, when a significant portion of North Atlantic and European climate variability is due just to NAO.

CLIMATE CHANGES ASSOCIATED WITH THE NORTH ATLANTIC OSCILLATION

Variations of zonal circulation intensity over the North Atlantic and displacement of centers of atmospheric action lead to significant climate changes over Europe. The pressure gradient between the Azores High and the Icelandic Low determines the strength of the mid-latitude westerly and, hence, the transport of relatively warm and humid air from the North Atlantic to Europe. During the mid-1990s James Hurrell and others showed that, on the interannual-to-decadal scale, the NAO intensification (or positive phase of NAO) is accompanied by displacement of the Azores High and Iceland Low to the north-northeast. At the same time, the zonal atmospheric circulation over the North Atlantic and Europe, and zonal winds in the low troposphere within the band restricted by 50 and 60 degrees N are strengthened. This accompanies displacement of pathways of most North Atlantic cyclones to northern Europe and associated increases in air temperature and precipitation there, while the anticyclonic hydrometeorological conditions prevail over central, southern Europe, and the Mediterranean region. The reverse tendency is observed during negative NAO phases, when the Azores High and Iceland Low shift to the south-southwest, and the westerly weakens. It is accompanied by more frequent cyclonic conditions over European regions close to the Mediterranean Sea and Middle East, while more frequent anticyclones occur over northern Europe.

Climate change is accompanied by a tendency of NAO strength and reduction of distance along latitude between the Azores High and Iceland Low in the 20th century. This and superimposed multidecadal North Atlantic variability lead to much more pronounced impacts of NAO on the European climate after approximately 1960. Some ideas about the NAO focus on the North Atlantic basin itself, invoking, for example, stochastic atmospheric forcing of the ocean, mixed, wind-driven, and thermohaline advection, and fully -oupled ocean–atmosphere modes in the North Atlantic region. It has also been suggested that the NAO may be teleconnected to the tropical Atlantic, as well as a local manifestation of a hemisphere-wide oscillation centered over the Arctic. At the same time, as shown by Gidon Eshel, NAO may be generated by processes in the North Pacific coupled system, which impacts the North Atlantic through the atmospheric bridge.

North Carolina

NORTH CAROLINA HAS an area of 53,819 sq. mi. (139,390 sq. km.), with inland water making up 3,960 sq. mi. (10,256 sq. km.), and territorial water 1,148 sq. mi. (2,973 sq. km.). North Carolina's average elevation is 700 ft. (213 m.) above sea level, with a range in elevation from sea level on the Atlantic Ocean, to 6,684 ft. (2,037 km.)at Mount Mitchell. North Carolina's topography separates the state into three regions: the Atlantic Coastal Plain (making up almost half of the state, where it is flat and slopes to sea level), the Piedmont (making up the other half of the state, inland from the coastal plain, rolling to hilly), extending to the mountain region (a very tiny area on the western border, part of the Appalachian Mountains). The shoreline has numerous bays and estuaries. The sandbars of Cape Hatteras, Cape Lookout, and Cape Fear extend far out into the Atlantic Ocean. Offshore are the barrier islands. The outermost barrier islands are called the Outer Banks, enclosing Pamlico Sound. Rivers and streams east of the Blue Ridge Mountains drain east toward the Atlantic. Those west of the Blue Ridge Mountains drain toward the Mississippi River. North Carolina has many natural lakes and swamps.

North Carolina has a humid subtropical climate with few temperature extremes and precipitation in all seasons. January temperatures average in the 40s to 50s degrees F (4–10 degrees C), cooler (mid- to high-30 degrees F, or 2–3 degrees C) in the mountains. Summers are hot (with daytime temperatures at lower elevations rising into the low 100s degrees F (about 40 degrees C), and the mountain areas staying cooler. The highest temperature recorded in the state was 110 degrees F (43 degrees C) on August 21, 1983 and the lowest temperature recorded in the state was minus 34 degrees F (1.1 degrees C) on January 21, 1965. The annual precipitation is fairly distributed over the state, with an average of 40–50 in. (102–127 cm.), though the mountains receive much more up to 80 in. (203 cm.) from air currents from the Gulf of Mexico. Rainfall is highest during the summer; autumn can be rainy along the coast. Winter snowfall is more prevalent in the mountains, though some can fall on the Atlantic Coastal Plain and the Piedmont.

North Carolina farmers produce a wide range of products (tobacco, soybeans, cotton, corn, poultry, hogs, and wheat). North Carolina takes advantage of its coastline for commercial fishing. Forests cover over half of North Carolina's land, lumber is produced in all areas of the state, and tree growth is rapid in the mild, moist climate. The state is known for furniture manufacturing, tobacco products, textiles, chemicals, industrial machinery, and electrical equipment. Fossil-fuel (mostly coal) burning steam plants, nuclear power plants, and hydroelectric power plants produce electricity.

IMPACT OF CLIMATE CHANGE

North Carolina is already experiencing the effects of rising sea levels (Long Bay raised 2 in. (51 cm.) in the last century) and eroding coastlines. In 1999, the Cape Hatteras Lighthouse was moved inland 2,900 ft. (884 m.) to prevent its collapse into the Atlantic. Rising temperatures and reduced rainfall 1999–2002 caused a severe drought. Climate models vary on temperature increases for North Carolina, from 1–5 degrees F (0.5–2.7 degrees C) in all seasons (less change in winter and summer, and more change in autumn and spring) by the end of the century. Potential risks include anticipated rising sea levels of an additional 12 in. or 31 cm., (causing loss of coastal wetlands, beach erosion, saltwater contamination of drinking water, and damage/decreasing stability of low-lying property and infrastructure) along with population displacement.

North Carolina's shoreline is especially susceptible to rising sea levels and tidal changes. Coastal marsh area could expand into low-lying areas and current coastal wetlands could disappear. North Carolina experiences frequent hurricane activity and landfall, and higher sea levels would have the potential to cause more damage with the storm surge. Higher temperatures could cause an increase in frequency and intensity of summer thunderstorms, causing flash flooding, decreased water supplies, changes in agriculture (cotton yield unaffected, rising corn and hay yields, and lower yields of wheat). While the forests may not change much, the types of trees growing in the forests could change with loss of trees unsuited to higher temperatures.

Human health risks include contracting certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents. Warmer temperatures would increase the incidence of heat-related illnesses and lead to higher concentrations of ground-level ozone pollution, causing respiratory illnesses (diminished lung function, asthma, and respiratory inflammation).

ADDRESSING HUMAN-INDUCED CONTRIBUTIONS TO CLIMATE CHANGE

Based on energy consumption data from the Energy Information Agency released June 1, 2007, North Carolina's total carbon dioxide emissions from fossil fuel combustion in million metric tons for 2004 were 150.16, made up of contributions by source from: commercial, 4.99; industrial, 16.49; residential, 7.31; transportation, 51.99; and electric power, 69.38. The Renewable Energy and Energy Efficiency Portfolio Standard became law on August 20, 2007, creating a target for electric public utilities to supply 12.5 percent of electricity from renewable energy or energy efficiency measures by 2021, and electric membership corporations and municipalities that sell electric power in the state to supply 10 percent of electricity from renewable sources by 2018.

North Carolina passed a bill in 2005 to appoint a commission to explore issues related to climate change. North Carolina established the Global Warming Commission, with members representing policymakers and stakeholders, to evaluate options for dealing with the impact of global warming and mitigation of greenhouse gas emissions. North Carolina joined the Climate Registry, a voluntary national initiative to track, verify, and report greenhouse gas emissions, with acceptance of data from state agencies, corporations and educational institutions beginning in January of 2008. Incentive programs to increase energy efficiency include the Energy Improvement Loan Program, low interest loans for individuals and organizations to make energy efficient improvements and develop renewable energy systems including biomass, the use of methane production from agricultural waste to generate electricity.

North Dakota

OVER THE LAST century, North Dakota has seen an average rise in temperatures of approximately 3 degrees F (1.6 degrees C), with some areas experiencing average increases of 5.5 degrees F (3 degrees C). Correlatively, during this time most of North Dakota has experienced a decrease in annual precipitation of 10 percent. While regional climate change forecast models are far from conclusive, it is estimated that North Dakota will prove highly susceptible to climate change through 2100, with average temperatures continuing to increase approximately 3–5 degrees F (1.6–2.7 degrees C). Conversely, future precipitation is expected to increase by 5–10 percent during the spring and summer months and 15–25 percent during the fall and winter, respectively.

The combination of rising temperatures and winter precipitation amounts therefore trends toward earlier and more dramatic spring snowmelts and higher stream-flow conditions in winter and spring, with an expected increase in potentially significant flood events such as the 1997 Red River flood of Grand Forks that destroyed nearly 90 percent of the city and caused over $1 billion in damage. Meanwhile, without large increases of precipitation, warmer summers and increased evaporation will lead to lower groundwater levels. This could have a variety of effects on both society and wildlife, causing lower water-quality and quantity levels and an increased need for irrigation practices, while ecologically threatening North Dakota's Prairie Pothole Region of wetlands, the key breeding home of over half of all U.S. waterfowl. A further concern is that such climate changes could increase the incidence of insects such as ticks and mosquitoes, leading to a rise in diseases such as Lyme disease, West Nile Virus, and malaria.

While North Dakota is one of the least populated states in the United States, ranking 47th out of 50, it produces enough greenhouse gas emissions to rank as a world-class polluter. This is largely in the form of methane from livestock production (a $1 billion industry comprising one-third of the state's agricultural sector), an ongoing net loss of carbon sequestered in soils (estimated at a near 20 percent loss over the last 150 years), and a dramatic increase in carbon dioxide emissions from coal production over the last few decades (now over 30 million short tons per year, up from fewer than five million tons in 1970). The state belongs to voluntary climate change initiatives such as Powering the Plains, developed by the Great Plains Institute, and the Western Governors' Association Clean and Diversified Energy Initiative. However, North Dakota has not yet committed to a strong mandatory policy for achieving suitable greenhouse gas emissions reduction.

Alternative energy sources such as solar and wind power could make valuable future contributions to North Dakota's economy and sustainability profile. North Dakota is believed to be the state with the largest overall capacity for wind power, and it has been estimated that, if wind turbines were maximally deployed, North Dakota could not only fully supply its own power needs, but it could generate upwards of 36 percent of the electricity currently required by the entire nation. However, wind energy has notoriously threatened birds. The state's 318 avian species provide not only important economic value through tourist bird watching, but occupy essential agro-ecological niches as plant pollinators, seed dispersers, and pest predators.

Norway

THE POPULATION OF Norway is less than 5 million. Norway emits only 0.2 percent of the world's greenhouse gases. However, greenhouse gas emissions increased approximately 10 percent 1990–2004. According to modeling scenarios, Norway will experience a 1.2 percent increase in yearly temperature degrees C compared to 1980–2000. Northern Norway will experience the highest yearly increase compared to other regions of the country. Norway has ratified the Kyoto Protocol and committed to stabilizing emissions at 1 percent above the 1990 emission level. Without new measures, emissions are expected to increase to 22 percent above the Kyoto commitment 1990–2010.

In the early 1990s, Norway began introducing policies to control greenhouse gas emissions. One of the first measures was a tax on carbon dioxide emissions introduced in 1991. Greenhouse gas emissions are also controlled through a license system under the Pollution Control Act, taxes to reduce methane emissions from landfills, and a system for emissions trading. From early 2005, an emissions trading system was introduced for 2005–07 (covering about 10–15 percent of Norway's greenhouse gas emissions). This is similar to the European Union (EU) emissions trading system, and includes carbon dioxide emissions from industries not subject to the emissions tax. Norway has a comprehensive policy for energy efficiency, focusing on the increased use of renewable resources and supports research and development into carbon capture and storage in North Sea geological structures, hydrogen technology, and wind power. Established in 2005, the Norwegian Commission on Low Emissions has committed to reducing emissions to two-thirds of 1990 levels by 2050 and has recommended the adoption of tax incentives for low-emission cars, electrifying oil fields with hydropower, and banning the disposal of organic waste in landfills.

Global warming will affect Norway's natural resources in diverse ways. Higher temperatures may result in the increased growth of fish, as well as more parasites and algal problems. While climate change will negatively affect cod (the most valuable catch in Norway), higher temperatures may have favorable effects for other species, including herring (the second most economically significant fish), and an increased growth rate of farmed fish. Warmer temperatures may result in the availability of more productive forestland, based on an anticipated higher tree line elevation and the expansion of the forest in northerly and westerly directions. Increased carbon dioxide concentrations and higher temperatures will likely result in an extended growing season, allowing harvesting twice a year, and increased plant productivity. An increased use of pesticides and herbicides and discharge of nitrogen would be expected due to erosion and loss of nutrients through runoff, and because higher temperatures speed up soil processes.

Nuclear Power

PRESIDENT GEORGE W. Bush, in a June 2005 speech delivered to a group of nuclear power plant workers intoned, "The 103 nuclear power plants in America produce twenty percent of the nation's electricity without producing a single pound of air pollution or greenhouse gases." Experts in the nuclear energy field, both for and against nuclear energy, find this statement lacking credibility. Nuclear energy critics cite the significant amount of greenhouse gases produced by the nuclear fuel cycle in aggregate. Not surprisingly, proponents of nuclear power generation focus on the reactors themselves, which produce nothing but water vapor from the cooling towers.

NUCLEAR POWER AND THE ENVIRONMENT

As a stand-alone device, nuclear reactors do not emit greenhouse gases. The nuclear reaction is contained and the heat generated is used to boil water to turn turbines and produce electricity. Instead of a chemical reaction, an atomic reaction is required, produced by a process of fission using uranium fuel. Due to the splitting of atoms and the radioactive movement of neutrons, no carbon dioxide, methane, or other greenhouse gases are produced. However, the byproducts are toxic, radioactive wastes requiring storage for thousands of years. Analyzing the entire nuclear cycle, including the upfront uranium mining and refining, reveals that large amounts of fossil fuels are required. This, in part, is where the greenhouse gases come from. Such steps are also required to produce aluminum. The difference is that aluminum-based products can be recycled and reused in other forms.

With uranium, the atomic alteration it undergoes to boil water cannot be reversed. Like fossil fuels, uranium is a non-renewable resource. Recent reports from the International Atomic Energy Association (IAEA) reveal that the mining of easy uranium in places like Saskatchewan, Canada and Australia will run out around 2020, while the cost to extract it rises significantly. This uranium supply aspect of the nuclear cycle is like that of the disappearing petroleum feed stocks.

Another aspect of nuclear power production is the dangerous chlorofluorocarbons (CFCs) dumped into the atmosphere during the enrichment of uranium, a complex technique needed to make the uranium suitable for use in fission reactors. It is so complex that only the United States, Britain, France, Germany, the Netherlands, and Russia export enriched uranium to other countries for use in their reactors. Regardless of the source, the enrichment process itself produces CFCs, which destroy the ozone layer. Furthermore, the CFC byproducts are 10,000 to 20,000 times more capable of holding heat in the atmosphere than carbon dioxide.

Like the oil industry, the nuclear industry is highly subsidized. This was reinforced in the U.S. Energy Act of 2005, which allocated $13 billion in subsidies. One of the rationales given is that nuclear-generated electricity will wean Americans from dependence on oil and strengthen national security. Looking at electricity generating statistics published by the Department of Energy (DOE) refutes this fallacy. In 2005, petroleum products fueled only 3 percent of electrical consumption. The bulk of the nation's petroleum is used for transportation, not for the production of electric power. In this energy-hungry sector, gas-electric hybrids and revitalized electric vehicles are being called upon to reduce petroleum consumption.

Nuclear power supplies 18 percent of the world's electricity, with countries such as France deriving 78 percent of their supply that way. In America, no new plant has been brought online since 1996, even as 19 percent of U.S. electrical production is derived from nuclear power. However, the dynamics of the nuclear industry have intensified with the rising public awareness of global warming. Relatively speaking, nuclear power is a kinder, gentler source of power for the climate. With this in mind, and the desire to meet its Kyoto commitment, Finland recently approved the world's largest nuclear reactor, at 1600 megawatts, to be brought online by 2009. Furthermore, the United States is giving nuclear technology to India to support their plans to build eight new reactors, in a deal struck in 2005. Comedians regularly lampooned the 2007 Bush administration for promoting nuclear energy as the foil to global warming, yet the federal government refuses to sign the Kyoto protocol.

RENEWABLE ENERGY SOURCES AS AN ALTERNATIVE TO NUCLEAR POWER

Building and commissioning massive, complex nuclear plants requires huge government subsidies. Contrast this with wind or solar energy that are distributed and less dense supplies of energy. The amount of solar panels produced on an annual basis is equivalent to the construction of two nuclear facilities. The renewable solar approach seems simpler and safer, and not one requiring subsidies. Such sound

Approximately 30 new nuclear power plants are under construction and another 200 are in the planning phase around the world. The United States has 49 new nuclear plants in the planning stages.

bytes are bolstered by the Rocky Mountain Institute, which believes that none of the centralized generating technologies, be it nuclear, coal, or natural gas, can compete with solar, wind, or other renewable sources in their efficiency and projected price drops over the coming decades. Already, in places like California, even without government subsidies, the 30-cent per kilowatt-hour crossover point has been achieved. Pacific Gas and Electric (PG&E) produces electricity in the summer at this cost, which is inline with the cost of a residential solar installation. While utility rates are trending upward, the cost of solar installations is dropping. Many advocates believe the time has come to shift from a centralized model of power distribution to a distributed one.

Renewable energy is everywhere, easy to tap, cheap to harness, and above all, human and climate friendly. It has the added bonus of feeding surplus electricity back into the electric grid. Nuclear power, however, provides tough competition with its powerful lobby claiming it is the best carbon displacer. A 2003 Massachusetts Institute of Technology study revealed that people concerned about global warming are neutral on the role of nuclear as either a solution or a problem in the climate crisis debate. What is not highlighted for the public is that for every $1,000 spent on nuclear reactors, another 10 tons of carbon dioxide is released into the atmosphere because renewable energy investment was denied these funds. Some executives, such as the head of PG&E, who manage nuclear reactors, have concluded that global warming is a major threat. While PG&E has not advocated the building of new nuclear facilities, the company is investigating the use of solar thermal, a technology relying on focused sunlight to boil water and drive a turbine to produce electricity. The head of the Southern Company holds the opposite position. In their 2005 annual report, this large utility in the southeastern United States claimed that, "... nuclear energy must remain an option for expanding our generating fleet because it has proven to be safe, reliable, and cost-effective, with relatively low environmental impact." Here are two different views from two different coasts on generating power for the future of American consumers, and both claim to want to better address the environment.

Global warming makes it tricky operating nuclear power plants. The European heat wave of 2003 caused river levels in France to fall, more so than usual, owing to the lack of rainfall. Electricité de France, the French power company, employed reservoir-fed high-pressure hoses to cool its nuclear plants. This partial solution was not enough and heated, secondary cooling water was discharged into the river. This 25 degree C water is a source of thermal pollution and a danger to aquatic life, and in an ironic twist, one of the symptoms of global warming is rising water temperature. Nuclear cooling water can contribute directly to warmer water, rather than indirectly doing so via the carbon dioxide route. In fact, global warming itself may be the reason for closure of nuclear power plants in the future.

Another factor when considering closing plants is the safety concern raised about nuclear facilities operating in geographies prone to earthquakes. A 6.8 temblor in July 2007, injured and killed people in Japan and forced the evacuation of thousands of people, while igniting a fire in a nuclear power plant. Japan operates 55 nuclear reactors within its boundaries, which generate 30 percent of its electrical supply. Although all of the affected reactors were shut down, more than 300 gallons of low-level radioactive water was dumped into the sea. While investigations continue, people remain jittery about the ability of nuclear facilities to remain safe during an earthquake. Furthermore, the reliance on nuclear as a centralized power source is hampered when plants are shut down. Power is removed from areas beyond a natural disaster, just when emergency workers and hospitals need electricity most.

For each ton of solid reactant carbon, 3.7 tons of carbon dioxide gas products are released into the atmosphere. The prevailing theory for global warming is based on the fact that an increase in atmospheric carbon dioxide concentrations leads to an increase in the average global surface temperature. Although carbon dioxide accounts for half of the associated temperature rise, other gases contribute to the balance. Methane from rice paddies and herds of cattle and chlorofluorocarbons from the nuclear fuel cycle and other industrial processes contribute, in part, to the second half of the temperature rise. Some analysts of the nuclear fuel cycle believe that as less accessible uranium is mined after 2020, more fossil fuel will be required to extract the uranium than would be to burn the petroleum directly. Going forward, the receding source of uranium will result in the production of more greenhouse gases those that produced by petroleum-fired generating plants.

THE FUTURE OF NUCLEAR INTERESTS

Safety concerns aside, the perceived atmospheric-friendly power produced by nuclear means that the next few decades for nuclear power generation and production of uranium are solid. Approximately 30 new nuclear plants are under construction and another 200 are in the planning phase around the world. Even the nuclear reticent United States has 49 such facilities in the planning stages, the last one was approved almost 30 years ago in 1979. The resurgence of nuclear power, owing directly to rising energy costs and the global warming phenomenon, has bolstered the stocks of uranium mining companies. These operators have seen spot prices for processed uranium ore rise from $10 a pound to over $130 a pound. Uranium has become a hotter commodity than silver, gold, or steel during the early 21st century because forecast demand will rapidly escalate as new nuclear plants, added to the existing 434 facilities worldwide, are brought online.

Government interest is high in promoting nuclear power, too. As part of the Bush Administration's 2005 Energy Bill, the White House authorized the Department of Energy to achieve the following: ensure by 2050, that the United States and the rest of the world's electricity needs are met by more than 30 percent of it being driven by nuclear power, establish an effective international proliferation regime, where there are nuclear fuel states and nuclear reactor states, and reestablish the United States as the leader in nuclear energy.

The current open fuel cycle used by the United States for its 103 nuclear power plants creates a massive problematic waste stream. If the United States started to store spent nuclear fuel at Yucca Mountain, the proposed U.S. Department of Energy storage facility for spent radioactive waste, it would immediately fill the facility. The challenge is to shift the process from an open to a closed fuel cycle. If not, 10 Yucca Mountain nuclear storage facilities would have to be built, with 10 times the space available at Yucca to store nuclear materials. With this in mind, the move to a closed fuel cycle will likely be made, and a smaller, cooler nuclear waste stream could result. The nuclear industry is pressing for this outcome, as well as for the use of Yucca Mountain as soon as possible.

It appears the U.S. government is on a fast track to implement strategies that make nuclear research, development, and deployment happen. This quest is reminiscent of the Space Race of the 1960s, when the United States sought to overtake the Soviets. Nuclear power in the eyes of the public has gone from the status of a pariah to a savior. Industry and government policy reinforces this perception. By looking at nuclear power plants through green-colored glasses, many see the reactor's performance of producing greenhouse gases at an outstanding level of zero. Without the glasses, those viewing the entire nuclear cycle see it as a contributor to global warming and the depletion of the world's uranium stocks as another example of unsustainable behavior.

Ocean Component of Models

CLIMATE MODELS ARE computer simulations representing the Earth in layers and boxes. These models use complex mathematical equations to determine future climate possibilities based on parameters of baseline conditions and changing variables, like increased greenhouse gases, and rising temperature. The equations in the separate cells are used to mathematically calculate numerous conditions including the flow of heat, moisture, sunlight, wind, and the condition of the adjacent cells. Early climate models provided uncertain projections because the equations failed to include the dynamics of the little-understood ocean circulation. Two-thirds of the Earth is covered by ocean, which acts as a heat reservoir and a heat transport system; changes in the ocean can cause widespread changes in climate. Every few years, a warming of the eastern Pacific near the equator creates El Niño conditions, altering rainfall and temperature patterns.

The ocean plays a central role in climate variability, modifying the flux of heat into the atmosphere, stimulating changes in the atmospheric circulation, which, in turn, modify the general circulation of the ocean. Studies of annually-averaged air-sea heat exchange have shown that a large transfer of heat from the ocean to the atmosphere occurs downstream from the subtropical western boundary currents.

EXAMPLES OF MODELS WITH OCEAN COMPONENTS

The addition of ocean circulation to climate models is the result of numerous studies that determined the circulation patterns of the ocean with fluid motion. These include the World Ocean Circulation Experiment, with nine years (1990–98) of observations (physical, chemical, and satellite), by approximately 30 nations to determine the baseline conditions for assessing future climate change. The second phase of the World Ocean Circulation experiment was Analysis, Interpretation, Modeling, and Synthesis, ending in 2002. Sophisticated numerical ocean models were also developed to provide a framework for the interpretation of the observations and for the prediction of the future ocean state.

The World Climate Research Programme is studying climate variability and predictability (CLIVAR), with research focusing on interactions between the ocean and the atmosphere and collaboration with companion research projects to study the role of the land surface, snow, ice, and stratospheric processes in climate.

The Global Ocean Data Assimilation Experiment (GODAE) began in 1997, to develop better ocean observations and ocean forecasts utilizing improved technology (in-situ and remote) to observe, measure, model, and assimilate data available worldwide to researchers needing comprehensive ocean and marine data and forecasts.

The Argo project, begun in 2000, deploys 3,000 profiling floats (spaced approximately 3 degrees apart throughout the world's oceans) to collect temperature, velocity, and salinity measurements on the physical state of the upper ocean, with emphasis on seasonal and decadal variability. The collected data will be used for initializing ocean and coupled ocean-atmosphere forecast models, data assimilation, and model testing.

With increasing data on ocean physics, chemistry, and biology, improved models are being created, incorporating the ocean component into computer models, and using more complex computing systems. The Parallel Ocean Program is a publicly available model developed at Los Alamos National Laboratories, using ocean circulation with depth as the vertical coordinate. Researchers, in adapting the Parallel Ocean Program for parallel computers to improve performance, also enhanced the model's physical representation of the real ocean. Higher resolution simulations have shown greater agreement with observations of sea-surface height variability in the Gulf Stream.

The Open Ocean Slab model includes sea ice in its component for figuring the ocean component mixed-layer temperature, including density of ocean water, heat capacity of ocean water, annual mean ocean mixed-layer depth, fraction of the ocean covered by sea ice, net atmosphere to ocean heat flux, internal ocean mixed-layer heat flux, simulating deep water heat exchange and ocean transport, heat exchanged with the sea ice (including solar radiation transmitted through the ice, and heat gained when sea ice grows over open water). The resulting mixed-layer depths in the tropics are generally shallow, while at high latitudes, in both hemispheres, there are large seasonal variations.

The Hadley Center Ocean Carbon Cycle (HadOCC) model includes ocean biology to provide a more accurate estimate of the chemical reactions of carbon dioxide in the surface waters, and for carbon dioxide entering at the surface to reach deep ocean waters. By using a reduced resolution from versions used for climate prediction, the model allows for greater testing of the carbon cycle, though it does show less accuracy in representing ocean physics. The model uses a simplified biological system, using only phytoplankton (nutrient and waste products). Dissolved inorganic carbon is taken up by phytoplankton growth and returned with biological breakdown. The model tracks the amount of carbon in dissolved inorganic carbon and in the four biological components. Even with the multiple simplifications in the model, the correlation with ocean observations for both Atlantic and Pacific models is good. The model does vary widely with observation at the equator, with the model showing excess surfacing of deep-water rich in carbon and releasing that carbon into the atmosphere.

The numerous complexities of interactions and the increasing ability to include these interactions in computer models provides a better picture of climate change possibilities, while maintaining the limitation of including so many real-life variables in a simulation.

Oceanic Changes

OCEANS ARE CONNECTED bodies of saline water that cover about three-quarters of the Earth and comprise more than 97 percent of the world's total water resources. Although continuous, the global ocean is divided into five oceans based on geographic location, geological barriers, and other criteria, into the Arctic, Atlantic, Indian, Pacific, and Southern oceans. Oceans have great influence on global weather patterns and climate. This influence stems from variations in ocean temperature caused chiefly by the movement of radiant solar heat absorbed by the ocean's surface. Recently, atmospheric changes and resultant changes in chemical and physical attributes of the oceans, including temperature, salinity, and acidity have threatened the global ocean's stability. For example, sea level has been rising due to thermal expansion and melting of the world's ice. This retreat of ice causes further absorption of radiant energy from the Sun into the darker colored sea that might otherwise have been reflected by ice. This then creates a positive feedback in the warming of the atmosphere and further melting of ice. A warming atmosphere has been linked to changes in rainfall and storm frequency and length. Changes like these have the potential to cause the ocean to change dramatically over a relatively small span of time.

CARBON CYCLING

The past two centuries have witnessed a significant rise in the amount of global carbon emissions and subsequent absorption by oceans around the Earth. The global ocean plays a vital role in the Earth's carbon cycle, about 50 times greater than that of the atmosphere. The oceans absorb from the air about half of carbon deposits from fossil-fuel burning sources. The ocean contains the largest pool of carbon on the Earth's surface; however, these carbon concentrations are not distributed equally. The surface of the ocean exchanges carbon with the atmosphere more rapidly because of mixing by winds at the surface, and because the temperature, chemistry, and pressure of water; all of which vary by depth, affecting the solubility of carbon dioxide and carbon-containing ions. In areas of upwelling (where colder water moves to the surface), carbon is released into the atmosphere, whereas in areas of downwelling (where water piles and sinks), carbon is absorbed from the atmosphere. Oceanic upwelling and downwelling illustrate that changes in distribution of water in one area are always accompanied by compensating water changes in another area. This process is called mass continuity.

The speed at which the ocean can exchange carbon with the Earth's atmosphere is important in regulating the pH level (or acidity) of the ocean and its nutrient and chemical stability. Once the ocean absorbs carbon dioxide, it combines with water to form carbonic acid and a series of acid-base products. Prior to the Industrial Revolution, global carbon emissions and uptake were in relative balance, which made for a healthy chemical and nutrient stasis. Currently, however, ocean carbon absorption is at a higher rate than its atmospheric exchange capabilities. Although this mediates the amount of carbon dioxide in the atmosphere, the imbalance has increased production of carbonic acid, which has resulted in a gradual decrease in pH, or the acidification, of ocean water.

RADIANT ENERGY AND OCEAN CURRENT

Radiant energy from the Sun is not uniformly distributed across the globe, because the Earth is spherical. Specifically, more energy per a given surface area arrives at the tropics, where the Sun is more directly overhead, than arrives at the poles where sunlight strikes the Earth at a greater angle. This has a number of effects. Evaporation is higher in these tropical waters, thereby affecting the concentration of ions in the water. This concentration of ions, in turn, increases tropical waters' ability to dissolve carbon dioxide. Heating and evaporation at the surface also creates chemical and physical differences in adjacent water masses by latitude and depth. These differences, along with prevailing winds caused by the Earth's rotation, are the primary drivers behind movements of water masses in the oceans.

Currents are the steady flow of ocean water in a prevailing direction. Ocean currents have been identified as the single most influential mechanism in the global climate system via their role in transferring heat to and from geographic regions. Long-term patterns in currents are dependent upon maintenance of the chemical and temperature gradients. Changes in the Earth's atmosphere can alter these gradients. For example, warmer air above the oceans affects evaporation, and, thus, the chemical content and temperature of water. A warming atmosphere can also alter the temperature and chemistry of water by diluting saline, or salty ocean with cold, freshwater from melting ice.

WATER DENSITY

The majority of the movement and circulation of water and energy throughout the ocean is driven by differences in density between adjacent water masses. Density is dependent on the salinity and temperature of the water. The thermohaline circulation, or Global Conveyor Belt, is initiated by density differences and distributes heat energy between tropical and polar regions. Rainfall is higher in the tropics, and this addition of freshwater into the ocean decreases the salinity, and, therefore, the density, of the ocean waters in these areas. The colder oceans receive less rainfall because of lower evaporation, and, thus, are saltier and denser. The higher density of colder portions of the oceans relative to the tropics creates a difference in sea height, with colder oceans depressed, and warmer oceans elevated, relative to each other.

The density of near-surface water in the tropics is further decreased by solar heating; however, its salinity is increased by evaporation. This upper, less dense, but more saline tropical water, thus moves in a poleward direction over the colder water. As it moves north, it releases heat to the atmosphere and the lower ocean and is thereby cooled. As it cools, its high salt content makes it denser relative to the water it is flowing over, and therefore sinks. This overturning circulation varies from year to year and as well as longer timescales. Changes in precipitation, runoff, ice melt, solar heating, and winds can strengthen or weaken the conveyor belt. This can affect short-term weather conditions, but can also alter climate in the long term if the circulation pattern settles into a new equilibrium.

OCEAN ECOLOGY

Oceans are home to the majority of plant and animal life on the planet. Climate change is expected to alter marine ecology both directly, through lower pH and elevated temperatures on the organismal level, and indirectly, via changes in community dynamics and food and habitat alteration on the aggregate level. A major concern is the possible effect climate change may have on ocean productivity. Phytoplankton, small plants found near the ocean's surface that comprise the basis for the marine food web, are the foundation for almost all ocean life, and play a key role in regulating global carbon levels. It is unknown how these organisms will react to changes in ocean acidity, increased nutrient mixing, and changes in temperature. However, any dramatic short-term alterations in foundational food web interactions are expected to have cascading effects through the food chain.

Species migration and shifts or expansion in species range are also expected as global ocean temperature continues to rise. Scientists expect that some organisms will thrive, as others will suffer. This is expected to upset ecological equilibrium in certain areas and likely affect commercial and recreational fisheries and tourism in susceptible areas. Warm water species are expected to move toward the poles. This trend has already been witnessed over the last decade in certain fisheries closer to the equator.

Oceanography

THE OCEAN IS arguably the largest habitat on the planet, and it houses an astounding array of life, from microbes to whales. Oceanography is the branch of Earth science that studies the Earth's oceans. It is the systematic scientific study of the oceans and deep sea with the goal of understanding their processes and phenomena. The relationship of oceans with other aspects of the Earth's environment is also highlighted in oceanographic studies. Biology, chemistry, geology and physics together make oceanography a richly interdisciplinary science. Although they contain most of the Earth's water and carbon and surface heat, and much of its biomass, the oceans do not operate alone. Together with the atmosphere, continents and ice-cover, they form a working platform, driven mostly by energy from the Sun.

Earth science has four main components: hydrosphere, solid earth, atmosphere and biosphere. Water at the Earth's surface or near it, is termed the hydrosphere. It includes oceans, water vapor, ground water, lakes, rivers, and polar icecaps. The water distribution in the hydrosphere is as follows: oceans—97.54 percent, icecaps—1.81 percent, groundwater—0.63 percent, others—0.02 percent. It is obvious that we live on a water planet.

Oceanography is studied in order to understand how oceans operate and how they interact with other aspects of the Earth system. Again, oceans are a vast source of food for the world's population. The oceans hold an enormous reservoir of minerals and they also hold reservoirs of fossil fuels or the potential for harnessing forces for energy development.

The study of oceanography may be divided into four branches: biological oceanography, chemical oceanography, geological oceanography and physical oceanography. Biological oceanography is the study of marine organisms and productivity, life cycles, and ecosystems. Biological oceanography spans studies of all levels of biological organization, from that of single genes, to organisms, to their population dynamics. It includes studies on how organisms interact with, and contribute to, essential global processes.

Chemical oceanography deals with water chemistry and biogeochemical cycling. It is the study of everything about the chemistry of the ocean and is based on the distribution and dynamics of elements, isotopes, atoms, and molecules. This ranges from fundamental physical, thermodynamic and kinetic chemistry to two-way interactions of ocean chemistry with biological, geological, and physical processes. It encompasses both inorganic and organic chemistry. Chemical oceanography includes processes that occur on a wide range of spatial and temporal scales; from global to regional to local to microscopic spatial dimensions and timescales from geological epochs to glacial-interglacial to millennial, decadal, interannual, seasonal, diurnal, and all the way to microsecond time scales. Geological oceanography is the study of the geology of the ocean floor including plate tectonics, ocean basin geology, and ocean history, while physical oceanography studies the ocean's physical attributes including temperature-salinity structure, water properties, mixing, waves, tides, and currents. Physical oceanography studies the physics of the ocean, the kinds of motions of water, the speed, and the direction of the water. Physical oceanography is the study of the fluid motions of the ocean. Its goal is to understand the processes at all time- and space-scales, to simulate these processes, and to make predictions if possible. Physical oceanographers are also interested in determining how much heat enters the ocean and where the heat is transferred.

These diverse topics reflect many basic disciplines (biology, chemistry, geology, meteorology, and physics) that oceanographers utilize to further knowledge of the world ocean and understanding of processes within it. Oceanography is born out of scientific curiosity and aids in the understanding of marine resources and their impact on humans and global climate changes. The aim of oceanography is an understanding of the oceanic circulation and the distribution of heat in it, appreciation of the interaction of oceans with the atmosphere, and the role they play in maintaining our climate.

Origin of the ocean basins is traced to many theories. In the cosmic school of thought, it is believed that the moon blew out of the Earth, only to be caught by the Earth's gravity as a natural satellite. The hole is said to be located in the region of the Pacific Ocean. This idea was popular until the evidence supporting the theory of plate tectonics gained support. In the plate tectonics theory, oceans are produced as diverging plates open the space between them. Triple junction theory states that a crack begins on a continental plate, joining cracks from three different directions, until a series of these cracks eventually separates the plate and produces a proto-ocean.

The supercontinent Cycle theory notes that the breaking apart of Pangaea has occurred several times with the production of supercontinents over and over, and with oceans breaking up the spaces between them. The most viable hypothesis for explaining the origin of the ocean water is that it is from the interior of the Earth. Earth's distance from the Sun and its mass were obviously crucial in the formation of the oceans.

The major oceans are Pacific, Atlantic, Indian, and Artic oceans. The Pacific Ocean is the largest and deepest, and covers 50 percent of the surface area of the world's oceans. Marine environments could be classified by light and location. Inhabitants of marine zones include planktons, nektons, and benthos. Water is found everywhere on Earth and is the only known substance that can naturally exist as a gas, liquid, and a solid, within the relatively small range of temperatures and pressures found at the Earth's surface. Oceans contain nearly 98 percent of all the water on or near the surface of the Earth. The residence time of ocean water is about 37,000 years. Changes to the coastal environment occur from the movement of ocean waters against the shore. Surface ocean currents are broad, slow, drifts of surface water, set in motion by the prevailing winds, but rarely causing erosion deeper than 164–328 ft. (50–100 m.). The gases that make up the oceans were trapped within the Earth as it formed. The major trapped volatile was water; others included nitrogen and carbon (IV) oxide. Seventy-one percent of Earth's surface is covered by water, and 29 percent of the surface area is land.

As a result of different water masses, the ocean can be viewed as stratified, with layers of water extending great distances with similar temperatures, or salinities, or most of water properties. There is unequal warming of the ocean; this leads to heat transfer, changes in density, and ultimately, movement of water masses via the thermohaline circulation process. Ocean and atmosphere form a coupled system. The coupling occurs through exchange processes at the interface. Ocean and atmosphere are coupled in climate models and circulation models; the computer models become the meeting point for observations, theory, and prediction. These exchange processes determine the energy and mass budgets of the ocean. Quantities exchanged between the ocean and the atmosphere in the energy budget are radiative energy and momentum, while in the mass budget quantities include evaporation, condensation, precipitation, and river run-off. The ocean plays a role in the climate system, which is complementary, and of comparable importance to that of the atmosphere. It transports heat in amounts comparable with atmospheric transport. It absorbs and releases carbon (IV) oxide. When it is heated, the ocean responds by storing some of the heat and by increased evaporation. Because the heat is mixed for some distance by the wind, temperature rises much less than it does on dry land under the same heating conditions. The evaporation has profound effects on the atmosphere and on climate.

When the ocean is cooled, it responds by generating vertical convective motions, which resupply heat to the surface. Thus, the temperature drop is much less than over land under the same cooling conditions. The overall result is that for the two-thirds of the Earth's surface covered by ice-free ocean, the temperature over the whole ocean ranges only from 28 degrees F (minus 2 degrees C, the freezing point of salt water) to 86 degrees F (30 degrees C), and at any one place by hardly more than 1.8 degrees F (1 degrees C) during the course of a day and 10.8 degrees (10 degrees C) during the course of a year. The relatively slow response of the ocean to heating and cooling results in the oceanic annual cycle being delayed, relative to that in continental regions.

The ocean plays a key, but frequently understated, role in determining the Earth's climate. Indeed, any possibility of predicting the evolution of climate beyond a few weeks demands that ocean behavior also be taken into account. With respect to sensitivity and contribution to long-term climate change, there is reason to believe that the ocean is now changing, in response to climate changes over the past few hundred years. It can be expected to change further as anthropogenic influences become increasingly marked. The effect of the ocean on the atmosphere could be either to moderate or to intensify these changes; it will certainly modify them.

The oceanic environment places unique demands on instrumentation that are not easily met by standard laboratory equipment. As a consequence, the development and manufacturing of oceanographic instrumentation developed into a specialized activity. Available equipment for observing the ocean and marine life include research vessels, moorings, satellites, submersibles, towed vehicles, floats, and drifters. Reversing thermometers are used to measure hydrographic properties. Nansen and Niskin bottles, CTDs, multiple water sample devices, thermosalinographs, remote sensors current meters, wave measurements, tide gauges, remote sensors and shear probes are all employed for measuring the dynamic properties of the ocean. The first international organization of oceanography was created in 1902, as the International Council for the exploration of the sea.

Scientific graduates have directly applied their training in teaching positions on M.Sc and Ph.D courses, in industrial research laboratories; in government research laboratories, including the Water Boards and in environmental protection agencies. Other Oceanography graduates apply their knowledge in a wide range of jobs within business and industry and in the military. Oceanography is a relatively young discipline, shaped by a continual flow of exciting discoveries. Oceanographers continue to help us understand the precarious balance of oceans, the atmosphere, ice, solid earth, and living organisms—the Earth system that affects our lives and the future of our planet.

OECD Annex 1 Expert Group on the UNFCCC

THE ANNEX 1 Expert Group (AIXG) of the Organisation for Economic Co-operation and Development (OECD) was created in 1994, as an ad hoc cadre of government officials from the departments of environment, energy, and foreign affairs of countries that have committed to Annex 1 of the United Nations Framework Convention on Climate Change (UNFCCC). Annex 1 acknowledges the impact of human behavior on global warming and climate change. The UNFCCC treaty of 1992 attempted to develop well-articulated methods of reducing global warming and formulating specific responses to climate change. Most OECD member states have signed Annex 1, as have other nations from Eastern Europe and the Commonwealth of Independent States, which was created after the break-up of the Soviet Union. Most nations who have signed the UNFCCC have also signed the more powerful Kyoto Protocol.

Countries who commit to the UNFCCC officially acknowledge that climate change is of major concern to all humans, recognize that human behaviors have led to increasing atmospheric concentrations of greenhouse gases (GHG) and warming temperatures, and admit that these phenomena are having a negative impact on the world's ecosystems and human health. Signatories from developed countries accept that industrialization has been, and continues to be, a major contributory influence to global warming and climate change, and understand that highly-industrialized nations are required to accept the lion's share of the blame for both phenomena. Without infringing on national sovereignty, parties to the UNFCCC accept responsibility for committing their own governments to international cooperation, to encourage domestic efforts to mitigate the potential for future environmental damage, while developing technologies and coping strategies for dealing with the impact of global warming and climate change on human health, the environment, society, and the economy.

Upon its creation, the Annex 1 Expert Group of the UNFCCC was charged with addressing the analytical issues raised by the UNFCCC, particularly those relating to fulfilling commitments of Annex 1. Official meetings are held twice a year, but group work continues throughout the year. The OECD and the International Energy Agency (IEA) provide secretariat support for the group by preparing informational and analytical papers directed toward member countries and other interested parties. The Annex 1 Expert Group has been instrumental in standardizing the reporting of national emission inventories and in developing GHG mitigation policies, such as those included in the Kyoto Protocol. Other efforts have focused on providing member nations with assistance in policy design, implementation, and performance. The group is also involved in providing assistance to countries in using the Clean Development Mechanism (CDM) and emission trading to meet the objectives of the UNFCCC and in educating government officials and the public about global warming.

AIXG programs are generally designed to deal with long-term issues concerning global warming and climate change and with the specifics of meeting goals of individual projects. Examples of long-term issues include understanding the relationship between GHG emissions and deforestation, supporting the development of alternative energies, generating cooperation from the private sector, as well as governments, in dealing with global warming and climate change, and using existing literature, forums, seminars, and case studies on climate change from specific countries and regions to develop plans for international cooperation in mitigating the effects of global warming and climate change.

Policy formation continues to be a major priority of the Annex 1 Expert Group, and much of the focus is on providing support to transition economies and on monitoring compliance with the terms of the UNFCCC. Because the Kyoto Protocol contains stronger monitoring and compliance measures, those activities are generally conducted through provisions specified in the Kyoto agreement. In addition to Kyoto's provisions, Annex 1 parties to the UNFCCC agree to regularly provide GHG projections and reports and furnish estimates of potential effects on emissions and sinks. Within those guidelines, member countries have developed a myriad of responses to dealing with UNFCCC requirements.

CURRENT AND ONGOING AIXG EFFORTS

Ongoing Annex 1 Group projects deal with developing policies on technology and climate change, gauging institutional capacity for dealing with climate change issues, keeping an eye on international emissions trading and the Clean Development Mechanism (CDM) and Joint Implementation, assessing specific roles in mitigating the effects of climate change, devising both short- and long-term strategies for meeting goals, and conducting seminars that bring experts from developed and developing countries together to discuss relevant issues. Past AIXG studies have dealt with assessing the role of electricity and aluminum in global warming and climate change, international cooperation in climate mitigation, technological collaborations on energy, wind power integration, the future of international cooperation on climate change, emissions trading, progress in implementing CDM, strategies for dealing with domestic greenhouse gas emission, and cooperation in the agricultural sector.

In March 2003, AIXG was involved in the OECD "Global Forum on Sustainable Development: Emissions Trading," which met in Paris, France. The forum served as a venue for bringing together OECD members with representatives from non-member nations to encouraging cooperation in dealing with common concerns such as GHG emissions and air pollution. In March 2007, the Annex 1 Expert Group again met in Paris to sponsor the seminar, "Working Together to Respond to Climate Change." Some 150 non-Annex 1 members attended the seminar, which focused on four major issues: ways to make the CDM operational, the potentials of sectoral-crediting mechanisms, technology and adaptation, and opening dialogues between AIXG members and non-members on technical and analytical issues. That same year, the Annex 1 Expert Group on the UNFCC, released two major reports dealing with methods of gaining political support for implementing the group's priorities and on developing techniques for overcoming non-technical barriers to the diffusion of energy-efficient technologies.

OECD Climate Change Documents

THE ORGANISATION FOR Economic Co-operation and Development (OECD) was established in 1960 and is based in Paris, France, with a membership of 30 countries. The organization continued the activities of the Organization for European Economic Cooperation (OEEC), which had administered the American and Canadian funds of the Marshall Plan for the reconstruction of Europe after World War II. OECD's main commitment is to foster cooperation among countries that adhere to the principles of democracy and free market economy. OECD's aims are to support sustainable economic development, to expand the job market, to raise living standards and contribute to the growth of global trade. In addition to working with its member countries, OECD also lends its expertise to more than 100 other countries.

One of OECD's branches is the Environment Directorate, which aims to supply governments with the analytical information to develop policies that are effective and economically efficient, as well as respectful of the environment. The Directorate compiles country performance reviews, data collection, policy analysis, projections, and modeling, and encourages the development of common approaches. Within the Environment Directorate, the Department of Climate Change, Energy, and Transport specifically assesses the impact of global climate change on economies, societies and the environment in the 21st century. The Department supports the integration of climate policy targets within larger policy areas. OECD also works closely with the Annex I Expert Group on the United Nations Framework Convention on Climate Change (UNFCCC), the group of government officials from Environment, Energy, and Foreign Affairs ministries from countries that are listed in Annex I to the UNFCCC, and those that have accepted the Annex I commitments. OECD provides secretariat support to the Annex I Expert Group. It offers analytical papers on issues relevant to the ongoing climate change negotiations, but that can also be useful to national policymakers and other decision-makers. In particular, OECD has suggested ways to share information under the Convention on greenhouse gases emission performance among countries, for example, through standardized reporting of national emission inventories and on greenhouse gases mitigation policies.

OECD DOCUMENTS AND POLICY

OECD's documents on climate change include both international policy issues, as well as national and sectoral policies. Guidelines on international policy issues emphasize the importance of identifying and analyzing policy frameworks that can facilitate adaptation to climate change impacts. In this area, OECD devotes particular attention to developing countries, and to particularly crucial sectors of intervention, such as water. The organization claims that climate change does not yet feature prominently within the environmental or economic policy agendas of many developing countries. This fact is a great disadvantage for developing countries, as data show that they might be particularly vulnerable to climate change impacts, and that climate change will likely affect the development potential for their economies. OECD documents and research address the points of convergence, as well as the opposing claims, of development and climate change, both with respect to mitigation of greenhouse gas emissions and adaptation to their effects. OECD's Development Co-operation and Environment Directorates work closely to identify linkages and explore effective policy responses in the areas of development cooperation and climate change. The focus is on natural resource management and climate adaptation responses.

In its "Domestic Policy Framework for Adaptation to Climate Change in the Water Sector. Part II: Non-Annex I Countries" (2006), for example, OECD has recommended an integration of the current meteorological trends and information on future water availability in the processes of water resources management and policy development. The document includes suggestions that an efficient way to start addressing adaptation in developing countries is through the strengthening of the fundamental building blocks of civil society. An effective adaptation to climate change can only be achieved through transparent governance based on the rule of law, cooperation among government agencies, and involvement of stakeholders (including local communities) in the decision-making process. The authors also stress the importance of accessible schooling, basic professional training, and medical care as essential elements in building community-level capacity and in adaptating to climate variability and change.

The OECD volume *Bridge Over Troubled Waters: Linking Climate Change and Development* (2005) points out that although climate change may seem a remote topic compared to pressing problems, such as poverty, disease and economic stagnation, it "can directly affect the efficiency of resource investments and eventual achievement of many development objectives." The authors argue for establishing a link between climate change and development priorities. They suggest ways in which development can be made more resilient to the impacts of climate change, taking into account the engineering and policy-making sectors. For example, at the engineering level, the impact of climate change in sea-level rise and glacial lake outburst floods should be taken into account when choosing the location and design of bridges and other infrastructure. Policy-makers should instead consider the implications of climate change on a variety of development activities, including poverty reduction, sectoral development, and natural resource management. The activities of OECD in this area aim to bridge the gap between the phenomena of climate change and development communities. The policies of climate change and those of development communities should attempt to consider their different priorities, time- and space-scales.

OECD documents aim to provide specific information "on the significance of climate change for development activities along with operational guidance on how best to respond to it within the context of other pressing social priorities." All too often, OECD researchers argue, development activities overlook climate change and the risks involved in the phenomenon. This is why *Bridge Over Trouble Waters*, among other OECD documents on climate change, argues for the adoption of longer-term perspectives than the ones generally adopted by developing communities. These often fail to integrate suitable policies of climate change adaptation into national development plans and poverty reduction strategies. Development priorities and policies of climate change adaptation are also sometimes perceived as polar opposites. The pressing challenges of poverty and inadequate infrastructure tend to overshadow the importance of investments in measures whose importance will not become clear until climate change impacts become fully evident.

In contrast with this existing situation, OECD recommends that information on climate change should be made more relevant for development initiatives and provide a more complete estimate of the cost effectiveness of including measures of climate change adaptation/limitation into development planning. In addition, the OEDC encourages the development of improved screening tools to identify the likely climate risks for development activities, in general, and for specific projects. Climate information should be made relevant to Environmental Impact Assessments (EIAs). EIA guidelines and checklists, however, would need to be modified to include the implications of projects for greenhouse gas emissions and the impact of the environment on a given project (at present only the impact of the project on the environment is taken into account). OECD documents point out that often the phenomenon of climate change does not need entirely new responses, but simply reinforces the need to implement measures that are already recognized as development or environmental priorities. Measures such as water or energy conservation, forest protection, flood control, building of coastal embankments, improvement of river flow, and protection of mangroves have already been listed as priorities in national and local planning documents, but have rarely been implemented. Thus, what the OECD argues for is not so much radically new plans for climate adaptation, but an effective implementation of measures that, in most cases, have already been approved.

To be more effective, OECD points out that the activities for climate change adaptation and mitigation should combine national goals with a bottom-up approach to the needs of local communities. In line with its free-market economy philosophy, OECD encourages the participation of the private sector in such activities. The organization also stresses the importance of trans-boundary and regional coordination. At present, most climate change action and adaptation plans are at the national level, while many impacts cut across national boundaries. Meaningful integration of a range of climate risks, from flood control, to dry season flows, to glacial lake hazards, can only be achieved through greater coordination on data collection, monitoring, and policies at the regional level. Finally, joint building of experience and sharing of tools and experiences, within and among governments and development cooperation agencies are needed for a successful implementation of climate change adaptation policies.

A relevant selection of OECD documents on climate change are specifically concerned with economic factors involved in the adoption of the Kyoto Protocol. "A Multi-gas Assessment of the Kyoto Protocol" (2000), for example, extends the analysis of the economic impact in limiting gas emissions, including not only carbon dioxide, but also methane and nitrous oxide. The document thus covers up to 80 per cent of greenhouse gas emissions listed by the Protocol. The inclusion of these gases reduces the estimated economic costs of implementing the Kyoto Protocol. The document points out that if each Annex I country or region takes individual action to respect its emission target under the Protocol, real income may, on average, be 0.33 per centlower. This compares favorably with previous estimates covering only carbon dioxide that showed 0.5 percent reduction in real income. In "Action Against Climate Change: The Kyoto Protocol and Beyond" (1999), OECD has stressed that the Kyoto targets alone will not be enough to avert climate change, but are best described as first steps in a global action. The document's authors argues on the necessity to achieve world-wide consensus for taking action and the economic impacts such action may have. Yet, even if this ambitious goal is reached, climate change may take place anyway, so that countries need to be prepared to face climate change impacts.

Several OECD documents have attempted to develop an implementation framework for a global greenhouse gas emissions trading system. "Linking Greenhouse Gas Emission Trading System and Markets" (2006), for example, takes as its point of departure the several different emission trading schemes (ETS) currently in operation, and those likely to emerge in the near future. In spite of the different sizes, design characteristics, and geographical scopes of these systems, the few existing links among them should be expanded. OECD has shown that linking the domestic ETSs of different countries or regions can be beneficial for all the parties involved. Establishing links between different markets increases their size and fluidity, so that the same environmental benefits can be gained at a lower overall cost, producing economic benefits.

In addition to these documents on general topics related to climate change, OECD has produced several statements on the impact of climate change on specific economic and social sectors. For example, the organization has studied ways to reduce greenhouse gas emissions from deforestation in developing countries (RED), usually by exploiting a market-based approach stressing efficient land-use options and incentives available to reduce emissions from deforestation. OECD has also produced documents that attempt to foster international collaboration regarding energy technologies in the context of climate change mitigation. Sharing information, costs, and efforts can facilitate a technical shift towards more climate-friendly technologies. It may also drive governments to allocate more funds in support for basic research and development. These forms of cooperation between countries are also recommended to engage more countries into action to mitigate greenhouse gas emissions. OECD has particularly focused on solar power technologies; the use of environmental-friendly technologies in agriculture and the development of seeds of high-yielding varieties (HYV); appliances that can bring significant greenhouse gas emission reductions at low cost to society, without compromising on quality standards, clean coal technologies; and wind power integration into electricity systems.

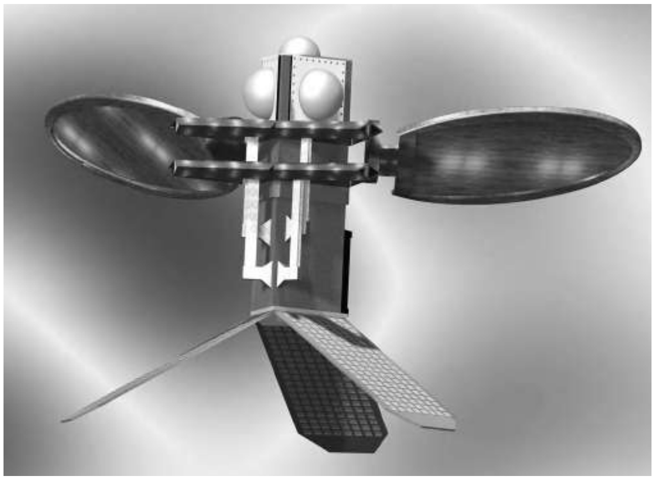
Office of Naval Research

THE OFFICE OF Naval Research (ONR) is based in Arlington, Virginia, and supports research conducted by the Navy and the Marine Corps. It was established in 1946, and serves as the technical adviser to the chief of naval operations and to the secretary of the Navy. Communication to the secretary of the Navy is via the assistant secretary of the Navy for research, development, and acquisition. The ONR mission is to "foster, plan, facilitate and transition scientific research in recognition of its paramount importance to enable future naval power and the preservation of national security."

The ONR has funded numerous scientists who have eventually won the Nobel Prize for their research. The first example is Felix Bloch, awarded the Nobel Prize for physics in 1952. He worked on magnetic mea-



Robofly is the Navy's stealth robotic flyer the size of an actual fly, capable of searching for chemical and biological warfare agents.

surement in atomic nuclei; for naval interest his work was in the field of naval medicine and nondestructive inspection. Two years later, Linus Pauling was awarded the Nobel Prize for chemistry for his research on the nature of the chemical bond. His work was of naval interest for its contributions to the foundations of chemical engineering. In 2005, John L. Hall and Theodor W. Hansch shared the Nobel Prize for physics for their work in laser-based precision spectroscopy. There was naval interest in this work because of its applications for precision timekeeping, as well as precision measurements.

There are four branches within the ONR: the Naval Research Laboratory (NRL), ONR Global (ONRG), Science and Technology (S&T), and the Naval Reserve S&T Program. There are seven main departments of research in the ONR S&T Division: Command, Control Communications, Intelligence, Surveillance, and Reconnaissance; Expeditionary Warfare and Combating Terrorism; Naval Air Warfare and Weapons; Ocean Battlespace Sensing; the Office of Transition; Sea Warfare and Weapons; and the Warfighter Performance Department. Within each department are subdepartments, or divisions. For example, within the Ocean Battlespace Sensing Department are the Ocean Sensing and Systems Applications Division and the Ocean, Atmosphere, and Space Research Division.

The ONR is led by a chief of naval research, a vice chief of naval research, an executive director, an assistant chief of naval research, a director of research, a director of transition, and a director of innovation. Additionally, an ONR inspector general acts to ensure efficient and ethical proceedings at the ONR, to oversee the ONR operations and programs and to "prevent and detect fraud, abuse, mismanagement, and waste."

Ohio

OHIO HAS AN area of 44,825 sq. mi. (116,096 sq. km.), with inland water making up 378 sq. mi. (979 sq. km.), and Great Lakes Coast water of 3,499 sq. mi. (9,062 sq. km.). Ohio's average elevation is 850 ft. (259 m.) above sea level, with a range in elevation from 455 ft. (139 m.) above sea level on the Ohio River, to 1,549 ft. (472 m.) at Campbell Hill. Most of Ohio is flat or gently rolling, with some rougher terrain between the major rivers and in the divide between the Great Lakes and Ohio River drainage systems. Lake Erie borders Ohio on the north and the Ohio River borders the south. Most of the rivers that drain into Lake Erie are short. Those flowing into the Ohio are comparatively long. Lake Erie is Ohio's most important lake, with many artificially created ports and interior lakes.

Warm to hot summer and mild to cold winters come from alternating dry polar air from Canada and warm-humid air from the Gulf of Mexico. In winter, polar air is dominant, often coming into conflict with modified gulf air, causing frontal or cyclonic storms. Gulf air is dominant in the summer. In fall, polar air passing over Lake Erie is modified, delaying the killing frost along the adjacent shoreline. The average annual precipitation is 48 in. (122 cm.), with distribution throughout the year, and snowfall usually melts quickly.

Western Ohio is part of the Corn Belt. Other major industries include agricultural crops (including corn and soybeans), dairy, and livestock. Vineyards and orchards (mainly cherry and peach), are found along Lake Erie, where the growing season is longest. Southern and eastern Ohio has woods, though forestry is a minor industry. Mining is important to Ohio's economy with coal, crushed stone, natural gas, sand and gravel, petroleum, lime, salt, and clays. Oil and natural gas are mined in eastern Ohio. The Gavin power plant in southeast Ohio burns coal supplied to the plant by a conveyor from 10 mi. (16 m.) away.

IMPACT OF CLIMATE CHANGE

Ohio experienced the effects of higher temperatures in 1993. While other states flooded, Ohio had the driest August on record since 1895. While climate models vary on the amount of temperature increase possible, potential risks include having decreased water supplies, increased risk for wildfires, population (both human and animal) displacement, changes in food production (with agriculture improving in cooler climates and suffering in warmer climates), and changes in rain patterns to downpours, with the potential for flash flooding and health risks of certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents, and heat-related illnesses. Warmer temperatures can cause heat-related illnesses and lead to higher concentrations of ground-level ozone pollution, causing respiratory illnesses, especially in Ohio's major cities, where air pollution problems already exist.

Higher temperatures and more frequent heat waves could raise average summer temperatures in Cleveland to Cincinnati's level, and Cincinnati's summer temperature to Atlanta's levels. With increased rain, the state's water supply would recharge, potentially causing increased soil erosion, providing additional flooding in places where flooding already occurs on an almost annual basis. Warmer temperatures would increase summer soil temperatures and increase evaporation rates, possibly requiring costly investment in irrigation systems. The coal mining and utility sectors would suffer losses with increasing global warming mitigation. Metal industries would particularly benefit from increased demand for metals, machinery and other components that would result from increased demand for products such as wind turbines and energy-efficient equipment. The increase in demand for alternative fuels such as ethanol would benefit the state's agricultural sector. Ohio is the nation's sixth largest corn producing state, and because of its location, it can easily serve the east coast.

ADDRESSING HUMAN-INDUCED CONTRIBUTIONS TO CLIMATE CHANGE

Based on energy consumption data from Energy Information Agency released June 1, 2007, Ohio's total carbon dioxide (CO_2) emissions from fossil fuel combustion in million metric tons for 2004 were 261.96, made up of contributions by source from: commercial, 11.43; industrial, 38.08; residential, 20.30; transportation, 71.16; and electric power, 120.98.

Ohio joined the Climate Registry, a voluntary national initiative to track, verify, and report greenhouse gas emissions, with acceptance of data from state agencies, corporations, and educational institutions beginning in January of 2008. Ohio legislators in the 2007–08 General Assembly will be considering a bill to form the Ohio Climate Commission to study impacts of global warming on the state, to recommend the appropriate state response to global climate change and associated impacts. Ohio has a long shoreline on Lake Erie, but the lake's water quality deteriorated so badly as a result of industrial and urban wastes that the fish population has declined. Efforts by the United States and Canada to clean the lake have shown results.

Current regulations in place require Ohio electricity suppliers to provide their customers with periodic environmental disclosure labels at the beginning of each calendar year, with quarterly disclosures in March, June, September, and December comparing actual environmental data and projected data. These disclosures indicate the generation resource mix and environmental characteristics associated with the electricity for which the customers are paying. Information supplied by the U.S. Department of Energy for 2005 indicated electric generation in Ohio originated from the following resources: 87 percent coal, 9 percent nuclear, 2 percent natural gas, 1 percent petroleum, and 1 percent hydroelectric and renewables. Although Ohio has historically relied to a great extent on coal-fired generation, the majority of new facilities constructed in Ohio over the past few years have been natural gas-fired. In addition, the Ohio Biomass Energy Program (OBEP) has been working to promote the use of biomass in Ohio.

Ohio State University

OHIO STATE UNIVERSITY (OSU), founded in 1870, is one of the United States' premier academic institutions for the study of global warming and climate change. Researchers and students strive to slow the climate change process, seeking alternative forms of energy, and affecting policy decisions in Ohio and beyond. The university has many well-known climate scientists, including Dr. Ellen Mosley-Thompson and Dr. Lonnie Thompson. OSU is also home to the Byrd Polar Research Center, a collaborative effort of polar and alpine scientists to understand global warming and climate change. In recent years, Ohio University has moved toward building new structures that meet the energy-saving guidelines of the Leadership in Energy and Environmental Design (LEED) program. Ohio State University focuses a significant amount of resources on comprehending climate change mechanisms and searching for feasible solutions.

Ohio State University features many majors, graduate degrees, programs, and co-curricular activities to educate students about the problems associated with global warming, the processes that cause climate change, and ways to mitigate the effects. Majors in the School of Environment and Natural Resources, the Department of Geography, the College of Math and Physical Sciences, and the College of Engineering have climate change components. OSU hosts an interdisciplinary Environmental Science Graduate Program that combines the physical, biological, and social sciences to address environmental research needs. This is one of the only programs in the nation of its kind. The Honors and Scholars Program expanded to include the Environment and Natural Resources Scholars program, which caters to high-ability undergraduate students with an interest in the environment, regardless of major. OSU is moving toward an academic curriculum that places global climate change and environmental issues at the forefront of teaching and research.

Two professors who work to better understand climate change are Dr. Ellen Mosley-Thompson and Dr. Lonnie Thompson. Ellen Mosley-Thompson is a professor in the Department of Geography and with the Environmental Sciences Graduate Program. Her research focuses on paleoclimatic reconstruction of chemical and physical properties in preserved ice cores. She is a fellow of the American Association for the Advancement of Science, has received multiple Distinguished University Awards, and, in 2003, she was inducted into the Ohio Women's Hall of Fame. Dr. Lonnie Thompson, professor in the School of Earth Sciences, is a member of the Ice Core Paleoclimatology Group. He is a Distinguished University Professor; in 2005, Thompson received the Tyler Prize for Environmental Achievement, which is considered by many in the field to be the equivalent of the Nobel Prize. His work is highlighted in Al Gore's documentary *An Inconvenient Truth*, and he is also a fellow of the American Association for the Advancement of Science. Both Dr. Mosley-Thompson and Dr. Thompson work with the Byrd Polar Research Center at OSU.

The Byrd Polar Research Center is an international leader in global climate change, polar, and alpine research. The center is named for renowned polar explorer Admiral Richard E. Byrd. Scientists, faculty, and students interact to further understand what the Earth's climate was like millions of years ago and how it is changing. Researchers collect an enormous amount of data, including ice-core samples, fossils, and evidence of change in geochemical and hydrological cycles. The center also uses satellite-generated images and computer models to construct detailed information about cloud formation, glacier size and movement, and storm system development.

Ohio State University has initiated the development of two green buildings on campus. The first building is the Nationwide and Ohio Farm Bureau 4-H Center. It opened in early 2008. This building includes carbon-reducing features, such as geothermal heating, the use of recycled rainwater, and environmentally-sound building materials. The student union, known as the Ohio Union, is under construction. The new Ohio Union will feature a location that discourages driving and encourages public transportation and walking, energy-saving lighting, and the reuse of existing union building materials. This building will open in 2010.

Oil, Consumption of

IN 1970, THE United States became unable to meet its total oil energy needs, and became an oil-importing nation. Until then, American oil fields in Texas, Louisiana, and California had been able to meet the national need. By 2012, it is likely that the world as a whole will consume around 100 million barrels of oil per day. Humans have known about oil and some of its uses for millennia, but it only became identified as a consumable unit, in terms of extraction, refining, and then commercial use, in the late 19th century. The first commercial oil wells were in Pennsylvania; the industry soon spread to Ohio, and then jumped south and west to the Gulf Coast, which still has the bulk of U.S. oil refineries.

HISTORY OF OIL CONSUMPTION

American and British engineers led the way in searching for new deposits of oil around the world, a process that rapidly accelerated around 1900. By then it had become obvious, to engineers at least, that oil was a safer (on average), cleaner, and smoother form of energy than that produced by coal. Big Coal remained dominant at the start of the 20th century, and most Americans continued to heat their homes with coal well into the 1930s, but those who switched over to oil found it cheaper, easier, and safer to use.

World War II proved an immense boon to the oil industry, both American and foreign. Thousands of new engineers received on-the-job training during the war, and governments as different as those of Nazi Germany and the United Kingdom perceived the need for more oil, something made evident by the dramatic success of Blitzkrieg, the German method of lightning warfare made possible by use of the combustion engine. The Age of Oil began sometime in the 1940s, and shows no sign of retreating today.

The 1950s and 1960s were, for American consumers, a golden age of oil use. Whether it was for the gas that ran their automobiles, or for home heating, oil cost Americans about $.25 a gallon, amazingly cheap by today's standards. Vehicles produced in the 1950s and 1960s reflect this fact; Americans delighted in long, over-built cars, complete with fins and tails. Few people worried, or even thought, about the future of oil consumption, for it seemed that there was plenty of oil to go around.

The switch from coal to oil was complete by the 1960s, with the vast majority of Americans heating their homes with oil. It was just about the same time that the nation, and much of the world, suffered through the coldest decade of the 20th century. Little-discussed today, the winters of the 1960s were so severe that some people, including scientists, spoke of a coming ice age (those discussions were renewed during the brutally cold winters of 1978, 1979, 1982, and 1983). Americans did not feel the pinch during the 1960s because gas and home heating oil remained at roughly the same low prices during that decade, but their European counterparts saw the prices of the same commodities double in the 1960s. By 1970, Europeans were making smaller, more fuel-efficient automobiles, while the American auto industry continued to go for size and impressive performance on the highway.

In many ways, the great turning point was in 1970. By that time, Americans were consuming about 8 million barrels of oil a day, and, for the first time, the nation became a net importer of oil. Americans were mildly surprised to learn that the great Gulf Coast oil fields and refineries were no longer able to meet the national energy needs, but there was little concern because the oil importing nations, such as Iran, Iraq, and Saudi Arabia, did not immediately raise their prices. Those nations lowered the boom in winter 1973–74, imposing the first oil embargo against Western nations that favored the state of Israel in its long struggle with its Arab neighbors. The oil embargo of that season doubled oil prices for Americans, who suddenly paid about $.58 per gallon at the pump, and literally tripled oil prices in many European countries. Of all the industrialized nations, Japan, with no oil reserves whatever, was the hardest hit by the 1973–74 embargo.

Conservation suddenly became the watchword of the day. Americans flocked to buy new, smaller automobiles, and a national campaign to keep thermostats lower had some success. Americans grumbled at the sudden onset of austerity, but throughout the mid-1970s, energy conservation and the exploration of alternative energy sources remained a national priority. American oil consumption remained steady, at about 9 million barrels per day, in the 1970s, and some milder winters (those of 1975, 1976, and 1977) provided some respite from the situation. However, the "failed" presidency of Jimmy Carter (1977–81) proved to be the breaking point, both in terms of the public attitude and public action. Carter came into office wearing cardigan sweaters, and he urged his fellow Americans to do the same. There was some movement toward his position until the Iran Hostage Crisis of 1979–81, which decisively altered American attitudes toward Arab (or in this case Persian) oil-producing nations. American national policy switched from energy conservation to aggressive defense of American oil conduits around the globe.

The 1980s saw a steady rise in American oil consumption, with the nation reaching about 15 million barrels per day in 1986. The suburban minivan appeared on the car market around that time; and the Sport Utility Vehicle (SUV) began to rule the road in the 1990s. After the triumphant result of the First Persian Gulf War, in which the United States led a coalition of forces to defeat Saddam Hussein's Iraq, oil prices fell to their lowest in almost a decade, and did not recover through the entire decade. In 2000, the United States hit a record of 20 million barrels of oil per day (in overall use), and about 50 percent of that was imported. Few concerns were registered at the time.

CONTEMPORARY HISTORY OF OIL CONSUMPTION

Yet all along, there had been the warning issued by geologist M.K. Hubbert back in 1960. Pointing out that new deposits of oil were scarcer by the year, Hubbert predicted that the industrial world would soon encounter oil peak, a moment at which the maximum daily amount could be extracted from the Earth, a moment from which the industrial world would have to accommodate itself to gradually lower levels of oil use. Few people wanted to believe Hubbert's theory, because there seemed to be no good alternative; the world had never enjoyed a fuel so usable as oil; and it seemed unlikely to find another. So, oil use continued to expand, and by about 2005, the rapidly-emerging industrial nations of China and India were together using as much as 10 million barrels a day.

Optimists had, in the past, expressed the view that Third World nations could not compete in the demand for oil because the price would rise so dramatically that they would fall behind. This was proven wrong early in the 21st century's first decade; oil use expanded everywhere, around the globe, and it was apparent that Third World nations, in some ways, had the upper hand. This was especially the case with China, which held a large part of the U.S. national debt.

Europeans and Japanese had long accustomed themselves to driving smaller cars and to making do with alternative methods of home heating, but Americans remained somewhat blasé till the disaster created by Hurricane Katrina in the early fall of 2005. Gasoline prices rose to the highest level ever seen in the United States, sometimes as much as $3.50 per gallon. Public outrage was directed at major oil companies like Exxon and Chevron, but congressional investigations found, as had always before been the case, no obvious evidence of price gouging. Rather, it was concluded, the United States needed a new energy policy.

No new policy emerged during the first 7 years of the administration of President George W. Bush. A former oil man, and with a former oil man as his vice-president, President Bush seemed content to continue in the same direction, with U.S. oil consumption rising to as much as 27 million barrels of oil per day around 2007. Many claimed that this consumption was unsustainable. The nation had to expand its repertoire in the area of energy use. Solar power, wind power, and other alternatives had to be employed before it was too late. Many authors spoke to this belief, two of the best known books being *The Long Emergency* and O*ut of Gas*. However, some claimed that oil was the best source of convertible energy ever discovered, and it had endured through a number of ups and downs in public sentiment since 1970. Oil would continue to be the backbone of American energy use. Some pointed to Jeff Goodell's *Big Coal*, which pointed out the shortcomings and dangers of relying on coal for the foreseeable future.

Most scientists were unsure of the sustainability of oil use. The critical factor was how much oil remained under ground, and how much of it could be rapidly converted into oil and natural gas. If new deposits were found, and if oil-rich nations like Saudi Arabia could be persuaded to pump more barrels per day, then the worldwide use of oil could continue, at least for a few decades to come.

Saudi Arabia remained the biggest single question mark. The House of Saud was notoriously secretive when it came to the total extent of its energy reserves. Some scientists believed that the oil fields of Ghawar, the largest ever found, might still be producing 20 years into the future, while others heeded the words of Matthew R. Simmons, whose *Twilight in the Desert* described what might soon be seen as the Saudi oil collapse. Many people disagreed with Simmons's figures, but they concurred that his statistics were correct, and if Saudi Arabia had to significantly lower its oil output, the industrial world would be shaken. Without enough oil to run its cars, heat its homes, and make numerous oil-rich products, the Western world would be in serious trouble.

Oil continues to have its defenders. There are those who point out, accurately, that oil is safer and cleaner than coal, at least once it is on land (there have been some disastrous spills from oil tankers over the decades). But their arguments run up against some fundamental, painful facts. Oil is running out quite rapidly. It has lasted longer, in some respects, than scientists of the 1970s thought. Oil may remain a big part of the energy use of industrial nations well into the future, but that will only be so if there are other energy sources to complement it. Otherwise, the world's oil reserves will be exhausted at some point in the 21st century.

Oil, Production of

THE PRODUCTION AND consumption of oil are regarded as contributing to global warming and climate change. Associated greenhouse gas emissions and alteration of the landscape in some regions are the contributing factors. Exploration, production, and refining have some impact, but the consumption, through combustion, is occurring at a staggering rate. Air samples, covering many years, have been analyzed from Antarctic ice cores. These data provide a strong correlation between increasing greenhouse gases and increasing supply and demand for oil.

Crude oil is a hydrocarbon fossil fuel also known as petroleum. It is a natural substance that requires millions of years to form or mature. Oddly enough, crude oil is organic, although many think of it as inorganic. It is not renewable, considering the millions of years necessary for it to mature. The maturation process is an environmentally-friendly process because the organic matter decays without releasing gases to the atmosphere. This is known as an anaerobic condition, meaning in the absence of oxygen. In essence, the organic matter does not release carbon dioxide (CO_2)or other gases to the atmosphere while maturing into oil. It is sequestered, keeping its contents locked in place. As time passes, if the deposit of organic matter is buried deeper and deeper, the temperature will also increase, leading to the generation of oil. Therefore, the existence of organic material, lack of oxygen, high temperature, and a long period of time, all combine to create crude oils of different characteristics. Many view crude oil as simply the black liquid extracted from the Earth that is then refined into gasoline. But, it has many uses, from plastics to pharmaceuticals, although it is most known and revered for its energy content. Its use as a source of energy results in greenhouse gas emissions, which are thought to contribute to, or cause, global warming.

CRUDE OIL

The existence of oil has been known for centuries, since there are many natural seeps in the world. The LaBrea tar pit in California is an example of a natural seep. Early use included sealing seaworthy vessels, but demand was minimal until the development of the combustion engine. The growth in demand for gasoline and diesel has driven the exploration, production, and refining of crude oil.

As a fuel, the combustion is an instantaneous oxidation process that then releases heat and greenhouse gases. These greenhouse gases, stored for millions of years, are now being released at an alarming rate. Crude oil was forming and accumulating beginning about 600,000 million years ago. The first major oil company, Standard Oil, was founded in 1870. If it is assumed that global oil reserves will last another 100 years, then the entire recoverable deposits of oil will have been consumed in less than 250 years. So, in a fraction of the history of the Earth, millions of years of stored heat and gas are being released to the atmosphere. Oil is just one of the fossil fuels that have contributed to the greenhouse gas inventory. Natural gas and coal also contribute.

The standard unit of measure for oil is a barrel, which contains 42 gallons. Within a barrel of oil are many different hydrocarbon chains, and although a liquid, a barrel of oil can also contain gases and solids at certain temperatures. Hydrocarbons are molecules of hydrogen and carbon atoms in many different combinations. The longer the chain, the greater the weight, and the greater the number of carbon atoms. The lighter hydrocarbon molecules are the gases, such as methane and ethane. The heavier molecules in oil are known as bitumen or tar. In essence, the heavier the hydrocarbon, the greater the potential greenhouse gas emission, because it is a function of available carbon atoms. However, tar and asphalt are not intentionally burned, but their use as paving and roofing materials also contributes because radiated heat is then trapped by the greenhouse gas effect.

The reserve (supply) of oil is finite, but the amount left in the world to produce is uncertain, and to some degree is dependent on commodity price. There will be new discoveries where oil flows or is pumped in what is known as primary production. There will also continue to be production from old fields through enhanced oil recovery methods. Enhanced oil recovery involves some type of stimulation, usually through improved production technology, that is applied to old fields "squeezing" additional oil out of reservoirs. Increasing price justifies more squeezing and the development of new techniques to recover even more oil. However, at some point in the future, the world annual production will begin to decline. There is more oil being produced today through enhanced recovery then there is from primary production.

One type of enhanced recovery uses carbon dioxide in what is known as a CO_2 flood. The CO_2 gas is injected into oil reservoirs, giving them extended life by increasing the amount of oil production. The gas acts as both a piston to move fluid, and as a cleansing agent to collect oil from rock pores. Much of the CO_2 can be recycled, and, ultimately, a portion could be sequestered in an abandoned oil reservoir.

The American Association of Petroleum Geologists estimated that the cumulative world production of oil exceeded 750 billion barrels by 1993. Production since that time has raised the cumulative figure to approximately 1,100 billion or 1.1 trillion barrels. This represents a volume of over 42 cubic mi. of oil, equal to covering the state of Illinois in 4 ft. (2.2 m.) of oil. Proven reserves, that is, oil remaining to be pumped out of the ground, are estimated at approximately 1.1 trillion barrels. Assuming that exploration and continued technological advances result in a further 1.1 trillion barrels of oil, ultimately 126 cubic mi. of oil will have been produced. Gasoline accounts for almost half of a barrel, and with other fuels included, such as diesel, the percentage is over 75 percent. The majority of oil produced is combusted and releases greenhouse gases.

OIL BYPRODUCTS, GREENHOUSE GASES, AND GLOBAL WARMING

About 33 percent of the global energy supply is from oil. Gasoline, diesel, and jet fuel are refined oil products and, together, these fuels power the majority of transportation in the world. The greenhouse gases from oil are CO_2, nitrous oxide, and even minor amounts of methane. CO_2 and nitrous oxide are byproducts through combustion. Petroleum fuels are the largest contributor of CO_2; coal is second, and natural gas a distant third. Nitrous oxides are also a significant issue from engine combustion. Conversely, the amount of methane released from oil operations is generally small. Minor amounts may be released during production operations, but usually it is flared if a market does not exist to gather for transmission in a pipeline.

Crude oil also can contain impurities such as sulfur. Sulfurous crude oil is known as sour crude, while oil that lacks sulfur is the more desirous sweet oil. In addition, impurities such as nickel, paraffin, and salts can be present in certain crude oils distributed around the world. It depends on the host environment and the type of organic matter. Oil with significant amounts of impurities creates additional concerns for local environments. Sulfur, in particular, can damage vegetation.

LAND USE ALTERATION

Alteration of landscape through the destruction of vegetation is thought to cause climate change, so the production of oil and the emissions from its eventual combustion are both concerns. The search for oil has literally covered the globe. Geologists and wildcatters have pursued the hunt for oil and natural gas on land and sea in all climates. There is an adage: "oil is where you find it," and the search for oil includes tropical rain forests and arctic tundra. These and other locations create significant challenges to production, while maintaining the ecosystem. To begin the search for petroleum, geologic basins are identified. These are large regions where layers of rock were formed through compaction of sediment and chemical action over millions of years. These regions were subsiding and were seas or swamps, so that sediment (material for rock formation) and organic matter (material for petroleum formation) could be deposited.

These geologic basins exist throughout the world on continents and continental margins. The Gulf of Mexico is a geologic basin that is active today because it is a depression that is collecting sediment from drainage off a significant part of North America. It is also receiving deposits of marine organic matter. The Illinois Basin, on the other hand, has thousands of feet of sediment and organic matter, but has not been an active basin for millions of years. In most regions, the surface conditions are not like the conditions that existed at the time the organic material and sediment were deposited.

When a discovery is made, if economic, it is developed. Development requires building roads, drilling wells, and installing separation equipment, storage facilities, and possibly pipelines. In delicate ecosystems, the development and production can potentially harm that system, changing

The oil industry has worked to reduce and eliminate traces of crude oil in the sea from offshore production facilities.

the landscape, and contributing to climate change. Helicopters are often used to minimize clearing of vegetation and minimizing footprints. Also, drilling technology has improved so that it is now possible to drill a number of wells from one location through a technique known as directional or horizontal drilling.

Other operations also can impact the air and the land. Petroleum may need to be artificially lifted from deep in the Earth. The lifting of petroleum can require enormous amounts of energy. Electricity is used to pump petroleum, and that electricity may come from the electric grid or from generators fueled by diesel or natural gas on location. Over time, the fluid pumped out of the ground will contain an increasing percentage of water and a decreasing percentage of oil. This fluid is separated in the field so that only the oil is transported. The produced water must be properly treated and disposed. Over time, vegetation may be stressed by contaminants related to oil production. Highly mineralized water and sulfur are two potential contaminants that can damage or destroy local vegetation, contributing to a change in the local climate, and possibly the global climate. If not properly cased, well bores can be an unwanted conduit for moving fluid from one rock layer to another, and, thus, saline water can contaminate fresh water. If after abandonment, the integrity of plugging operations is flawed, then near surface aquifers can become contaminated and be a potential threat to vegetation.

Oil is transported for refining by truck, pipeline, and tanker. Tankers can be of enormous size, holding over 2 million barrels of oil. As a comparison, an onshore discovery of one million barrels would be considered respectable today in the United States onshore setting. Albeit small, it might require 20 years to deplete. Although the threat of a supertanker breakup is very low, if such an event were to occur, it would be a concern in the climate change debate. The ocean's plankton create oxygen and its destruction through toxicity or smothering from the oil will kill the plankton. Although a supertanker spill would be a huge scale environmental catastrophe, many can argue that the ocean's massive volumes and surface area reduce such an event to a minor, temporary problem. The oil industry has worked to reduce and eliminate all traces of crude oil in the sea from offshore production facilities. This oil is in trace amounts in the water that is released.

Refineries crack the hydrocarbons into products for marketing. Again, energy is consumed in the process and flares may be needed to burn gases in quantities too small to capture. It is the refined products, primarily gasoline and diesel fuel, that are of concern in the global warming and greenhouse gas debate.

CHANGING ATMOSPHERE

Based on trapped gases in ice cores in Antarctica, there has been a dramatic increase in greenhouse gases in the global atmosphere since the beginning of the Industrial Revolution. Samples indicate that in the last 200 years, CO_2 has increased by 35 percent, methane by 600 percent, and nitrous oxide by 18 percent. Data for CO_2 suggest that about 100 years ago there was an increase in the growth rate of atmospheric concentration, followed by another rate increase beginning about 50 years ago. About 50 years ago, the world consumption of hydrocarbons, combined oil and gas, surpassed coal in terms of energy content. The trend appears to be growing at an increasing.

A number of factors and processes unrelated to oil contribute to the rise in greenhouse gases, but the combustion of oil contributes to the concentration of CO_2. The production of oil also contributes to atmospheric methane through the escape of light end hydrocarbons in the logistics. A portion of nitrous oxide gas is also indirectly produced as a result of oil in the form of fertilizers and exhaust from gasoline and diesel engines.

CO_2 is the major source of greenhouse gas. It is possible to use CO_2 in the production of oil from mature oil fields where production is marginal. This is known as enhanced oil recovery in a process known as a CO_2 flood. The CO_2 is pumped into the reservoir where it moves fluid by expansion and pressure, and by acting as solvent, collecting oil in the gas. The fluid is then brought to the surface where the CO_2 is recycled to continue the process. Long-term, the CO_2 is sequestered in the reservoir so that it is not part of CO_2 inventory in the atmosphere.

Oklahoma

OKLAHOMA HAS AN area of 69,903 sq. mi. (181,048 sq. km.), with inland water making up 1,224 sq. mi. (3,170 sq. km.) Oklahoma's average elevation is 1,300 ft. (396 m.) above sea level, with a range in elevation from 289 ft. (88 m.) above sea level at Little River, to 4,973 ft. (1,516 m.) above sea level at Black Mesa in the Panhandle. The topographic features include the Interior Plains, making up the largest part of the state (hilly with changes in elevation to the High Plains); Coastal Plain (relatively flat and sometimes swampy); and the Interior Highlands (mountains, ridges, and valleys). Oklahoma has numerous smaller rivers and two major tributaries of the Mississippi River (the Arkansas River and Red River). The larger lakes are man-made by dams to control navigation, decrease flooding, and improve the water supply.

Oklahoma's climate conditions vary depending on the time of year and region of the state; it is warm and dry in most of the state. Northwestern Oklahoma is cooler and drier than southeastern Oklahoma. Temperatures range in the extremes from below 0–100 degrees F (minus 17 to 38 degrees C). The highest temperature recorded in the state was 120 degrees F (49 degrees C) on June 27, 1994 and the lowest temperature recorded in the state was minus 27 degrees F (minus 33 degrees C)on January 18, 1930. Oklahoma occupies a transitional precipitation zone, with a humid sub-tropical east and a semi-arid west. The length of growing season, in the warm and wet southeastern Oklahoma, averages 238 days, in the colder dryer panhandle the growing season lasts only 168 days. The amount of precipitation varies; the southeastern part of the state averages 50 in. (127 cm.) of moisture per year, and the Panhandle averages 15 in. (38 cm.) of moisture in the year.

Major industries include agriculture (wheat, corn, hay, and melons). Oklahoma ranks fourth in the United States for cattle production and second in the production of wheat. The state is rich in fossil fuel deposits (petroleum, oil, natural gas, and coal). The Arkansas River contains a system of lakes and dams to control flooding, ensure waterway transportation, provide water, and generate hydroelectric power. The largest aquifer in the world, Ogallala Aquifer, lies underground beneath eight states, including Oklahoma. The level of water in the aquifer has been dropping steadily for decades, and it is a limited resource. With conservation measures, the rate of depletion has slowed, but not stopped.

IMPACT OF CLIMATE CHANGE

Oklahoma experiences periodic droughts, occurring particularly in semiarid areas of western Oklahoma, the most famous of which occurred during the Dust Bowl. The Dust Bowl is the name coined for the seven-year period of severe drought that affected areas of the Midwest during the 1930s. A combination of below-normal rainfall, higher summer temperatures, strong winds, and erosion-causing agricultural and ranching practices devastated fertile land. Topsoil from Oklahoma and other states was picked up by the wind and carried away.

Climate models vary on temperature increase for Oklahoma, from 2–6 degrees F (1–3 degrees C) in the winter, from 1–5 degrees F (1–2.7 degrees C) in summer and fall, and from 1–4 degrees F (1–2 degrees C) in spring by the end of the century. Potential risks include possible increase in frequency and intensity of summer thunderstorms; decreased water supplies (eastern Oklahoma has plentiful surface water for supplying Oklahoma City, western Oklahoma relies on groundwater for irrigation, and the panhandle relies on groundwater from the Ogallala aquifer); flooding in urban areas and along tributary streams, more intense rains would increase contamination of water supplies by erosion, chemicals, and runoff from mining, oil, and gas areas. Temperature changes could decrease wheat yields and cause drier conditions. This could lead to drier soil, and a need for additional irrigation. Health risks include certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents, and heat-related illnesses.

ADDRESSING HUMAN-INDUCED CONTRIBUTIONS TO CLIMATE CHANGE

Based on energy consumption data from the Energy Information Agency released June 1, 2007, Oklahoma's total carbon dioxide emissions from fossil fuel combustion in million metric tons for 2004 were 98.97, made up of contributions by source from: commercial, 2.31; industrial, 19.79; residential, 3.72; transportation, 28.92; and electric power, 44.23. All areas had improved over 2003 estimates. Oklahoma ranks eighth in the nation in terms of its potential to produce wind energy, with the ability to provide 17 times the state's entire annual electricity consumption through well-sited wind farms.

Oklahoma joined the Climate Registry, a voluntary national initiative to track, verify, and report greenhouse gas emissions, with acceptance of data from state agencies, corporations, and educational institutions beginning in January of 2008. A number of private-sector initiatives to reduce carbon pollution have been started in Oklahoma, inspiring the use of renewable and alternative forms of energy. In 2001, the state passed the Oklahoma Carbon Sequestration Enhancement Act, a voluntary program allowing agriculture and industry to join forces in reducing harmful carbon pollution by restoring vegetation that absorbs carbon dioxide in the soil. The principal soil conservation effort is directed toward covering the badly eroded lands with pasture grasses or trees to prevent further soil removal. Contour plowing, strip cropping, terracing, crop rotation, no-till farming, and other soil-conserving measures are also actively encouraged.

Oklahoma lawmakers have shown their reticence to implement climate-change reduction schemes before adequate research is completed. Republican U.S. Senator James Inhofe, representing Oklahoma, is concerned with the implications of creating federal laws with economic impact to address the global warming issue. Inhofe is skeptical of the impact of human action on global warming, and has submitted arctic climate assessments from a variety of scientists for support of current global warming being part of a natural cycle. When Representative Dennis Adkins, Oklahoma's state house energy chairman, testified in Washington, D.C., he indicated federal global warming legislation passed in a hurry could be costly to the economy and the people. He also pointed to advances that Oklahoma and other states are making with renewable energy options and their limitations. He urged federal lawmakers to consider the impact of regulations on the economy and the environment.

Oman

THE SULTANATE OF Oman, located on the Arabian Peninsula, has a land area of 119,498 sq. mi. (309,500 sq. km.), with a population of 2,595,000 (2006 est.), and a population density of 21.5 people per sq. mi. (8.3 people per sq. km.). The country is largely covered by arid desert. However, there is heavy subsistence farming throughout the country. Oman's economy is dominated by the petroleum industry, although the government has sought to diversity the economy to remove its dependence on oil for its power industry. In spite of its small population, Oman contributes to global warming, with the per capita emission of carbon dioxide at 5.6 metric tons in 1990, rising to 6.1 metric tons in 1992, 7.3 metric tons in 1995, 8.7 metric tons in 1999, and 12.5 metric tons in 1993.

The generation of electricity in Oman comes entirely from fossil fuels, with the production of electricity making up 30 percent of the country's carbon dioxide emissions. An increase in the electricity network was implemented in the first and second Five Year Plans undertaken by the Omani government in 1976–80 and 1981–85, respectively. In addition, 28 percent of emissions came from manufacturing and construction, 17 percent from non-electricity energy industries, and 12 percent from transportation. Some 58 percent of Oman's carbon dioxide emissions come from gaseous fluids, with 28 percent from liquid fuels, and 11 percent from gas flaring. Coral reefs off the coast of Oman, located in both the Gulf of Oman and the Indian Ocean, have experienced serious bleaching as a result of a rise in water temperature.

The Oman government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. They accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on January 19, 2005, which took effect on April 19, 2005.

Orbital Parameters, Eccentricity

THE SUN SHOWERS the Earth in solar energy with varying intensity over time, while the Earth's orbital motion about the Sun affects how that energy is received. Eccentricity is the degree that the orbit deviates from a perfect circle. Seasons on Earth are modulated by the eccentricity of the orbital path around the sun, the precession effect, and the position of the solstices in the yearly revolution. Eccentricity plays not only a role in the diversity of the seasons, but also in the degree of climate change affecting Earth over the long term.

Johannes Kepler (1571–1630) discovered, through astronomical observations, that the Earth moved in an elliptical path around the sun. This could be expressed mathematically, and one of the parameters, eccentricity, ranges between a value greater than zero and a value less than one. A zero value produces a perfectly circular orbit, while unity ensures a parabolic encounter with the sun of a celestial body, such as a comet, that will never return. The smaller the value of eccentricity, the more circular is the orbit. Earth's eccentricity has been measured to be 0.0167 and so its orbit is not quite circular.

A not quite circular orbit means that the Earth is closer to the Sun at some times of the year, and farther away during other times. The perihelion, the closest approach to the sun, happens in January. This results in Northern Hemisphere winters that are slightly milder than if the orbit was perfectly circular. Over time, changes in the occurrence of perihelion, called the precession of the equinoxes, takes place every 22,000 years. This means that 11 millennia from now, the perihelion will occur in July instead of January and produce seasons even more severe than they are today.

KEPLER'S LAW OF EQUAL AREAS

Kepler's Law of Equal Areas says that an imaginary line drawn from the center of the Sun to the center of the Earth will sweep out equal areas in equal time intervals. This means that the duration of the seasons is proportional to the area of the Earth's orbit swept between the solstices and equinoxes. Consequently, when eccentricity is greatest, seasons occurring furthest away, at aphelion, are longer in duration. Northern hemisphere summers are slightly longer than the winters, because summer occurs at aphelion, when the Earth is furthest from the Sun and moving at its minimum orbital velocity. In 2006, summer was almost five days longer than winter. However, changes in the Earth's orbit over time will alter the location of the solstices and equinoxes. Eventually, Northern Hemisphere summers will become shorter, and winters will become longer, alternating duration, and changing how much solar radiation is absorbed by the Earth's surface. Any cooling effect derived from such changes will be negated by an eccentricity that will be almost reduced by a factor of two. A reduction in the average orbital radius tends to raise average surface temperatures in both hemispheres and cause changes in climate for thousands of years. Global warming ebbs and flows over a millennial time scale.

Planetary eccentricity is modulated by the gravitational pulls among the planets in the solar system. Earth's eccentricity alternates between nearly zero, to almost 0.0500. Consequently, the eccentricity of Earth's orbit is governed by the mathematical timing of 100,000- and 400,000-year periods. This, in turn, affects the strength of the Earth's seasons. Coupled with the varying tilt of the Earth's axis over time, and the changing precession of the Earth's orbit, the changing severity of summer and winter throughout the ages is thought to control the expansion and contraction of the polar ice sheets. Cooler summers in the Northern Hemisphere enable snow and ice to last longer. Since the greater land mass is located there, huge ice sheets over thousands of years are built up, covering the darker land and reflecting more sunlight. This process tends to lower the Earth's average surface temperature. On the other hand, warmer summers in the future will contribute to shrinking ice sheets, uncovering of landmass, and the absorption of more solar energy rather than its reflection. The average surface temperature of the Earth will rise.

Whatever the conclusion as to the ultimate cause of global warming, the orbital mechanics of the solar system will play a big role over the long-term. Such factors as eccentricity are understood, but there is little humanity can do to control the motion of the Earth.

Orbital Parameters, Obliquity

THE EARTH'S ORBIT and orientation around the Sun affects how solar energy is received. Obliquity is the degree of the Earth's tilt as it completes its daily rotation and yearly revolution around the Sun. It is the angle an imaginary rotational axis would make with the plane of the Earth's orbit. The axial tilt, which varies over time from 21.5 to 24.5 degrees and back again, is the reason for the seasons. A complete tilt cycle takes 41,000 years to complete. In concert with the eccentricity of the orbital path around the Sun and the precession effect, obliquity is a factor of climate change affecting Earth's average surface temperature over the long term.

Chinese astronomers in the 11th century determined Earth's obliquity of the ecliptic. They observed that during the changing seasons, the extreme northern and southern declination of the Sun defined the obliquity. Astronomers also deduced that the difference of the peak height of the Sun on the longest day and shortest day of the year was double the obliquity factor.

The Earth's obliquity is about 23 degrees and 26 minutes. Its axial tilt is consistent during the year as it revolves around the Sun. During an annual orbit, each hemisphere alternates between being tilted towards the Sun and then tilted away from the sun. This changing exposure to the direct rays of the Sun is the cause for the seasonal variety and why the Northern Hemisphere enjoys summer while the Southern Hemisphere experiences winter, and vice versa. The half of the Earth's sphere tilted toward the Sun receives more sunlight in a given day and accepts it an angle closer to the vertical. The longer days and more direct rays of light deliver more heat, which contributes to global warming. Fortunately, the Earth is currently in an orbital cycle where the summer-time tilt occurs when it is furthest from the Sun, thereby moderating potential temperature extremes.

Obliquity is a major factor in climate change with the ebb and flow of ice ages on a planetary scale. When obliquity is low, the higher latitudes receive less solar energy. The days are shorter and the sunlight is less direct. The loss of summer heat is much greater than the milder winters experienced during periods of lower obliquity. Furthermore, the warmer winters do not reduce the snowfall enough in the higher latitudes to offset melting. Over time, ice ages dominate the Northern Hemisphere and as the obliquity increases again, interglacial periods return. Earth is currently experiencing one of these interglacial cycles.

Earth's tilt, or the obliquity of the ecliptic, changes over time. The effect is gradual and its changes are not felt on a daily or yearly basis, but on the scale of thousands of years. Although the obliquity and the precession of the equinoxes are related, their respective movements are independent of one another. The tilt is a back and forth movement in a plane perpendicular to the orbital plane, while the changing of the equinoxes is a wobble, or circular rotation, about a plane at right angles to the line of axial tilt.

Milutin Milankovitch (1879–1958), a mathematician, looked for patterns in Earth's orbital variations.

He determined the amount of light energy received for each aspect of Earth's orbital variations, including its tilt. In his 1930 book, *Mathematical Climatology and the Astronomical Theory of Climate Change*, Milankovitch claimed that ice ages occurred when variations in the Earth's orbit caused the landmass-laden Northern Hemisphere to receive less sunshine during the summer months. Such shorter and cooler summers left some winter snow for the following winter to build upon, thereby accumulating thick ice sheets over the years. The snow's white reflective surface would redirect solar radiation back into space and average surface temperatures would continue to drop over the millennia. An ice age would eventually dominate the Northern Hemisphere. Milankovitch predicted ice age cycles overlapping every 100,000 and 41,000 years, with additional mini-cycles occurring every 19,000 to 23,000 years.

The directional angle that Earth's rotational axis tilts defines, in part, these extreme cold periods and the relatively warm periods the planet experiences. The rare warm period currently being experienced has led to the rise of human civilization on Earth. The complex interaction of orbital variations, solar intensity, and the unprecedented increase in greenhouse gas concentrations in the atmosphere is yet to be fully understood. While humanity cannot control celestial mechanics, it can modify its own behavior when it comes to greenhouse gases emissions.

Orbital Parameters, Precession

THE ORBIT AND rotational behavior of the Earth moving about the Sun affects the amount of solar energy received. Precession is the phenomenon where the Earth wobbles about on its axis, just like a spinning top. Consequently, the solstices and equinoxes occur earlier each year. The winter solstice occurs a few weeks before perihelion, the closest approach Earth makes to the Sun. Over time, the summer solstice will occur closer to perihelion and the summer heat will become even greater. This precession of the equinoxes takes 25,800 years to complete. During the period of a precessional cycle, the North Pole follows a circle in space, perpendicular to Earth's imaginary axis of rotation. In concert with the eccentricity of the orbital path around the Sun, and the varying tilt of the Earth's axis in space, precession is a factor of climate change affecting Earth's average surface temperature over the long-term.

The Greek astronomer Hipparchus (c.190–c.120 B.C.E.) compared astronomical observations 169 years apart, and found that the Earth's axis around which the night sky appeared to rotate shifted gradually. He discerned a 2-degree shift by looking at the Earth's shadow on the moon during a lunar eclipse. From this observation, Hipparchus could determine the Sun's position among the stars and identify Earth's changing axial position.

Earth is not a perfect sphere and its equatorial bulge is a factor in the precession phenomenon. Centrifugal force generated during Earth's daily rotation creates the bulge and provides the force that wobbles Earth ever so slightly. The gravitational forces of the moon (responsible for the tides) and the Sun (responsible for Earth's orbit) on the bulge provide the impetus for Earth's precession.

The Earth achieves perihelion on January 3rd, which is close to the Northern Hemisphere's December 21st winter solstice. This timing of Earth's closest approach to the Sun and the shortest day of the year reduces seasonal differences in the amount of solar radiation received by the Northern Hemisphere. The fact that the Northern Hemisphere is closer to the Sun in winter than in summer, produces a relatively warmer winter, thereby reducing the overall variability of the yearly seasons. By contrast, 11,000 years ago, the Earth reached its closest point to the Sun during the Northern Hemisphere summer, increasing both the summer heat and the overall seasonal variability of Earth's climate.

Changes in Earth's orbital eccentricity over time, by itself, has little impact on the total amount of radiation received. The effect is on the order of .01 percent. However, as the eccentricity cycle is modulated by the precession cycle, the effect can be greater or lesser as time passes. When Earth's orbit is highly elliptical (eccentricity is high), the effect of precession on the seasons is strong. When Earth's orbit is almost circular (eccentricity is low), the effect of precession on the seasons is negligible.

Milutin Milankovitch (1879–1958) understood these changing orbital parameters and saw the effect that the precession of the equinoxes had on climate, as well as the ebb and flow of the ice ages. When climate extremes were maximized by the right combination of factors, including the summer solstice occurring during perihelion, the time was ripe for an ice age. With the corresponding winters colder in the Northern Hemisphere, more snow fell, for a longer duration, overwhelming the extreme season of summer heat and, in turn, feeding the glacial ice sheets. Because snow is an effective reflector of sunlight, the snow-covered landmasses of the Northern Hemisphere did not warm as they once had when winter ended. Milankovitch argued that this was just enough to cause the periodic cycle of the ice ages.

Sediment and ice cores have been a useful tool to find Earth's temperatures for the past half-million years. These datapoints highlight how rare Earth's present warm spell is, allowing human civilization to flourish for the past 11,000 years. This relatively warm period is due, in part, to the wobble of Earth's rotational axis over time. The associated precession of the equinoxes has aligned the Earth-Sun pattern such that the Earth's Northern Hemisphere points away from the hot Sun while it is furthest away from it. This moderates both the summer heat and winter cold to provide a more livable climate.

Oregon

OREGON'S AVERAGE ELEVATION is 3,300 ft. (1,006 m.) above sea level, with a range in elevation from sea level along the Pacific Ocean, to the peak of Mt. Hood at 11,239 ft. (3,426 m.). Mountain ranges, including the Coast Range, and the Cascades, divide Oregon. Inland from the Coast Range of mountains is the Willamette Valley, which includes the Willamette River, flowing toward the Columbia River. The Columbia Plateau is northeast of Willamette Valley and west

Mountain ranges divide Oregon. West of the Cascades, Oregon's climate is moderated by the Pacific Ocean.

of the Cascades. East of the Cascades is high plateau, and the Great Basin, an area of high desert.

Oregon's mountain ranges absorb moisture and precipitation. West of the Cascades, the climate is moderated by the Pacific Ocean, giving cool summers (average summer temperatures below 70 degrees F or 21 degrees C) and mild winters (above freezing even during the coldest months). The Willamette Valley receives almost 48 in. (123 cm.) of rain per year. The Columbia Plateau northeast of Willamette Valley, and west of the Cascades has a mild climate. The Cascades experience below freezing temperatures in the winter months, with heavy snowfall (up to 50 ft. or 15 m.), and snow remains for many months. East of the Cascades and the Great Basin, an area of high desert has dry air and extremes of hot and cold, while receiving less than 10 in. (25 cm.) of rain per year. The highest temperature recorded in the state was 119 degrees F (48 degrees C) on July 29 and August 10 of 1898, and the lowest temperature recorded in the state was minus 54 degrees F (minus 48 degrees C) on February 9 and 10, 1933.

The state supports a population of over 3.5 million people. Forests used for logging cover more than 40 percent of Oregon. The Grand Coulee Dam retains some water from spring runoff for summer use, and supplies hydroelectric energy throughout the west.

IMPACT OF CLIMATE CHANGE

The flood of 1996, caused by a combination of heavy snowstorms followed by warm temperatures and rain, resulted in the overflow of most of Oregon's waterways. Low-lying areas like Tillamook became lakes. In addition to the weather, logging and road-building may have been contributing factors.

Lumber is a major industry and preservation is a concern. Commercial logging started in the 1800s and has claimed 90 percent of the forests that once grew in the Pacific Northwest, creating checkerboards of clear-cut and uncut forest vulnerable to environmental pressures. More than half the remaining untouched forest areas in Olympic National Forest are slated for cutting during the next 50 years, as is 69 percent of the old growth in Oregon's Siuslaw National Forest. Trees absorb carbon dioxide (CO_2), and as more trees are cut, the less CO_2 can be absorbed.

Climate models vary on the amount of temperature increase during the 21st century, from 2.5–10.4 degrees F (1.4–5.8 degrees C). Potential risks include smaller snow pack (average water content of the Northwest snow pack declined by 30 percent between 1950 and the 1990s); rising sea levels between 4–35 in. (10–89 cm.); decreased water supplies; increased risk for wildfires; population displacement; changes in food production (with agriculture improving in cooler climates and decreasing in warmer climates); and changes in rain patterns to downpours, with the potential for flash flooding and health risks of certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, rodents; and heat-related illnesses.

With a predicted decrease in Cascade snow pack, access to fresh water will diminish and affect crops, forests, and potable water supplies, and possibly cause decreased hydroelectric output. Rising sea levels will change the coastline, including beach erosion and land loss, making infrastructure (roads and buildings) vulnerable with the possible displacement of populations. The impact of climate change on agriculture will be mixed; some crops, like potatoes and wine grapes, could be negatively impacted by rising temperatures, decreasing yields. By comparison, the orchard crops will mature more quickly at higher temperatures, with increased quality and market share value. Some areas may need to change crops for those with higher drought resistance and adaptability to a warmer climate.

ADDRESSING HUMAN INDUCED CONTRIBUTIONS TO CLIMATE CHANGE

Based on energy consumption data from Energy Information Agency, Oregon's total CO_2 emissions from fossil fuel combustion in million metric tons for 2004 were 42.50, made up of contributions by source from: commercial, 1.78; industrial, 7.32; residential, 2.58; transportation, 22.80; and electric power, 8.03. In 1997, the state legislature adopted a CO_2 emissions performance standard of 675 pounds of CO_2 per MWh for electric generating units. Oregon's Greenhouse Gas reduction target is to stabilize by 2010, fall to 10 percent below 1990 levels by 2029, and fall to 75 percent below 1990 levels by 2050.

Oregon's governor appointed the Climate Change Integration Group in June of 2006 to develop a climate change strategy for Oregon that provides long-term sustainability. Oregon holds member status with the Western Regional Climate Action Initiative, in which the partners will set an overall regional goal for reducing greenhouse gas emissions. Oregon joined the Climate Registry, a voluntary national initiative to track, verify, and report greenhouse gas emissions, with acceptance of data from state agencies, corporations, and educational institutions beginning in January of 2008.

Portland, Oregon is the base for Earth Share of Oregon, a nonprofit federation of 68 local and national environmental conservation groups for workplace fundraising. Founded in 1989 to provide stable funding sources, Earth Share has raised over $8.5 million. Earth Share supports groups seeking to reduce global warming (through tree planting, recycling, proposing energy policies, monitoring industry practices, preserving natural habitats, and ensuring the availability of clean water).

Oregon Climate Service

THE OREGON CLIMATE Service at Oregon State University offers monthly climate statistics for various stations in Oregon. It is located on the Oregon State University campus in Corvallis, Oregon, and is the state depository for weather and climate information. It is affiliated with Oregon State University's College of Oceanic and Atmospheric Sciences (COAS). Oregon Climate Service data may be accessed on the World Wide Web. They include a monthly means and extremes dataset for stations throughout the state for the years 1961–90. Parameters contained in this dataset are mean temperature, extreme mean, precipitation, and degree days. There are also two other monthly datasets dealing with precipitation and temperature for individual years. The time period varies for each observation station. The daily precipitation dataset dates back to 1961 and consists of precipitation evaluations measured in hundredths of an inch for various locations in Oregon. Daily data are also available for Corvallis, Oregon beginning July 1, 1996 to the present.

The OCS mission is to collect, manage and maintain Oregon weather and climate data, to supply weather and climate information to those within and outside the state of Oregon, to educate the people of Oregon on current and emerging climate debates, to perform independent research related to weather and climate topics. OCS liaises with: National Climatic Data Center, Western Regional Climate Center, National Weather Service, Natural Resources Conservation Service, Climate Prediction Center, American Association of State Climatologists and other state climate offices. On average, the Oregon Climate Service receives approximately 6,000 telephone or mail enquires per year. It publishes the Oregon Weather Summary, a monthly report on the current climatic conditions in Oregon. In addition, OCS has published numerous data summaries and special reports, which include climate zone summaries, agricultural regions summary, local climatological data, precipitation maps of Oregon, Oregon counties, U.S. States, and the United States in general.

The OCS is partially funded by the State Government. It has been active in crucial areas of research for the understanding of global warming, such as El Niño/Southern Oscillation and its influence on Western climate, climate change, drought and flood studies, precipitation mapping (the PRISM project), and wind modeling. George H. Taylor is the State Climatologist for Oregon and directs the OCS, supervising its staff of 10. He is in favor of trying to reduce the human impact on climate, but he is not persuaded that anthropogenic greenhouse gases either from coal-fired power plants or motor vehicles emitting carbon dioxide are the main causes. Taylor believes that natural variations and cycles of climate have a bigger role. He describes climate system, as "very, very complex," and states that "the more we learn, the more we see that we really don't understand it." This is why he is skeptical of models that stress human impact on weather as the main cause of global warming.

University of Nottingham

Oregon State University

OREGON STATE UNIVERSITY (OSU) is a four-year research and degree-granting public university, located in Corvallis, Oregon in the United States. Total student enrollment (undergraduate and graduate) is more than 19,000. Eighty-one percent of students are Oregon residents. OSU offers more than 200 academic degree programs and is most noted for engineering, environmental sciences, forestry, oceanography, and pharmacy. The university has more majors, minors, and special programs than any other college in Oregon. OSU is one of only two universities in the United States to be designated as a land-grant, sea-grant, space-grant, and sun-grant institution. Cornell University is the other. The Environmental Sciences (ES) Graduate Program provides curricula leading to M.A., M.S. and Ph.D. degrees in environmental science.

The curriculum integrates thinking across disciplines, especially life, physical, and social sciences. Environmental science explores natural processes on Earth and their alteration by human activity. OSU has exceptional strength in many of the disciplines, including science, agriculture, forestry, engineering, public health, liberal arts, social science, and oceanography and atmospheric science. The degrees administered by the program are OSU's contribution to the Joint-Campus Graduate Program for Environmental Sciences, Studies, and Policy, which links environmental graduate programs among the major research universities in Oregon. The ES Graduate Program develops scientists who will be able to analyze and understand environmental systems, predict environmental change, and participate in the management of the environment. Each student completing a major in the ES Graduate Program will perform research and complete a thesis, dissertation, or research project. Each student will complete a core of ES graduate courses that will integrate concepts across the physical sciences, life sciences, and social sciences. Each student will also develop depth in a carefully designed, interdisciplinary area of concentration or track. Tracks that are currently available include ecology, biogeochemistry, social science, quantitative analysis, water resources, and environmental education.

Oregon State University College of Oceanic and Atmospheric Sciences (COAS) is one of the leading oceanography and atmospheric sciences institutions in the nation. Graduate research programs leading to a Masters degree in science or a Doctoral degree are offered at OSU. Advances in understanding and simulating atmospheric boundary layer processes directly support applications to geographically-localized studies of climate and weather, which is of particular value to agriculture, forestry, and the economic development of the Pacific Northwest. Major research initiatives in the area of climate variability and change require expertise in observing and modeling of physics and chemistry of the atmosphere, and in the modeling and analysis of climate variability.

Courses offered at Oregon State University that focus on Global Warming and Climate Change include the following:

ATS 320: Man's Impact on Climate: Survey the climate and the factors that influence the climate. Examine sources for changes in atmospheric composition, the expected consequences of these changes, problems predicting future changes, and what can be done about the changes.

ATS 412: Atmospheric Radiation: Radiative transfer in the Earth and planetary atmospheres, absorption and scattering of sunlight, absorption and emission of terrestrial radiation, absorption and scattering cross sections for molecules, cloud droplets and aerosols. Applications include enhancement of photochemical reaction rates in clouds, remote sensing, and the Earth's radiation budget, radiative-convective equilibrium, radiative forcing due to changes in atmospheric composition and climate change.

Organisation for Economic Co-operation and Development (OECD)

THE ORGANISATION FOR Economic Co-operation and Development (OECD) was tasked by its founding convention (December 14, 1960) with assisting member countries with sustaining economic expansion, increasing employment, raising their standards of living, and maintaining financial stability while developing a sustainable global economy benefiting humankind. The OECD seeks to meet these goals by the collection, evaluation, and dissemination of pertinent data, by fostering cooperation between governments and economies, and by assisting governments in developing and evaluating policies that positively and negatively impact these goals. In 1961, the OCED absorbed the Organization for European Economic Cooperation (OEEC) that starting in 1947 had administered American and Canadian aid for the post-World War II Marshall Plan reconstruction of Europe.

OECD INSTITUTIONAL ORGANIZATION

The OECD promotes democracy and local, regional, national, and global market economies and maintains co-operative relations with more than 100 countries and economies, including 70 developing and emerging market economies with which it exchanges views and shares its expertise and accumulated experience. The OECD currently has 30 member counties (Australia, Austria, Belgium, Canada, Czech Republic, Denmark, Finland, France, Germany, Greece, Hungary, Iceland Ireland, Italy, Japan, Korea, Luxembourg, Mexico, the Netherlands, New Zealand, Norway, Poland, Portugal, Slovak Republic, Spain, Sweden, Switzerland, Turkey, United Kingdom, and the United States) and invited five more countries (Chile, Estonia, Israel, Russia, and Slovenia) to join in May 2007, and is investigating offering membership to Brazil, China, India, Indonesia, and South Africa. Membership in the OECD is by the invitation of the OECD governing body, the Council. The Centre for Co-operation with Non-Members (CCNM) is responsible for the OECD's relationship with non-members. The CCNMs Global Forums examine trans-boundary issues that impact members and their relationships with non-members.

The Council is comprised of one representative from each member country, plus a representative of the European Commission, and meets per a regular schedule. The OECD Secretariat, who is also charged with accomplishing the Council dictates, chairs the Council. All Council decisions are by consensus. The overall direction of the OECD is set at an annual meeting of the Council attended by member representatives at the ministerial level. The OECD Forum held during the ministerial meeting allows access to OCED ministerial attendees by outside business, labor, and nongovernmental organizations. The OECD is headquartered in Paris, France, and employs a secretariat staff of 2,500, conducting business in French and English, with a 2007 budget of €340 million.

The OECD uses approximately 200 policy-specific committees to review and evaluate all policies and developments pertinent to fulfilling the OECD mission statement. These committees review, evaluate, request, participate in, and contribute to the work of the OECD. Approximately 40,000 senior member state representatives participate in these committees each year and continue their interaction and access to information online through a dedicated and secure OECD internet network. These committees create new rules of governing international co-operation, develop and negotiate formal agreements between countries, develop agreed upon standards, create models, or produce guidelines for all of the topics pertinent to the OECD mission statement.

The OECD monitors and analyzes all events that impact the economies of its member states and the global economy making short- and medium-term economic projections for its member states and the global economy. The OECD Secretariat is responsible for the overall collection, analysis, and dissemination of the data. OECD committees review the data and assess possible national and international policy ini-

The signing of the Organisation for Economic Co-operation and Development (OECD) by 20 countries at the Salon de l'Horloge, Quai d'Orsay, Paris, on December 14, 1960. The OECD currently has 30 member countries.

tiatives based on the data. The OECD Council recommends policy initiatives based on the work of the committees, and governments choose whether or not and how to undertake the policy initiatives. The OECDs four decades of collecting, monitoring, and comparing of economic and social data has made its statistical database of trends, forecasts, and analyses in economics, societal evolution and norms, trade, the environment, agriculture, technology, governmental policies, taxation, poverty, and development the largest in the world.

FULFILLING THE OECD MISSIONS

The OECD seeks to fulfill its missions by concentrating on seven major areas: the monitoring, collection, analysis, and collection of data; assisting constituent and corresponding governments; promoting employment, education, and social welfare; promoting sustained economic development without harming the environment; assisting in financial matters relevant to its mandate; promoting efficiency and fairness in governments and business; and fostering innovation.

The OECD is one of the largest hardcopy and online publishers in economics and public policy and maintains an innovative online library of statistical databases, books, and periodicals, as well as providing online consultations. Key OECD publications include: OECD Economic Outlook; OECD Factbook; OECD Economic Surveys; Going for Growth. The OECD assists constituent and corresponding governments by sharing comparative policy experiences, solutions to common problems, and effective practices and policies. The OECD also seeks to harmonize national and international policies and to coordinate their implementation. The OECD promotes employment, education, and social welfare by advocating policies that foster: equal access to education, accessible quality health care, social inclusion, employment, and the introduction of information technologies to the world's impoverished. The OECD is not a source of funding source and does not grant or lend money.

The OECD promotes sustained economic development without harming the environment by advocating policies that foster: the application of science and technology; creating markets based on sound environmental practices; and decrease over-consumption, pollution, and waste. The OECD also sponsors for its member states discussions on energy issues through the International Energy Agency (IEA) and the Nuclear Energy Agency (NEA).

The OECD Environment Directorate provides governments, policymakers, academics, businesses, and interested parties with the statistical database necessary for evaluating economic and development growth and how this growth or lack thereof relates to governmental policies and innovations. Country performance reviews, policy analyses, modeling, projections, and cooperative approach analyses are examples of the information available. This allows governments and interested parties to compare policy experiences and initiatives so as to improve their own domestic management and international cooperative efforts by learning from the positive and negative policy and practice experiences of others.

The OECD seeks to provide member states and developing countries greater access to financial services. The OECD promotes best practices in the international financial arena, facilitates greater access to financing through investment policy reforms, analyzes the effect of domestic tax structures on domestic markets and labor, and seeks to provide better insurance and pension options for aging populations.

The OECD promotes efficiency and fairness in governance, administration, and management, by encouraging fair competition ethical practices, citizen-participation in policy-making, and fair tax structures. The OECD encourages companies to manage themselves more effectively, discourages corruption, and seeks to make weak public administration more effective. The OECD encourages its committees to mutually examine and evaluate governmental performance through peer reviews.

The OECDs current regional initiatives concentrate on Europe, the Caucasus and Central Asia, Asia, Latin America, the Middle East and North Africa with special attention given to relationships between OECD member states and West Africa. The OECDs Support for Improvement in Governance and Management (SIGMA), a joint venture with the European Union, helps addresses management and governance issues in Central and Eastern Europe. The OECD also assists Brazil, China, and Russia on these issues programs individualized to each country.

The OECD also maintains relationships with various international assemblies, organizations, and bodies, such as the Council of Europe, the Economic Committee of the NATO Parliamentary Assembly, the International Labour Organization, the Food and Agriculture Organization, the International Monetary Fund, the World Bank, and the International Atomic Energy Agency. The OECD cooperates with many United Nations agencies and coordinates the European Conference of Ministers of Transport. The OECD fosters innovation in biotechnology, information and communications technologies, and evaluates the improvement in these areas by setting benchmarks keyed to each country.

The OECD is funded by formalized assessments on its member states that are based on the size of the member's economy. The United States assessment pays for 25 percent of the OECD budget, with Japan paying the second largest assessment. Special projects approved by the OECD Council are funded by contributions designated for the specific programs. The OECDs budget is determined biennially and is audited by the Office of the Auditor-General under the auspices of the OECD Board of Auditors, comprised of four members of national audit offices of member states. The Board certifies the audit to the Council, which, assuming there are no problems, approves the management of OECD.

Oxygen Cycle

THE OXYGEN CYCLE allows for the regeneration of freely available diatomic oxygen (O_2) in the atmosphere. Oxygen accounts by volume for approximately 21 percent of the atmosphere, is reactive with myriad inorganic and organic substances, and is vital to living organisms for aerobic respiration and energy production. The cycle involves any source of oxygen within the world, and is not limited to the oxygen animals must breathe to sustain life; any compound containing an atom of oxygen is considered part of the oxygen cycle. Furthermore, the cycle is composed of many distinct biological and geological chemical reactions that together allow oxygen initially consumed and lost from the atmosphere to be released back into the atmosphere.

These reactions take place among the three different primary reservoirs, or storage areas of all of Earth's oxygen. These storage areas are varied and differ in physical and chemical form. The lithosphere, which contains the vast majority of the Earth's total oxygen, comprises the entirety of the Earth's crust and the uppermost portion of the mantle (tectonic plates can be viewed as lithospheric plates); in this reservoir, oxygen is bound in the form of rocks and minerals, primarily in silica (SiO_2) and alumina (Al_2O_3). The second reservoir is the biosphere, in which all living matter resides, including bacteria, plant life, animals, and human beings. The oxygen bound in this reservoir is found in the macromolecules of life, including nucleic acids, carbohydrates, proteins, and water. The last oxygen reservoir is the atmosphere, which is composed of approximately 20.95 percent oxygen gas, .038 percent carbon dioxide (CO_2), and water vapor (H_2O).

All of the reactions that drive the oxygen cycle occur between any two different reservoirs of oxygen. However, two chief reactions account for most of the activity in the use and regeneration of oxygen on Earth; these are cellular respiration and photosynthesis, both of which occur between the atmospheric reservoir and the biospheric reservoir. Other notable reactions contributing to the cycle include the commonplace reaction between the atmosphere's free oxygen and the lithosphere in the form of the oxidation of minerals and carbon dioxide emissions (for example, from volcanic eruptions). The biosphere and lithosphere interact in the oxygen cycle through weathering and absorbed soil nutrients for organisms and deposition of organism shells and bones into the lithosphere.

The primary action of the oxygen cycle occurs through photosynthesis and cellular respiration. Together, they represent the ability of diatomic oxygen gas to be used and produced by living organisms from the oxygen present in the air. Cellular respiration is the process by which an organism consuming food generates energy to sustain life. Most organisms use oxygen to maximize the amount of energy the food can yield, using oxygen as an electron acceptor in the electron transport chain, and using oxidative phosphorylation. Photosynthesis involves combining atmospheric carbon dioxide with water to generate carbohydrate sources and oxygen gas. The reactions are complementary:

Cellular Respiration: $C_6H_{12}O_2 + O_2 \text{ -> } CO_2 + H_2O$
and
Photosynthesis: $CO_2 + H_2O \text{ -> } C_6H_{12}O_2 + O_2$

There are other reactions involving oxygen that are vital for life that occur within a single reservoir. The ozone-oxygen reactions allow for stratospheric ozone to absorb ultraviolet light radiated from the sun, in addition to the visible light photosynthesis requires, which can cause damage to DNA, and break other important chemical bonds. The net reaction for the generation and breakdown of ozone by the absorption of ultraviolet light is:

O_3 (ozone) + UV Light Energy -> O_2 + O (reactive radical)
O (reactive radical) + O_2 (atmospheric oxygen gas) -> O_3 (ozone)

Other important reactions include the dissolving of oxygen in bodies of water, which allows for aquatic life to undergo aerobic cellular respiration and the evaporation of different bodies of water.

The oxygen cycle is not an isolated system; rather, it has intimate links with many other geological and biological cycles, such as the carbon cycle and the hydrologic cycle. Additionally, other smaller cycling systems, such as the nitrogen and sulfur cycles, require oxygen from the atmosphere, living organisms, or the ground to make their vital nutrients available for uptake and binding to useful substrates. For example, the oxidation of sulfur creates sulfur dioxide, which may then react with water vapor to form sulfuric acid, which can delivered to, and taken up by, plant roots; the sulfur can be used to make cysteine, an important structural amino acid.

Current scientific theories and opinions indicate that the oxygen cycle itself has not always been native to the Earth. In the far geological past, when the Earth was first cooling and forming, the atmosphere contained virtually no free oxygen and was primarily composed of hydrogen and helium gas. As conditions changed, a second type of atmosphere formed, composed of volcanic emissions, still largely devoid of diatomic oxygen gas. While life first developed on Earth, oxygen was released as a waste product from the most ancient forms of life, cyanobacteria. The oxygen cycle, thus, could not have been native to the Earth and must have developed as the Earth matured, because oxygen seemingly was not present. An interesting side note is that if the regeneration of free atmospheric oxygen stopped by cessation of photosynthesis and other oxygen cycle reactions, current estimates indicate that at current rates of oxygen consumption, it would take approximately 5,000 years for the Earth to deplete the atmosphere.

Pacific Ocean

THE PACIFIC OCEAN—named the "peaceful sea" by Ferdinand Magellan, a Portuguese explorer leading a Spanish expedition—is the largest ocean in the world, covering 65.3 million sq. mi. (169.2 million sq. km.), encompassing 32 percent of the total surface of the Earth, and holding 46 percent of the Earth's water. Altogether, there are 25,000 islands in the Pacific, the vast majority south of the equator, which bisects the ocean.

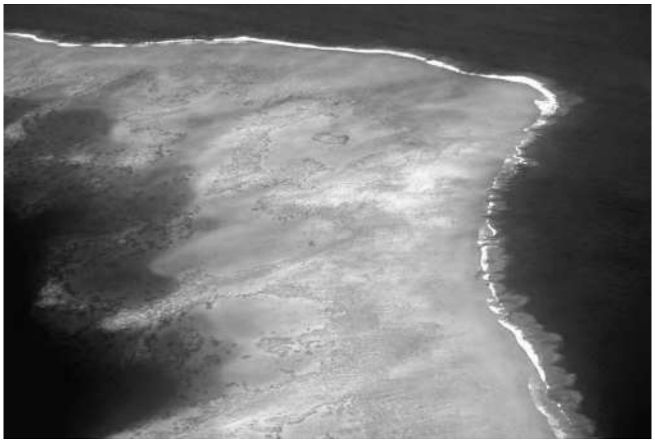
RISING SEA LEVELS

Global warming and climate change pose many real threats to the Pacific Ocean. The major focus of much attention around the world has been on the rising water levels, which is likely to inundate many of the low-lying Pacific Islands. Independent countries such as Fiji, Kiribati, the Federated States of Micronesia, Nauru, Palau, Samoa, and Tuvalu risk losing the vast majority of their land if the rising world temperature continues to raise the water level of the ocean. Atolls in French Polynesia and in Wallis and Futuna are also under threat. In addition to those places, all the countries in the Pacific have an increased risk of flooding, which could lead to permanent soil loss, as well as an increased risk of the prevalence of insect-borne diseases such as malaria and dengue fever as mosquitoes find further breeding grounds. The rising sea levels also threaten mangrove swamps in many areas, including off the northeastern coast of Australia, and in many Pacific Islands, with 13 percent of the world's mangrove swamps at risk of being lost.

For this reason, many of the countries in the Pacific have been at the forefront of urging countries around the word to embrace the Kyoto Protocol and limit carbon dioxide emissions. The Republic of Nauru, the country with the highest per capita rate of carbon dioxide emissions in the Pacific, went as far as adding a long addenda to the Kyoto Protocol, arguing that it did not feel that the protocol went far enough. Two U.S. territories in the Pacific, Guam and American Samoa, have considerable carbon dioxide emissions. The Solomon Islands, Papua New Guinea, and Vanuatu have, respectively, the lowest rates of carbon dioxide emissions in the Pacific, at rates similar to that of many African countries.

CHANGES TO MARINE LIFE

Other problems in the Pacific Ocean regarding global warming focus on the marine flora and fauna. The area most dramatically affected has been the bleaching of coral reefs around the Pacific, with studies by the International Ocean Institute of the University



Reefs in Fiji, in the Pacific Ocean. Global warming and climate change many cause a rise in sea level.

of the South Pacific in Fiji conducting surveys of coral reefs in the southwest Pacific as part of the International Coral Reef Initiative. In many cases, the damage to coral reefs has come from overpopulation, and through overexploitation through tourism, but even many reefs located in remote parts of the Pacific have experienced bleaching, showing that the damage can be ascribed as much to global warming as to other problems.

As well as coral reefs, there have been significant changes to the marine life, especially the fish in the Pacific. The most dramatic changes have been the reduction in the diversity of fish shoals, as well as the decline in the number of fish, the latter probably as much from overfishing as from global warming. However, there still remain large numbers of tuna fish and also some cluepoids in the central part of the Pacific Ocean, as well as sardines and jack mackerel along the coast of Chile, anchovy off the coast of Ecuador and Peru, mackerel and Saury off the Pacific coasts of Mexico and the United States, and sardine and salmon off the Pacific coast of Canada.

Some 4 percent of the ozone in the Earth's stratosphere is lost each decade, and a hole has appeared over Antarctica, leading to a higher risk of skin cancer from ultraviolet light in places such as Australia, New Zealand, Chile, and southern Argentina. Although there has been a great focus on their effects on humans, the ultraviolet rays have also been linked to the reduction in the plankton population in the southern part of the Pacific Ocean. The removal of much of the plankton has major effects on the food chain throughout the Pacific, especially on the whale population, which has been growing following a moratorium on commercial whaling in 1986, although Japan continues whaling for ostensibly "scientific" reasons.

One last major area of problems in the Pacific Ocean through global warming and climate change has been changes in the ocean currents, which have been caused by the rise in the temperature of the water. Although few Polynesians travel long distances in traditional canoes, as they did about 1,000 years ago during the populating of many of the islands, the currents are very important, not just for shipping, but also for the movement of marine life such as shoals of fish. The warmer temperature and changes in the current seem to have had major effects on the spawning process of some fish species, and this may be responsible for a decline in the population of certain fish.

Although there is a serious worry about global warming and its effects on the Pacific Ocean, one report in 1997 by scientists from the Lamont-Doherty Earth Observatory at Columbia University claims that the vast size of the Pacific Ocean has led to the dissipation of many of the effects of global warming and climate change, and might account for the fact that the world's temperature has only risen half the level of that in some projections.

Geelong Grammar School, Australia

Pakistan

PAKISTAN, IN SOUTHERN Asia, is situated on the Arabian Sea. Pakistan shares borders with Afghanistan (to the north and northwest), Jammu and Kashmir (to the northeast), India (to the east and southeast) (796,095 sq. km.) and Iran (to the west). Pakistan has an area of 307,374 sq. mi., and supports a population of approximately 150 million. Pakistan's topography is varied, with mountains to the north and west, and includes four regions: northern plateau, Baluchistan plateau, southeast desert, and Indus plain. The Indus River, the major river in Pakistan, divides the southern part. Only 5 percent of Pakistan's land has forests, although trees are an essential resource for rural communities and wildlife. Extensive logging in northern areas has resulted in slope instability with the potential for soil erosion and water pollution. Overgrazing results in desertification and soil salinity.

Pakistan's climate is mostly dry, with extremes in elevation and temperature. In the mountain regions of the north and west, temperatures fall below freezing during winter; in the Indus Valley area, temperatures range between about 90–120 degrees F (32–49 degrees C) in summer. Precipitation (often in July and August) is scarce in most of the country, ranging from more than 20 in. annually in the Punjab region, to less than five in. in the arid southeast and southwest.

Pakistan already faces complex environmental problems of air, water, and soil pollution, as well as overuse of natural resources causing deforestation, desertification, and energy and water shortages. Ten percent of households lack access to improved water supply, and 38 percent lack improved sanitation. Air pollution and water shortages are common in the south, with increasing health problems. Warmer temperatures could increase the incidence of heat-related illnesses, lead to higher concentrations of ground-level ozone pollution causing respiratory illnesses (diminished lung function, asthma and respiratory inflammation especially in those persons already susceptible), and increase the risk of contracting certain infectious diseases from water contamination or disease-carrying vectors. Rising sea levels associated with global warming will cause problems on the Indus delta and coastal plains with the loss of land, displaced coastal villages, and population displacement. Flooding and storm surges associated with sea-level rise could increase the incidence of water-borne diseases.

Pakistan's environment minister, speaking at the United Nations, voiced concern for climate change impacts on the environment, the economy, and humans. Some problems already experienced include decreased agricultural productivity (arid land and decreasing water supply) and melting glaciers in the Himalayas in the northern part of Pakistan. The minister indicated Pakistan's major goals include water management, improving energy production, changing agricultural practices, tree planting for carbon sequestration, and establishing a committee for research, advising, and action. Like all preparedness measures, financial resources are necessary for development and implementation. While the future is a concern for Pakistan, solutions for current water quality and energy deficiencies are taking priority.

The University of Peshawar is home to the Department of Environmental Sciences (DES), formed by the university in collaboration with the Pakistan government's Environment and Urban Affairs Division in 1987. DES educates at the graduate level and postgraduate level in Environmental Sciences, Public Health Safety, Natural and Occupational Hazards, Applications of Remote Sensing to Environmental Monitoring and Hazard Mapping. The University of Peshawar uses geographic information systems for planning and natural resources management, performs research, and informs government policymakers in sustainable industrial growth, resource conservation, and environmental preservation.

Palau

THE REPUBLIC OF Palau, formerly known as Caroline Islands, is a group of 200 islands located in the Pacific. In total, they have a land area of 177 sq.

mi. (459 sq. km.), with a population of 20,000 (2006 est.), and a population density of 111 people per sq. mi. (43 people per sq. km.). Because of the prosperity of Palau, it has one of the highest rates of per capita carbon dioxide emissions in the world, and is the country with the 15th largest rate of emissions. It was 15.3 metric tons per person in 1990, but was steadily reduced to 12.3 metric tons per person by 2003. Much of this comes from heavy use of electricity in air conditioning, and also, in spite of the size of the islands, relatively heavy use of private automobiles.

Palau is expected to suffer from rising water levels. This will probably lead to the permanent loss of some of the low-lying islands, with the others at risk from flooding. With the country's public water system badly contaminated and posing a serious health risk in January 2002, flooding could overwhelm the water supply for the country, and could cause the spread of insect-borne diseases such as malaria.

The government of Palau took part in the UN Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and it accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on December 10, 1999, with it entering into force on February 16, 2005.

Paleoclimates

PALEOCLIMATES ARE, LITERALLY, past climates. The term "paleo" is, however, normally reserved for those time periods that are prehistorical, although usage of the term to describe climate in the first millennium C.E. and earlier is not uncommon. Like reading a historical text, paleoclimates give glimpses into the varied past of Earth's climate system, and understanding of paleoclimates may well be critical to understanding how Earth's climate will change in the future.

Unfortunately, understanding of this critical climate history does not come easily. Unlike present climate that is carefully recorded and catalogued by various observational and physical measurements, paleoclimate records must be extracted from Earth's geological history; in particular, the archives of sedimentary rocks and large ice sheets. These geological archives do not contain precise measurements of climatic variables such as temperature and precipitation, but rather record environmental responses to ambient climate conditions. As such, the climate indicators extracted from the geological record are known as proxy data.

PROXY DATA

An example of the use of proxy data would be conducting a North American winter snow survey by searching North American garages for snow shovels in the summer. In regions where snow shovels are common in garages, a researcher might reasonably interpret cold winter temperatures and the presence of snow. The shovels, though not actually snow, are a proxy for the occurrence of winter snow. In regions without snow shovels, winter temperatures are either warmer with no snow, or snow is removed in a different way. Because proxy data may be definitive in one sense, but ambiguous in another, using them to decipher the nature of

The Petrified Forest, in northeastern Arizona, has one of the best fossilized records of the Late Triassic period in the world.

paleoclimates requires a suite of data types, or a multi-proxy approach. Fortunately, paleoclimatologists have proven extremely innovative in their development of climate proxies, which range from preserved vegetation in ancient pack rat middens (nests) to the relative abundances of different stable oxygen isotopes (notably ^{16}O and ^{18}O) in the shells of small, ocean-dwelling plankton known as foraminifera.

Some of the oldest proxy data are those related to preserved vegetation. That vegetation may be actual fossils (permineralized plant material or traces of plant material) or simply desiccated (mummified) plant remains, some of which can be tens of millions of years old in cold climates. Vegetation is used as a climate indicator in two primary ways. The first is based on the observation that certain types of plants inhabit certain types of climates. Alders, for example, prefer wetter climates, while Ponderosa Pines thrive in drier conditions. As such, if a plant fossil is found in a given location and there is reasonable certainty that the plant actually grew there, climate in that location can be interpreted based on the known preferences of the identified vegetation.

This is relatively straightforward when the preserved plant material is from a known, living species such as an Alder or Ponderosa Pine. It becomes increasingly difficult further back in geological time when many plants are unknown. In these instances, the climate tolerances of the extinct plant's nearest living relative are used to interpret climate. The other common use of preserved vegetation as a climate indicator is through a statistical process known as leaf margin analysis. Statistical studies of large, modern data sets have indicated that the shape of a leaf's margin (smooth or toothed, elongated or rounded) has some correlation to the climatic conditions that the plant prefers. By performing the same analyses on ancient leaves, scientists can compare ancient leaf samples to the modern climate interpretation and make some assessment of paleoclimatic conditions.

While analyses of preserved vegetation continue to provide significant insight into paleoclimates, more recently, scientists have developed a suite of chemically based climate proxies that make use of the lengthy climate records stored in the sediments of the ocean floor. The most common of these chemical proxies is based on the stable isotopes of oxygen (in particular ^{16}O and ^{18}O, which are the most abundant). Because different isotopes of a given element have different masses, they are relatively easier or harder to evaporate and, inversely, relatively harder or easier to precipitate. This means that water vapor will always have more ^{16}O than the liquid it evaporated from and is, therefore, lighter. Liquid precipitation will always have more ^{18}O than the vapor it condensed from and is, therefore, heavier. These processes can be used to decipher past climate.

For icehouse climates with large, continent-spanning ice sheets, the relative volume of water stored in large glaciers largely influences the oxygen isotopic concentration of global seawater. Because lighter isotopes evaporate preferentially, precipitation is almost always lighter than the global ocean. If precipitation falls as snow and is then trapped as glacial ice, the overall ocean isotopic composition will get heavier as more and more of the light isotope is locked up in growing ice sheets. If climate warms and ice sheets begin to melt, the lighter isotopes are returned to the ocean and the ocean isotopic composition becomes lighter. Thus, changes in the oxygen isotopic composition of ocean water can be tied to growing and shrinking ice sheets and, by extension, cooling and warming climate.

The primary source of information on past oceanic oxygen isotopic composition is the shells of ocean dwelling microorganisms, in particular, foraminifera. Foraminifera create their shells out of calcium carbonate ($CaCO_3$). The oxygen incorporated into the foraminifera shells comes from the ocean water and, therefore, reflects the ocean's oxygen isotopic composition. The exact isotopic ratio of the shell, however, is also influenced by the ambient temperature and, to a lesser and largely negligible extent, salinity, as well as the organic processes of the foraminifera. Empirically derived equations relate the oxygen isotopic composition of calcium carbonate shells to the ocean temperature and oxygen isotopic composition. If any two of those values are known, the third can be calculated. While the isotopic composition of ancient foraminifera shells can be measured in the laboratory, the overall oceanic oxygen isotopic composition and temperature in the past must either be estimated or derived from other proxies.

CLIMATE EXTREMES

This panoply of proxy climate indicators records a startling array of paleoclimates in Earth's history.

Climatic conditions on Earth have ranged from extreme icehouse conditions with, potentially, the entire planet covered in glaciers (a paleoclimate known as Snowball Earth) to extreme hothouse conditions, with atmospheric carbon dioxide concentrations as much as 20 times higher than those at present, and tropical forests extending nearly pole to pole. Earth's climate has also apparently resided everywhere in between these extremes and at times moved rapidly from one to another.

Whether it is because the current climate falls relatively in the middle of the climate spectrum, or because extremes are more likely to be preserved in the geological record, or because understanding of extremes may provide the greatest insight into the climate system as a whole, the extreme paleoclimate events are the most studied. In the realm of extreme warmth, there were the hothouse climates of the Cenomanian/Turonian boundary (90 million years ago) and the Early Eocene Climatic Optimum (52 million years ago), or nearer-term warm climates like the Miocene Climatic Optimum (14 million years ago), the mid-Pliocene warm period (3.5 million years ago) or the Altithermal of the middle Holocene (5,000 years ago).

At the other end of the spectrum lie the extreme cooling of Snowball Earth (630 million years ago), the rapid inception of large Antarctic ice sheets (35 million years ago), or the peak glaciation of the last glacial maximum (18,000 years ago). Equally fascinating, though even more difficult to quantify, are transient or abrupt climate changes such as Pleistocene Heinrich and Dansgaard-Oeschger events where circum North Atlantic temperature changed by as much as 9 degrees F (5 degrees C) in 30 or 40 years or the Initial Eocene Thermal Maximum, when temperatures in the Arctic Ocean reached 73 degrees F (23 degrees C) for 50,000 to 100,000 years. Climate extremes such as these in Earth's history, and incomplete explanations for them, help show that the current climate samples a very finite portion of Earth's climatic possibilities, and if scientists wish to have a solid understanding of what the climate of the future may hold, paleoclimates must first be understood.

Paleozoic Era

THE PALEOZOIC ERA is the earliest of three geologic eras of the Phanerozoic eon. This era spanned from roughly 542 million years ago to roughly 251 million years ago. The Paleozoic era is subdivided into six geologic periods: the Cambrian, Ordovician, Silurian, Devonian, Carboniferous, and Permian. The Paleozoic covers the time from the first appearance of abundant, hard-shelled fossils to the time when the continents were beginning to be dominated by large reptiles and modern plants. The oldest geological period was classically set at the first appearance of creatures known as trilobites and archeocyathids. The youngest geological period marks a major extinction event 300 million years ago, known as the Permian extinction.

At the start of the era, all life was confined to bacteria, algae, sponges, and a variety of enigmatic forms known collectively as the Ediacaran fauna. The Cambrian Explosion resulted in an exponential increase of life-forms. There is some evidence that simple life may already have invaded the land at the start of the Paleozoic, but substantial plants and animals did not take to the land until the Silurian and did not thrive until the Devonian. Although primitive vertebrates are known near the start of the Paleozoic, invertebrates were the dominant life-forms until the mid-Paleozoic. Fish populations exploded in the Devonian. During the late Paleozoic, great forests of primitive plants thrived on land forming the great coal beds of Europe and eastern North America. By the end of the era, the first large, sophisticated reptiles and the first modern plants had developed.

The Paleozoic era began shortly after the breakup of a supercontinent called Pannotia and at the end of a global ice age. During the early Paleozoic, the Earth's landmass was broken up into a number of relatively small continents. Toward the end of the era, the continents gathered together into a supercontinent called Pangaea, which included most of the Earth's land area.

The Early Cambrian climate was probably moderate at first, becoming warmer over the course of the Cambrian, as the second-greatest sustained sea level rise in the Phanerozoic got underway. Gondwana moved south with considerable speed. By the Ordovician period, most of West Gondwana (Africa and South America) lay directly over the South Pole. The Early Paleozoic climate was also strongly zonal. The climate became warmer, but the continental shelf marine environment became steadily colder. The Early Paleozoic ended, rather abruptly, with the short, but apparently severe, Late Ordovician Ice Age. This cold spell caused the second-greatest mass extinction of Phanerozoic time. The Middle Paleozoic was a time of considerable stability. Sea levels had dropped coincident with the Ice Age, but slowly recovered over the course of the Silurian and Devonian.

The slow merger of Baltica and Laurentia and the northward movement of bits and pieces of Gondwana created numerous new regions of relatively warm, shallow seafloor. The far southern continental margins of Antarctica and West Gondwana became increasingly less barren. The Devonian period (410 to 360 million years ago) resulted in diversifiaction of life on the land, including the first terrestrial vertebrates, the amphibians, and the first forests of trees. In the waters fish continued their diversification with the rise of the lobe-finned and ray-finned fish. The Devonian ended with a series of turnover pulses which killed off much of Middle Paleozoic vertebrate life, without noticeably reducing species diversity overall. Global cooling tied to Gondwanan glaciation has been proposed as the cause of the Devonian extinction, as it was also suspected of causing the terminal Ordovician extinction. Rocks in parts of Gondwana suggest a glacial event. The forms of marine life most affected by the extinction were the warm-water to tropical ones.

The Late Paleozoic consisted of the Carboniferous period (360 to 286 million years ago), also known as the Mississippian period. The period began with a spike in atmospheric oxygen, while carbon dioxide plummeted. This destabilized the climate and led to multiple ice age events during the Carboniferous. The supercontinent of Pangaea was assembled during this time, causing the uplift of seafloor as continental land masses collided to build the Appalachian and other mountains. This created huge arid inland areas subject to temperature extremes. The Permian period spanned the time interval from 286 to 245 million years ago. During the Permian the assembly of Pangaea was completed and a whole host of new groups of organisms evolved.

The Permian ended in the greatest of the mass extinctions, where over 90 percent of all species were extinguished. With the assembly of Pangaea and resulting mountain building, many of the shallow seas retreated from the continents. The Permian saw the spread of conifers and cycads, two groups that would dominate the floras of the world until the Cretaceous period with the rise of the flowering plants. The end of the Permian, also the end of the Paleozoic era, was marked by the greatest extinction of the Phanerozoic eon. During the Permian extinction event over 95 percent of marine species went extinct, while 70 percent of terrestrial taxonomic families suffered the same fate. The fusulinid foraminiferans went completely extinct, as did the trilobites. The majority of extinctions seem to have occurred at low paleolatitudes, possibly suggesting some event involving the ocean. The exact cause of the terminal Permian extinction remains unknown; however, many theories have been hypothesized. Regardless, this event proved to be a massive and severe crisis for life. Many groups of organisms went extinct at that time. Surviving groups diversified during the Triassic period and gradually a more modern world developed.

University of California, San Diego

Panama

LOCATED IN CENTRAL America, the Republic of Panama has a land area of 29,157 sq. mi. (78,200 sq. km.), with a population of 3,343,000 (2006 est.), and a population density of 111 people per sq. mi. (43 people per sq. km.). Only 7 percent of the land in the country is arable, the second lowest percentage in Central America, with 20 percent used for meadows and pasture, and 44 percent of the land forested. The level of carbon dioxide emissions in Panama was 1.3 metric tons per capita in 1990, rising to 2.3 metric tons per person in 2001, and then falling slightly to 1.9 metric tons per person by 2003. Most of this comes from liquid fuels, which make up 89 percent of all carbon dioxide emissions from the country, with cement manufacturing contributing 6 percent, and solid fuels (coal and charcoal) contributing another 3 percent.

The Caribbean coast of Panama has long had problems with hurricanes, but the rising water temperature in both the Caribbean Sea and the Pacific Ocean have led to increased worry over flooding, and has caused some bleaching of coral reefs in the Archipelago de Bocas del Toro off the northwest coast of the country. Although some 30 percent of the country has been set aside for conservation, the deforestation of many areas used for pasture has led to soil erosion, which has also helped contribute to the destruction of the mangrove swamps. There have also been effects on the wildlife in the pristine cloud forest on the Quetzal Trail around the Parque Nacional Volcán Barú, and worries about flooding, which in turn could lead to a spread of insect-borne diseases such as malaria and dengue fever.

The Panamanian government of Guillermo Endara took part in the UN Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and that of Ernesto Pérez Balladares signed the Kyoto Protocol to the UN Framework Convention on Climate Change on June 8, 1998. The Kyoto Protocol to the UN Framework Convention on Climate Change was ratified on March 5, 1999, and came into force on February 16, 2005.

Papua New Guinea

LOCATED IN THE Pacific, on the eastern half of the island of New Guinea, Papua New Guinea has a land area of 178,703 sq. mi. (462,840 sq. km.), with a population of 6,331,000 (2006 est.), and a population density of 34 people per sq. mi. (13 people per sq. km.). In spite of having a tropical monsoon climate, only 0.1 percent of the land is arable, with 82 percent of the country forested. Conservationists and environmentalists condemn the rate of the timber logging industry as unsustainable.

Some 55 percent of the electricity in the country comes from fossil fuels, mainly liquid fuels, which account for 93 percent of Papua New Guinea's carbon dioxide emissions. The remainder of the electricity in the country comes from hydropower. Plans to harness the power of the Purari in the early 1970s were shelved, with the Ramu River used to generate hydropower from the 1980s.

The effect of climate change and global warming in Papua New Guinea has been significant. A rise in temperature has led to the bleaching of some coral reefs off the south coast of the country, which has exacerbated the problems from logging and the crown-of-thorns starfish. There has also been a decline in the fish stocks, both in diversity and numbers. In addition, some parts of the country have experienced flooding, which has led to an increase in the prevalence of insect-borne diseases such as malaria and dengue fever.

The Papua New Guinea government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. It signed the Kyoto Protocol to the UN Framework Convention on Climate Change on March 2, 1999, and ratified it on March 28, 2002, with it entering into force on February 16, 2005.

Paraguay

THIS LANDLOCKED SOUTH American country has land borders with Argentina, Bolivia, and Brazil, and covers an area of 157,047 sq. mi. (406,752 sq. km.). It has a total population of 6,036,900 (2003 est.), with a population density of 38.4 people per sq. mi. (14.5 people per sq. km). However, the real population density for much of the country is higher, as the country is bisected by the Rio Paraguay (Paraguay River), and the vast majority of the population lives in the eastern half of Paraguay. Only 6 percent of the land is arable, although 55 percent of it is used for grazing animals.

The main environmental problem in the country is the lack of arable land. This has resulted in deforestation to create more farmland, although officially 35 percent of Paraguay remains forested. The western half of the country, the Chaco Desert, has extremely poor soil and is used for cattle grazing and ranching, but the cattle industry has faced many problems. Even in the more fertile eastern half of Paraguay, the soil is poor, and much of the land is also used for grazing cattle, for which there are 9,400 head per 1,000 people in the country.

The underdeveloped economy and the low standard of living have helped reduce the effect of the country on global warming, with Paraguay ranking 157th in the world for carbon dioxide emissions per capita of 0.5 metric tons of carbon dioxide per capita in 1990, rising to a peak of 0.9 per capita in 1998, and then falling back to 0.7 in 2000–03. Much of this was because of the low use of electricity by the poor in rural areas and in shantytowns, and the relatively low use of cars.

There has been a sharp increase in car usage in recent years that has coincided with a marked decline in public transport. The railway network that covered parts of eastern Paraguay closed down in the 1970s, and only operates a tourist train, leading to an increase in road haulage, and the tram system in Asunción, the capital, was closed for general use in 1995. There have also been few environmental controls in the country. However, Paraguay has been active at the international level, as a member of the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in 1992, and as one of the early countries to sign the Kyoto Protocol to the UN Framework Convention on Climate Change, which was done on August 25, 1998. Paraguay was the 13th country to ratify the Kyoto Protocol, which took place on August 27, 1999.

One of Paraguay's main contributions to reducing the threat of global warming was the construction of the Itaipu Dam, which started generating power in 1982. By 2000, it was supplying hydroelectric power to much of the country, making 93 percent of all electricity generation in Paraguay; and providing 20 percent of the electricity used by Brazil, generating significant income for the Paraguayan economy. Subsequently, work has begun on the Yacyretá Dam, located on the Paraguayan-Argentine border, which will provide electrical power for sale to Argentina.

Penguins

FROM THE TROPICS to Antarctica, penguins depend on predictable regions of high ocean productivity where their prey aggregate. There are between 16 and 19 species of penguins, all generally restricted to the southern hemisphere, with the greatest species diversity found in New Zealand. Changes in precipitation, sea ice, ocean temperature and productivity, and prey distributions associated with

Changes in precipitation, sea ice, and ocean temperature associated with global warming are affecting penguins.

global climate warming are affecting penguins and changing their distribution and abundance. BirdLife International includes climate change among the threats for seven of 10 species of penguin listed as endangered or vulnerable.

The global climate signal is strongest in the Antarctic Peninsula, where air temperature has increased, glaciers have retreated, and ice shelves have collapsed. Adélie and Emperor penguins, the most ice-associated and southerly of the penguin species, are suffering more reproductive failures because of increases in rain and snow, early breakup of ice, and blocking of colony access by icebergs. Gentoo and Chinstap penguins, more northerly and less ice-tolerant, have extended their ranges farther south, but suffer more failures because of increased precipitation. Snow covers nest sites and rain soaks the down of chicks, which then freeze. King penguins, the second largest species, harvested during the whaling era for their oil, have increased and expanded their range northward.

Many of the temperate species of penguins are in decline because of human perturbations including harvest, accidental capture by fisheries, petroleum pollution, breeding habitat destruction, and climate variation that changes the distribution and abundance of their prey. Temperate penguins also suffer from increases in rainfall or air temperatures, as young chicks cannot regulate their body temperatures when their down is wet. Increased frequency of El Niño events associated with global warming reduced Galapagos penguins to about half of what they were in the 1970s. During El Niño, the water warms, ocean productivity declines, and penguins quit breeding, and under the strongest and longest events, penguins die. Peruvian penguins declined after the 1972 El Niño and have never recovered, in large part because the anchovy fishery, the second largest fishery in the world after Alaskan Pollack, harvests much of their prey to make fishmeal.

Patagonian penguins, the most common of the temperate penguins, have declined by 22 percent since 1987 at their largest breeding colony, in Argentina. They swim farther north during incubation than they did a decade ago, likely a reflection of shifts in their prey in response to climate change and reductions in prey abundance due to commercial fishing. African penguins are only 10–20 percent of their previous number, because humans are harvesting more of the ocean's produce than in the 1950s. African penguins are also shifting their breeding locations because of changes in prey distributions linked to climate. Breeding colonies in protected reserves are no longer near sources of food. Ocean productivity will likely continue to decline as climate warms, which is a problem for penguins, as they need areas of high productivity to survive. As global sentinels, penguins are showing that global climate change is creating new challenges for their populations.

Penn State University

PENNSYLVANIA STATE UNIVERSITY (also known as Penn State) is a large public multicampus university with its main campus located in University Park, Pennsylvania. The University has 24 campuses located throughout the U.S. state of Pennsylvania, including a virtual World Campus. The enrollment at Penn State is over 84,000 students, placing it among the 10 largest public universities in the United States. Penn State offers more than 160 majors. Pennsylvania State University ranks in the top five in the world in total number of citations in the area of global warming research. Penn State Institutes of Energy and the Environment is the central coordinating structure for energy and environmental research at Pennsylvania State University.

The concept of the Penn State Institutes of the Environment arose from intense interactions between Penn State's administration and faculty and remains a novel partnership between the two. It is organized under the Office of the Vice President for Research (OVPR) and is designed to position the environmental faculty to compete vigorously in this new interdisciplinary environmental science and engineering prototype. It facilitates environmental research, teaching, and outreach across eight colleges, including the University Park colleges of Agricultural Sciences, Earth and Mineral Sciences, Engineering, Health and Human Development, and the Liberal Arts, plus the Hershey College of Medicine and Harrisburg Capital College. The PSIEE promotes Penn State's interdisciplinary environmental enterprise through a wide variety of activities.

The PSIEE has been instrumental in assisting faculty and departments in the creation of world-class programs such as climate change, and hydrogen energy, as well as other areas.

Courses offered at Pennsylvania State University that focus on global warming and climate change include:

EARTH 103: EARTH IN THE FUTURE: PREDICTING CLIMATE CHANGE AND ITS IMPACTS OVER THE NEXT CENTURY.

The United States is actively working on national assessment of the impacts of the climate change predicted to occur over the next century. The U.S. National Assessment has developed three major documents: an overview written for Congress, a foundation document giving the sources of information and their interpretation, and a series of regional and sector (water, health, agriculture, forests, and coastlines) reports. These reports present an exceptional opportunity to connect advances in the natural sciences to society. The course has four major objectives: (1) to gain an understanding of climate science and of the possible scenarios of how climate may change in the future; (2) to analyze the linkages between climate and major human and natural systems (e.g., agriculture, human health, water, coastal ecosystems, and forests), necessary to assess the potential impacts of climate change; (3) to demonstrate that the impacts of climate change, and the way in which society responds, are dependent on factors such as age, economic capability, lifestyle (e.g., urban vs. rural), generational differences, and cultural differences; and (4) to understand the different types of responses that humans may have to climate change, including adaptations to change and possible mechanisms to mitigate the factors that are forcing change to occur.

GEOSC 320: GEOLOGY OF CLIMATE CHANGE

Geologic records provide a critical perspective on climate change, with implications for our behavior. Ice cores, ocean sediments, tree rings, and others reveal that agriculture and industry have arisen during a few thousand years of anomalously stable climate. Natural changes half as large as the entire difference between ice-age and modern conditions have occurred repeatedly in mere years, affecting hemispheric or broader regions. Such climate jumps have been linked to changes in greenhouse gases, but not driven by them. Students in this course will learn how records of recent climate changes are recovered, read, and dated, how the climate system works and has worked, and the causes of ice-age cycles and faster climate jumps.

BIOL 436: POPULATION ECOLOGY AND GLOBAL CLIMATE CHANGE

In this course, students investigate the factors shaping the characteristics of populations and their dynamics in time and space, with emphasis on the responses of populations to climatic fluctuation and global climate change. These concepts include the science of climate change, how temperature trends are estimated, the data used in assessment reports by the Intergovernmental Panel on Climate Change, large-scale climate systems such as the North Atlantic Oscillation and the El Niño Southern Oscillation, the basic characteristics of populations, how population densities are estimated, and the types of population data used in studies of population responses to climate change.

Fernando Herrera
University of California, San Diego

Pennsylvania

BECAUSE OF PENNSYLVANIA'S interior location in the northeast, it is in prime position to experience the many negative effects associated with global warming. By 2100, average summer temperatures in Pennsylvania could increase between 7–9 degrees F (4–5 degrees C). This temperature change could cause extreme cases of precipitation. Some parts of the state could experience up to a 50 percent increase in rainfall, while other areas face drought conditions.

In Philadelphia, by 2050, heat-related deaths during a typical summer could increase by 90 percent, from about 130 deaths per summer to more than 240. Currently, "red alert" air quality days happen about two days every summer in Pittsburgh. By the middle of the century, this number could rise to five days per summer. Also, ozone levels in the city are already above the Environmental Protection Agency's healthy standard at least 10 days out of the year. Global warming could cause this number to increase to 22 days in the near future, meaning more cases of respiratory diseases such as asthma. Loss of wildlife and habitat are also possible threats caused by global warming, which could mean a loss of tourism dollars.

Over the last century, the average temperature in Harrisburg, Pennsylvania, has increased 1.2 degrees F (0.6 degrees C), and precipitation has increased by up to 20 percent in many parts of the state. Over the next century, climate in Pennsylvania is expected to change even more. Precipitation is estimated to increase by about 10 percent in spring, by about 20 percent in winter and summer, and by as much as 50 percent in fall. The amount of precipitation on extreme wet or snowy days is also likely to increase, which would cause an increase in extremely hot days in summer because of the general warming trend. Although it is not clear how severe storms would change, an increase in the frequency and intensity of summer thunderstorms is possible.

Higher temperatures and increased frequency of heat waves may increase the number of heat-related deaths and the incidence of heat-related illnesses. Pennsylvania, with its irregular, intense heat waves, could be especially susceptible. Similar but smaller increases have been projected for Pittsburgh, from about 40 heat-related deaths to 60, or a 50 percent increase. Winter-related deaths could drop from 85 per winter in Philadelphia, to about 35 per winter if temperatures warm.

The complications that global warming could have on the major cities in the future will also be felt by the rural areas that make up a large portion of the state. Pennsylvania's farming and agriculture industries are vital to the state's economy, as well as the outdoor tourism market; both would be greatly debilitated by effects of global warming. In 2001, more than 4.5 million people spent nearly $3 billion on hunting, fishing, and wildlife viewing in Pennsylvania, which in turn supported 56,113 jobs in the state.

HEALTH VARIABLES

Climate change may also increase ground-level ozone levels. For example, high temperatures, strong sunlight, and stable air masses tend to increase urban ozone levels. If a warmed climate causes increased use of air conditioners, air pollutant emissions from power plants also will increase. A preliminary modeling study of the Midwest, which included the area around Pittsburgh, found that a 4 degrees F (2 degrees C) warming, with no other change in weather or emissions, could increase concentrations of ozone, a major component of smog, by as much as 8 percent. Currently, ground-level ozone concentrations exceed national

The Delaware River overflowing in 2005. Pennysylvania has some of the most intense flooding in the United States.

ozone health standards in several areas throughout the state. Ground-level ozone has been shown to heighten respiratory illnesses such as asthma, as well as other complications. In addition, ambient ozone reduces crop yields and is harmful to ecosystems.

Warming and other climate changes may cause an increase in disease-carrying insects, thus the potential for the spread of diseases such as malaria and dengue fever is increased. Mosquitoes flourish in many areas around Pennsylvania. Some can carry malaria, while others can carry encephalitis, which can be lethal or cause neurological damage. Incidents of Lyme disease, which is carried by ticks, have also increased in the northeast. If conditions become warmer and wetter, mosquito and tick populations could increase in Pennsylvania, increasing the risk of these types of diseases.

WATER RESOURCES

Pennsylvania's valuable water resources would also be affected by changes in precipitation, temperature, humidity, wind, and sunshine. Changes in stream flow tend to coincide with changes in precipitation. Water resources in drier climates are more sensitive to climate changes. Because evaporation often increases with the onset of a warmer climate, the result could be lower river flow and lower lake levels, especially in the summer. If this happens, groundwater will consequently be reduced. In addition, a rise in precipitation could lead to increased flooding. Pennsylvania's Susquehanna River drains much of the eastern two-thirds of the state, and the Allegheny and the upper Ohio rivers drain most of the western third. A warmer climate would lead to earlier spring snowmelt, and could result in higher stream flows in winter and spring and lower stream flows in summer and fall. However, changes in rainfall also could have significant effects on stream flow and runoff. This alerts many Pennsylvanians because some of the most intense flooding on record in the United States has occurred in Pennsylvania.

Perfluorocarbons

THE PERFLUOROCARBONS ARE a group of chemically related greenhouse gases covered by the Kyoto Protocol. Although emissions of perfluorocarbons are low compared to many other pollutants, they are of great concern because the perfluorocarbons are extremely powerful greenhouse gases with very long atmospheric lifetimes. Furthermore, the release of man-made perfluorocarbons is on the rise, due to increasing aluminum and semiconductor chip manufacture. Annual releases of PFM, the most abundant perfluorocarbon, are the global warming equivalent to about 70 megatons of CO_2, roughly one two-hundredth of the amount of CO_2 released annually.

In the context of climate change, the most important perfluorocarbons are perfluoromethane (PFM) and perfluoroethane (PFE). Also of interest in a wider environmental context are the oxygenated perfluorocarbons, PFOS and PFOA. These latter compounds are highly soluble in water, and they are found in the ocean environment and in living tissues, but rarely in the atmosphere. Since 1980, the atmospheric concentration of PFM has risen by around 30 percent, despite reductions in emissions per ton from the aluminum industry, and is thought to have risen by around 70 percent since 1960. The atmospheric concentration of PFE has doubled from its concentration in 1980, and is believed to be more than 10 times higher than its 1960 value.

The perfluorocarbon molecules are strong absorbers of infrared radiation, and are therefore powerful greenhouse gases. Although the atmospheric concentration of perfluoromethane is around 100,000 times lower than CO_2, the radiative forcing due to this atmospheric loading of PFM is as much as one five-hundredth of the radiative forcing due to CO_2. (Radiative forcing is a measure of the global warming effect of a chemical at a given atmospheric concentration.) PFM is a much more powerful greenhouse gas than CO_2 as measured by its global warming potential. The global warming potentials of PFM and PFE are 7,390 and 12,200, respectively.

The PFCs are extremely environmentally stable; they are only very slowly destroyed by the action of sunlight and oxygen. The main pathway for removal of PFCs from the environment is via high temperature combustion processes when air is taken into vehicle engines or power station furnaces. This environmental stability arises from the molecules' chemical structure. The PFCs are related to simple hydrocarbons by replacement of all hydrogen atoms by fluorine. For example, the simplest hydrocarbon is methane, CH_4. The corresponding PFC is perfluoromethane, CF_4. The carbon-fluorine chemical bond is tremendously robust with respect to normal mechanisms by which the atmosphere cleans itself. Consequently, the atmospheric lifetimes of PFM and PFE are around 50,000 years and 10,000 years, respectively.

Natural PFM emissions from soils give rise to a background "clean air" concentration of about 40 pptv (parts per trillion by volume). Its concentration has been increasing throughout the latter half of the 20th century, to its current value of about 75 pptv due to industrial activity. Both PFM and PFE are produced as a by-product of the electrochemical extraction of aluminum from its ores. Over the past 20 years, the global aluminum industry has significantly improved its performance: currently, an average of 400 grams of PFM and about 40 grams of PFE are released per ton of aluminum produced, down by almost two-thirds since the 1980s. However, this per-ton emissions reduction has been somewhat offset by increases in aluminum production volumes. The semiconductor chip manufacturing industry is a major source of PFE and a secondary source of PFM. Consequently, the increase in chip manufacture is a major influence on the growing emissions of PFE.

Oxygenated perfluorocarbons, PFOS (perfluorooctane sulfonate) and PFOA (perfluorooctanoic acid) are thought to be harmful to human health. The U.S. Environmental Protection Agency regards PFOA as a "likely carcinogen"; it has been shown carcinogenic in rodents, as well as causing immune and reproductive system damage. PFOA and PFOS are released to the environment from manufacture and use of nonstick materials, fabric protectors, and fire-fighting foams. Due to their high water solubility and extremely long environmental lifetime, they are found in low concentrations in the blood of humans worldwide, and in many animals, including U.S. dolphins, Chinese pandas, and Arctic polar bears.

Peru

PERU'S 0.5 PERCENT contribution of greenhouse gases to the world's atmosphere is small, compared to the impact on Peru expected as a result of climate change. Peru is ranked as the fourth country most impacted by climate change. El Niño has regularly affected the 386,102 sq. mi. (one million sq. km.) of Peruvian territory, with droughts in the Andean south, and floods in the northern Pacific coast. These impacts, however, are small compared to the impacts of climate change. The 125 mi. (200 km.)-long White Mountain Range, the world's largest ice-covered tropical range and Peru's main concentration of ice, has been losing volume in the last 50 years. The glaciers are melting, leading to glacier reduction, the formation or increase of glacial lakes, and changes in ecosystem composition. The glaciers of White Range Park have retreated 82 ft. (25 m.) in the last 50 years according to CONIDA, Peru's aerospace agency, and CONAM, the Peruvian environmental agency.

Glacier retreat has implications for downstream river flows. In rivers fed by glaciers, summer flows are supported by glacier melt (with the glacier contribution depending on the size of the glacier relative to basin area, as well as the rate of annual melt). If the glacier is in equilibrium, the amount of precipitation stored in winter is matched by melt during summer. However, as the glacier melts as a result of global warming, flows would be expected to increase during summer—as water is released from long-term storage—which may compensate for a reduction in precipitation. As the glacier gets smaller and the volume of melt reduces, summer flows will no longer be supported and will decline to below present levels. The duration of the period of increased flows will depend on glacier size and the rate at which the glacier melts; the smaller the glacier, the shorter lived the increase in flows and the sooner the onset of the reduction in summer flows. In 18 glaciers in the Peruvian Andes, mass balances since 1968 and satellite images show a reduction of more than 20 percent of the glacial surface, corresponding to 11,300 million cu. m. of ice, according to B. Morales-Arnao and INAGGA-CONAM.

In addition to the White Mountain Range, 19 mountain range glaciers exist in Peru, which according to a study elaborated by the Corporation For the Development of Santa in 1970, occupied 965 sq. mi. (2,500 sq. km.) These mountain ranges lodge 1,500 lagoon glaciers. The White Mountain Range is one of the most sensible thermometers to measure global warming, showing that in the last half-century the Peruvian mountains have lost hundreds of cubic meters of ice. Peru was hit in 1998 with the destruction of the Machu Picchu hydropower station, and rebuilding costs amounted to $160 million, according to RGS Ltd.

Glacial lakes are formed on the glacier terminus due to the climate change–induced glacier retreating processes. The majority of these glacial lakes are dammed by unstable moraines, which were formed by the glaciations of the cooler period of climate within the last millennium. Occasionally, the lake happens to burst and suddenly releases an enormous amount of its stored water, which causes serious floods downstream along the river channel. This phenomenon is known as glacial lake outburst flood (GLOF). Since 1702, more than 25 catastrophic GLOFs have occurred in the White Mountain Range. They come with little or no warning, and are made up of liquid mud that transports rolling stones and blocks of ice with the capacity to destroy cities and lives. The most serious GLOFs destroyed parts of the city of Huaraz in 1725 and 1941, as well as the GLOF from Lake Jancarurish in 1950. Additionally, two other destructive avalanches from the summit of North Huascarán destroyed, in 1962 and 1970, several villages and caused the deaths of more than 25,000 inhabitants.

Peruvian Current

ORIGINATING IN THE frigid waters off the coast of Antarctica, the Peruvian Current moves north along the western coast of South America. When in reaches the continental shelf along South America, the current rises, carrying cold water with it to the surface of the Pacific Ocean. The prevailing winds of the South Pacific and Earth's rotation cause the Peruvian Current to rotate; the Coriolis Force causes the current to rotate clockwise. The Peruvian Current extends 125 mi. (201 km.) west from the coast of South America. As the current moves north through the coasts of Chile, Peru and Ecuador it splits into two masses where Cabo Blanco, Peru, meets the Gulf of Guyanquil. The main current turns west into the Pacific Ocean, while the remnant of the current moves along the coast of Ecuador. At that point, the second branch of the Peruvian Current also moves west, rejoining the main current near the Galapagos Islands.

The Peruvian Current is also known as the Humboldt Current after its discoverer, German scientist Alexander von Humboldt. The Peruvian Current affects Peru year round, and moderates the climate of Chile in spring and summer, when it displaces a subtropical center of high pressure. Ordinarily the coast of Chile would warm in spring and summer, but the onset of the Peruvian Current diminishes temperatures and forestalls any rain. The air that accompanies the current is dry, keeping the coast arid. Some weather stations along the Chilean coast have never recorded rainfall; others areas receive considerably less than 1 in. (2.5 cm.) of rain per year. The northern coast of Peru is dry from May to November, and receives light rain between December and April. Even though some areas of the coast are humid, rain nevertheless does not fall. The arid coastline supports few plants, and so sunlight either is absorbed by the land or radiates back into space. Rainfall along the southern coast of Ecuador totals 12 in. (30 cm.) per year, though in the north, where the Peruvian Current weakens, rainfall increases tenfold. Some regions receive as many as 197 in. (500 cm.) of rain per year.

With Peru located near the equator, one might expect warm temperatures, but the Peruvian Current keeps the coast of Peru at 75 degrees F (24 degrees C). Lima varies from 70 degrees F (21 degrees C) in January and 50 degrees F (10 degrees C) in June. Areas inland from the current often record temperatures of 90 degrees F (32 degrees C). Periodically El Niño disrupts the Peruvian Current, bringing warm water from the tropical Pacific to the western coast of South America. Temperatures along the coast rise and rain falls on some parts of the coast.

As it cools the western coast of South America, the Peruvian Current creates a climate of unremitting dryness. Temperatures are moderate but rainfall is scant. Seabirds inhabit the western coast of South America but humans have only colonized the region in small numbers. The deserts of Chile are especially forbidding. Without rain, the land ceases to sustain plant life. In contrast to the sterility of the desert, life abounds in the ocean. The Peruvian Current carries plankton to the surface of the ocean, and fish feed on it in large numbers. Seabirds in turn feed on the fish. Despite creating an arid climate, the Peruvian Current teems with life.

Pew Center on Global Climate Change

IN 1998, WITH a grant from the Pew Charitable Trusts, and within the context of increasing concern over the impact of climate change, the Pew Center on Global Climate Change was established. It is a nonprofit, nonpartisan, independent organization. The role of the Pew Center is to build a bank of credible information about climate change and its impacts, and to try to provide solutions to the problems created by climate change. The Pew Center aims to provide an objective forum for research, and development of sensible solutions and policy suggestions.

Underpinning this mission is the commitment by Pew Center staff to educate policymakers and the general community about the causes and consequences of climate change. In so doing, the Pew Center has commissioned many significant reports on the impacts of climate change in various contexts, including domestic and international policy, economic and environmental impacts, and practical solutions. For example, reports have focused on the relationship between developing and developed worlds in relation to climate change policies. Many reports highlight the effects of climate change on marine ecosystems. The Pew reports offer policymakers and the public the opportunity to access and learn about detailed case studies from across the world on this topic. The Pew Center also hosts conferences and workshops on climate-related topics to stimulate engagement and interaction between business, government, and nongovernmental organizations. Staff from the Pew Center also regularly participate and attend key meetings on climate change issues, such as negotiations on the UN Framework Convention on Climate Change (UNFCC).

Within the policy center, staff at the Pew Center for Global Climate Change investigate how policies can be changed and developed within the areas of science and technology, market-based mechanisms, adaptation, international engagement, cross-sector policies, transportation, manufacturing agriculture, and energy production and use policies. Staff members also work within the United States at congressional and state levels to encourage policymakers, and politicians in these areas, to activate plans and legislate on climate change solutions and issues.

UNDERSTANDING CLIMATE CHANGE THROUGH INTERNATIONAL DIALOGUE WITH BUSINESS

The Pew Center's position on climate change is that there is strong scientific consensus that climate change is real, happening now, and is largely the result of human-induced activities. For example, the Pew Center cites the emissions of carbon dioxide and other greenhouse gases produced by industrial processes, fossil fuel combustion, and changes in land use as the primary cause of climate change. The result of these activities is that there will be an additional warming over the 21st century, and that there will be a global increase of 2.5 degrees F (1.4 degrees C) to a global average of 10.4 degrees F (5.7 degrees C). The Pew Center identifies a number of consequences from global warming, including sea-level rise, coastal inundation, beach erosion, flooding from coastal storms, changes in precipitation patterns, increased risk of droughts and floods, threats to biodiversity, and potential public and environmental health problems.

At an international level, the Pew Center is working to develop an international forum for agreement on climate change through the Climate Dialogue at Pocantico, established in 2005. This was a forum convened by the Pew Center on Global Climate Change to give senior policymakers the forum to informally discuss core issues with other policymakers and stakeholders in an international context. These meetings, held between July 2004 and September 2005, resulted in an agreement between the 25 international participants; the dialogue was then presented to the wider community as a platform for initiated change and options for promoting the climate change effort in an international arena. Participating countries and members include Argentina, Australia, Brazil, Canada, China, Germany, Japan, Malta, Mexico, Tuvalu, the United Kingdom, and the United States; senior executives from Alcoa, BP, DuPont, Eskom (South Africa), Exelon, Rio Tinto, and Toyota; and experts from the Pew Center, the Energy and Resources Institute (India), and the World Economic Forum.

The Pew Center has also established the Pew Center's Business Environmental Leadership Council (BELC). Business interests represented include diversified manufacturing, oil and gas, transportation, utilities, and chemicals. The BELC was created when the Pew Center was established, due to the belief that engaging business must be one of the cornerstones for effecting change in relation to addressing climate change impacts. This council is based on the understanding that businesses that are proactive in climate-proofing their business, and minimizing their impact, will have a future competitive advantage. To date, the BELC is the largest consortium of businesses working together to combat climate change, with a membership of 44 members. Together, the membership represents $2.8 trillion in market capitalization and over 3.8 million employees.

These companies are providing leadership by negotiating the establishment of emissions reduction objectives; through investment in new best practice and climate friendly technologies; and by supporting programs designed to achieve cost-effective emissions reductions. For example, 32 of the companies represented within the BELC have greenhouse gas reduction targets. Many of these companies are also implementing strategies in energy supply, energy demand solutions, process improvement, waste management practices, transportation, carbon sequestration and offsets solutions, and emissions trading and offsets.

Overall, the Pew Center advocates that the reduction of emissions of carbon dioxide and other greenhouse gases is the crucial first step to addressing this problem. To do so, it proposes a restructuring of the global economy away from its current reliance on fossil fuels to increased dependence and use of renewable and more efficient energies.

Philippines

THE PHILIPPINES ARE located across 7,107 islands forming an archipelago in southeastern Asia, east of Vietnam. The country lies squarely in the typhoon belt, and is affected by an average of 15 storms (five to six of them direct strikes) annually. Most of the population of 91 million is at risk from landslides, flash flooding, and tsunamis. The Philippines face severe environmental problems, ranging from water pollution, soil degradation, deforestation, and loss of coral habitat, and are expected to suffer from rising sea levels and increased storm intensity.

The Philippines have already been feeling the impact of oscillations in Pacific sea temperatures known as El Niño and La Niña. In El Niño periods, the islands tend to see a decrease in rainfall, leading to droughts. During La Niña periods, rainfall can come in intense bursts, leading to landslides and flash flooding. Supertyphoons are also on the rise, with 2007 bringing a number of category 4 and category 5 cyclones into the Pacific basin.

Deforestation, both in the rainforest and the country's vast mangrove swamps, is another serious environmental issue for the Philippines. After a series of devastating landslides in the 1980s, the government instituted a ban on timber harvesting. Still, the country lost a third of its forest cover to logging 1990–2005. Deforestation has slowed to 2 percent annually, and the government has been more aggressive about pursuing illegal loggers.

With over 36,000 km. of shoreline, a rising sea level will have devastating consequences for the Philippines. Some models show a 100 cm. rise in ocean levels on the Philippine coast by 2080. In the heavily populated capital city of Manila, this rise would potentially displace up to 2.5 million people, and put millions more at risk for flooding from storm surges.

The Philippines is home to southeast Asia's second-largest coral reef system, covering 9,676 sq. mi. (25,060 sq. km.) As temperatures rise, coral bleaching events are expected to become more severe, leading to the eventual death of the reef. The impact will be felt in several ways: it will signal the end of an important habitat; it will destroy the livelihood of more than a million fishermen along the coast; it will reduce an important source of food from the Philippine market; and it will make the coast more vulnerable to storm surge and rising tides, as bleached reefs have been shown to be less of a buffer to sea level rise.

Carbon emissions rose 40 percent between 1990–98, but with CO_2 emissions at 1,000 metric tons per capita in 1998, the Philippines is not a significant contributor to global carbon emission totals. An estimated 73 percent of emissions come from liquid fuels, 18 percent from solid fuels, and 9 percent from cement manufacturing. Climate change has already cost the Philippines billions in lost agricultural production, reduced fish yields, storm damage, and a reduction in tourism. The government is taking steps to educate the public and to institute sustainable policies.

Phillips, Norman

NORMAN PHILLIPS IS a theoretical meteorologist who pioneered the use of numerical methods for the prediction of weather and climate changes. His influential studies led to the first computer models of weather and climate, as well as to an understanding of the general circulation of the atmosphere, including the transports of heat and moisture that determine the Earth's climate. His 1955 model is generally regarded as a ground-breaking device that helped to win scientific skepticism in reproducing the patterns of wind and pressure of the entire atmosphere within a computer model.

Phillips received his B.S. from the University of Chicago in 1947 and his Ph.D. in 1951. He was the first to show, with a simple general circulation model, that weather prediction with numerical models was possible. The advent of numerical weather predictions in the 1950s also marked the transformation of weather forecasting from a highly individualistic effort to a cooperative task in which teams of experts developed complex computer programs. With the first digital computer in the 1950s, scientists tried to represent the complexity of the atmosphere and its circulation in numerical equations. Nineteenth- and early 20th-century mathematicians such as Vilhelm Bjerknes and Lewis Fry Richardson had failed to come up with adequate mathematical models. Through the 1950s, some leading meteorologists tried to replace Bjerknes and Richardson's numerical approach with methods based on mathematical functions, working with simplified forms of the physics equations that described the entire global atmosphere. They succeeded in getting only partial mathematical models. These reproduced some features of atmospheric layers, but they could not show persuasively the features of the general circulation. Their suggested solutions contained instabilities as they could not account for eddies and other crucial features. Discouraged by such failures, scientists began to think that the real atmosphere was too complex to be described by a few lines of mathematics. The comment of such a leading climatologist as Bert Bolin is revealing of this skepticism. In 1952 Bolin argued that there was very little hope for the possibility of deducing a theory for the general circulation of the atmosphere from the complete hydrodynamic and thermodynamic equations. Yet, computers opened up new possibilities in the field, although the first digital specimens were extremely slow and often broke down.

Jule Charney was the first to devise a two-dimensional weather simulation. Dividing North America into a grid of cells, the computer started with real weather data for a particular day and then solved all the equations, working out how the air should respond to the differences in conditions between each pair of adjacent cells. It then stepped forward using a three-hour step and computed all the cells again. The system was slow to operate and it had imperfections, yet its completion paved the way for more researches to be carried out. It was Norman Phillips who sought to address the problems in Charney's model. The challenge for meteorologists now became the computation of the unchanging average of the weather given a set of unchanging conditions such as the physics of air and sunlight and the geography of mountains and oceans. This was a "boundary problem." A parallel problem that they had to face was that of the "initial value," where the operation of calculating how the system evolves from a particular set of conditions found at one moment becomes less accurate as the prediction moves forward in time.

Phillips was inspired by "dishpan" experiments carried out in Chicago, where patterns resembling weather had been modeled in a rotating pan of water that was heated at the edge. For Phillips this showed that "at least the gross features of the general circulation of the atmosphere can be predicted without having to specify the heating and cooling in great detail."

Phillips argued that if such an elementary laboratory system could effectively model a hemisphere of the atmosphere, a more advanced tool such as a computer should be able to do it as well. Although certainly more advanced than a dishpan, Phillips's computer was still quite primitive. Thus, his model had to be extremely simple. By mid-1955 Phillips had devised improved equations for a two-layer atmosphere. To avoid mathematical difficulties, his grid covered not a hemisphere but a cylinder, 17 cells high and 16 in. in circumference. The calculations allowed the representation of a plausible jet stream and the evolution of a realistic-looking weather disturbance over a period of a month.

This settled an old controversy over what procedures set up the pattern of circulation. The simulation-based approach became the generally accepted method to devise circulation models. For the first time scientists could visualize how giant eddies spinning through the atmosphere played a key role in moving energy from place to place. Phillips's model was quickly hailed as a "classic experiment," the first true general circulation model (GCM). Phillips used only six basic equations (PDEs) which have been since described as the "primitive equations". They are generally conceived of as the physical basis of climatology. These equations represent well-known physics of hydrodynamics. The model was able to reproduce the global flow patterns of the real atmosphere. Phillips was awarded the Benjamin Franklin Award in 2003.

Phytoplankton

PHYTOPLANKTON ARE A group of free floating microscopic organisms predominantly classified as algae. Over 4,000 species of phytoplankton have been identified and this list is rapidly growing. Phytoplankton are mostly single cellular organisms and all are autotrophic (i.e., they contain photosynthetic pigments). These pigments allow phytoplankton to use the sun's energy to convert CO_2 and inorganic nutrients, through photosynthesis, into biological molecules such as proteins and carbohydrates. This process of creating new biological molecules is called primary production. Phytoplankton are the only primary producers in the open oceans, and thus form the basis of the food chain in over 70 percent of the world's surface area.

Specific aspects of primary production are often considered more carefully and these warrant definition. The Net Primary Production (NPP) refers to the amount of organic carbon available after respiration has been subtracted from the total amount of photosynthesis. It is an important term because this is the amount of carbon that is available to the rest of the foodweb, and is the upper limit on respiration. The Net Community Production (NCP) is the difference between net primary production and heterotrophic respiration. It is measured by gross changes in oxygen or biomass in a specific time. The New Production is the fraction of primary production driven by newly-available nitrogen. This is principally the nitrate and nitrite that becomes available when deep ocean waters are brought up into the euphotic zone, but could include sources from the atmosphere or river inputs.

The global distribution of phytoplankton throughout the world's oceans is not evenly distributed. This distribution is the result of growth being limited by the availability of nutrients. High concentrations of phytoplankton are seen in upwelling areas, such as the Benguela Current off the southwest coast of Africa.

PHYTOPLANKTON AND CLIMATE CHANGE

CO_2 does not limit phytoplankton growth. CO_2 is not thought to limit phytoplankton growth in any region of the ocean. Primary production, in general, is limited by the availability of inorganic nutrients. Therefore it is not expected that increased atmospheric concentrations of CO_2 will have a significant impact on the phytoplankton population in the oceans.

The "Biological Pump" Locks Away CO_2. The "Biological Pump" is the mechanism by which anthropogenic CO_2 is taken from the atmosphere and stored in the deep ocean, which transfers carbon from the surface to the deep ocean, across the barrier of the permanent thermocline. The pump is powered by phytoplankton fixing carbon and sinks to the deep ocean. This removes CO_2 from the surface ocean, causing more CO_2 to be drawn from the air to maintain equilibrium. Carbon is locked away from the atomosphere as a result of being taken below the permanent thermocline. This contrasts to primary productivity on land which builds plants (such as trees) and in turn animals to, locking CO_2 away from the atmosphere.

Although increasing levels of CO_2 do not have a fertilizing effect on the oceans, the longer growing season in temperate and polar regions is expected to lead to an increase in primary productivity.

Plants

THE ANCIENT GREEKS were the first to identify a relationship between climate and plants. Following this insight, other naturalists recognized that fossilized plants revealed the climate in prehistory. Plants colonized the land 410 million years ago, shaping the climate as they spread throughout the globe. By absorbing carbon dioxide, plants have the potential to cool the climate. By releasing water vapor into the atmosphere, plants have the potential to warm the climate by trapping heat, or to cool the climate by forming clouds. Rooted to the ground, plants must either adapt to the climate or die. Sudden climate changes threaten some species with extinction, whereas hardier species survive. From equator to pole, climate determines what plants grow at given latitudes.

HISTORY OF THE RELATIONSHIP BETWEEN CLIMATE AND PLANTS

Theophrastus, a pupil of Aristotle and the founder of botany, may have been the first to ponder the relationship between plants and climate. He understood that each species of plant is adapted to a particular climate, and that in a foreign climate a plant will not thrive and may not survive. Plants are thus an indicator of climate. The mangrove, for example, is an indictor of a climate wet enough to form swamps. With the work of Theophrastus, the promising synthesis of botany and the study of climate was in its infancy, but the Romans did not bring this synthesis to maturity. The Romans were a practical people, with no interest in the theoretical relationship between plants and climate. The Middle Ages were no better for the study of the relationship between plants and climate. The emphasis on theology undercut any progress in science.

In 1876, Norwegian botanist Axel Blytt revived Theophrastus's notion that plants are an indicator of climate. Working on prehistoric climates, Blytt identified fossils of trees that no longer grew in Denmark. From this observation, he posited that the climate in Denmark had once been suitable for these species of trees, but was no longer. The climate was not therefore a static, unchanging entity. Rather, the climate has changed over time. Working in a similar vein, Swedish geologist Ernst Von Post identified fossils of *Alnus*, a genus of tree, in the strata of rocks throughout Europe. *Alnus* is adapted to a warm wet climate, and Von Post tracked the tree fossils as they migrated from southern to northern Europe at the end of the Cenozoic Ice Age. As the glaciers retreated, *Alnus* rooted itself in the warm wetlands that followed the ice age.

PLANTS AND CLIMATE CHANGE

Fossilized pollen can likewise pinpoint changes in climate. The evergreen red beech is adapted to warm locales. The abundance of its pollen 8,000 years ago implies that this time correlates with the maximum temperature since the end of the Cenozoic Ice Age. On the other hand, the abundance of pollen from *Phyllocladus*, a shrub that is adapted to the cold, at 26,000 years ago and again at 20,000 years ago, indicates these years as the coldest during the ice age.

Photosynthetic algae evolved in the ocean as early as four billion years ago. From this beginning, the first plants colonized land 410 million years ago, before animals. By 360 million years ago, the beginning of the Carboniferous period, plants had spread throughout the planet, forming lush forests. The temperature and amount of carbon dioxide in the atmosphere were both higher than today. So lush was the growth of plants that when they died, they formed one layer upon another. Under heat and pressure, these many layers of plants formed the vast deposits of coal, natural gas, and petroleum that humans are now exploiting. The immensity of these deposits underscores the massive growth of plants during the Carboniferous period.

The fact that plants absorb carbon dioxide during photosynthesis has an important consequence for the climate. Carbon dioxide correlates with temperature. A high concentration of carbon dioxide correlates with high temperatures, whereas a low concentration of the gas correlates with low temperatures. This relationship holds true, because carbon dioxide is a greenhouse gas: it traps sunlight that reflects from Earth, preventing light, in the form of infrared radiation, from returning to space. In trapping sunlight, carbon dioxide traps heat, thereby increasing the temperature of the atmosphere. Plants lower the concentration of carbon dioxide by absorbing it during photosynthesis. When plants absorb carbon dioxide faster than Earth produces it through volcanism, the concentration of carbon dioxide diminishes, and temperatures decline. In this context, plants may have contributed to the onset of the Ice Ages by absorbing carbon dioxide.

The absorption of carbon dioxide is cyclical. In spring and summer, when plants grow vigorously, they absorb large amounts of carbon dioxide. In autumn, however, plant growth slows and in winter it stops. The decay of dead plants in autumn returns the carbon dioxide that they had absorbed while alive to the atmosphere. The Northern and Southern hemispheres contribute to the carbon dioxide cycle in opposite fashion, for when plants are growing vigorously in the Northern Hemisphere, they are dead and decaying in the Southern Hemisphere, and vice versa.

In another sense, the carbon dioxide cycle spans eons of time. In the Carboniferous period, lush forests absorbed prodigious amounts of carbon dioxide, storing it in their tissues as sugars. Upon the death of plants, their conversion to coal, natural gas, and petroleum locked up these vast amounts of carbon dioxide. Since the Industrial Revolution, humans have burned these fossil fuels for energy, and in the process liberated carbon dioxide, returning to the atmosphere the carbon dioxide that plants had absorbed during the Carboniferous period. The liberation of this carbon dioxide has increased global temperatures. Humans are burning fossil fuels constantly, leading climatologists to predict that humans will, by 2080, double the amount of carbon dioxide in the atmosphere, further increasing temperatures and perhaps leading to the flooding of coastal cities.

Plants absorb carbon dioxide through their stomata, pores on the leaves. At the same time, plants shed water through their stomata. Plants transpire as water vapor more than 90 percent of the water that they absorb through their roots. Through transpiration, plants change the climate, though not in a straightforward way. On the one hand, water vapor is a greenhouse gas, absorbing as heat the sunlight reflected from Earth.

The warmth of the Carboniferous period, a time of abundant plant growth, was due to the greenhouse effect. Along with carbon dioxide, the water vapor transpired by plants contributed to a warm climate. On the other hand, the water vapor that plants transpire forms clouds, which reflect 30 percent of sunlight back into space before it can heat the Earth. In their role in forming clouds, plants cool the climate.

One scientist predicted that a doubling of carbon dioxide concentration might cool, rather than heat Earth, because plants will, in transpiring water vapor, hasten the formation of clouds.

CLIMATE CHANGES AND THE GREENHOUSE EFFECT

The product of a long evolutionary history, plants are adapted to the climate in a way that humans are not. Humans fashion their material culture to suit the climate, or, when climate worsens, they migrate to a more hospitable locale. Plants, rooted to the ground, must adapt or die. Migration is not an option, though seed dispersal is a kind of intergenerational migration. Through dispersal, seeds travel roughly one kilometer per year, a rate too slow to adapt a plant to rapid climate change. As the climate deteriorates, some plant species die out, to be replaced by hardier species. In Neolithic and Bronze Age Denmark, for example, the climate was warmer and wetter than it is today.

The climate was warm and wet enough to sustain the growth of oak trees. In the Iron Age, however, temperatures dropped to current figures. Unable to cope with the decline in temperature and moisture, oak trees died out and were replaced by grasses and heather. In New Hampshire, the tree *Pinus strobus* was for centuries the most numerous tree in the region's deciduous forests. *Pinus* came through the fire of 1665 unscathed, but was unable to cope with climatic catastrophe. In 1921, a tornado, and in 1938 a hurricane, swept through the forests, felling large trees of several species. The catastrophes wiped out *Pinus*, ending centuries of its dominance, and leaving other species to reconstitute the forests.

These sudden changes in climate and flora are dramatic and easy to quantify. No less dramatic has been the effect of hydrofluorocarbons on climate and plants. Humans have released large quantities of hydrofluorocarbons into the atmosphere, where they have thinned the ozone layer. Consequently UV-B radiation, a type of ultraviolet light, penetrates the ozone layer in greater amounts than in the past. UV-B radiation damages half of all plant species. Damaged plants grow small leaves and short shoots and photosynthesize at a slow rate. These effects are magnified by the fact that several crops are among the plants sensitive to UV-B radiation. One study concluded that a 25 percent reduction in the ozone layer would halve soybean yields.

The tropics support lush vegetation, with more than 80 in. of rain per year, temperatures nearly uniform and warm year-round, and abundant sunshine. Trees have thin bark, for they don't need insulation against the cold or protection against water loss. Trees grow in layers, with those in the innermost layers able to survive without exposure to direct sunlight. Because sunlight does not penetrate to the rainforest floor, little vegetation grows along the ground. At higher latitudes north and south of the tropics, rainfall diminishes and temperatures vary year round. These climates have seasons, with vigorous plant growth in spring and summer and dormancy in autumn and winter.

To cope with a diminution in rain, plants in temperate climates have evolved small leaves to minimize the loss of water through transpiration. In areas that have a dry season, trees evolved the shedding of leaves to stop transpiration and, in other species of trees, the growth of needles rather than leaves to minimize transpiration. With their needles, the evergreens and conifers are adapted to short summers because they can carry out photosynthesis as soon as temperatures warm, whereas deciduous trees must regrow their leaves before they can photosynthesize. Evergreens and conifers grow where winter is cold enough to freeze the ground. Once the ground freezes, roots cannot absorb water, making winter a period of drought and favoring trees that can minimize transpiration in response to frost-induced drought.

In contrast to the rainforest, sunlight penetrates to the forest floor in temperate forests, permitting the growth of plants, often grasses, in abundance along the ground. As the dry season lengthens and rainfall diminishes still further, forest gives way to grassland. Grasses need less water than trees. Trees grow alongside grasses on the African savanna, but few trees grow on the Russian steppe. There, grasses are the dominant flora. At high latitudes, temperatures fall below 40 degrees F (4 degrees C) for six to nine months per year. Summers are brief, with temperatures above 50 degrees F (10 degrees C). Rainfall ranges between 10–40 in. (25–102 cm.) per year, with between 15–24 in. (38–61 cm.) typical. This climate favors the growth of coniferous forests. In addition to their needles, conifers have thick bark to retard water loss and to protect against the cold. Temperature separates coniferous forest from tundra. Where summer temperatures exceed

50 degrees F (10 degrees C), conifers predominate, but wherever summer temperatures fall below 50 degrees F (10 degrees C), tundra results. Grasses and sedges are the tundra flora. During the 50 or 60 days of summer, the sun melts a thin strip of ground. Free from the grip of ice and benefiting from the nearly continuous sunlight of summers in high latitudes, plants grow vigorously and then are dormant for the long, bitter winter.

EFFECTS OF CLIMATE CHANGE ON PLANTS

The increase in temperatures that is the likely outcome of the greenhouse effect will affect plants. By one estimate, a two or three degree F increase in temperature will raise crop yields in the temperate zone, though an increase above 3 degrees F (1.7 degrees C) will decrease yields. Any temperature increase will likely reduce yields in the tropics, where crops are already at their maximum heat tolerance.

The climate of the future is sure to affect plants. Despite predictions to the contrary, the increase in carbon dioxide will likely increase temperatures. One study suggests that a doubling of carbon dioxide in the atmosphere will triple the growth rate of plants and trees. Forests will grow more densely and will extend their range to higher latitudes. Plants will grow more vigorously on marginal land. Another study indicates that a doubling of carbon dioxide will shift temperate forests 310 to 621 m. (500 to 1,000 km.) north in the northern hemisphere, and south in the southern hemisphere. The concentration of carbon dioxide is likely to double by 2080, but trees are not likely to migrate so far so fast. Global warming therefore endangers temperate forests. As the climate warms, trees will advance north and south, taking over ground that had been tundra. As temperatures rise, dead plants will decay more rapidly, liberating still more carbon dioxide into the atmosphere.

The cutting down of forests will surely harm the plants that survive. The amount of rainfall will decrease as forests are cut down. With fewer forests, the rate of transpiration will diminish. Whereas forests absorb sunlight, bare ground reflects sunlight back into space. A 15 percent decline in rainfall would replace the forests of South America with grassland. A 30 percent decrease in rainfall would replace the forests of Zaire with grasses. A 70 percent decrease in rainfall would make the Amazon basin a desert.

The climate of the future may imperil many plant species, but as a kingdom, plants are resilient. They have survived the Ice Ages and the predation of herbivores in warm climates. Humans are fortunate that plants are so adaptable, for with their agriculture, humans are dependent on plants. Life would not exist without the diversity of plants. The most numerous form of terrestrial life during the Carboniferous period, plants occupy every biome. Even in deserts, their seeds lie dormant, awaiting the infrequent rains. Plants have adapted to every climate, from the tropics to frigid tundra. Even bodies of water are home to plants. The survival of plants depends on their ability to adapt to the climate of the future. The survival of the rest of the biota depends on the success of plants.

Pleistocene Era

THE INCREASING FREQUENCY and intensity of glacial-interglacial cycles toward the end of the Pliocene (1.806–5.332 million years ago) set the stage for the Pleistocene epoch (11.8 thousand years ago–1.806 million years ago), which is the final phase of the Quaternary period. Some argue that the lower Pleistocene boundary may be set too late because the general trend toward significant cooling and glaciation had begun in the mid-late Pliocene (2.75 million years ago). Hence, the term Plio-Pleistocene may be used to delineate this transitional phase between the two epochs.

Strong glacial-interglacial phases are the key climatic features that characterize the Pleistocene epoch and have shaped much of the modern landscape. Glacial stages may be referred to as ice ages, and are used to describe a period of extensive ice sheet presence in the polar, high latitude continental, and alpine regions. Glacial phases are synonymous with reduced global temperatures. Quaternary glacial-interglacial cycles occurred with a 41,000-year periodicity, starting in the late Pliocene (2.75 million years ago) to mid-Pleistocene (1.11 million years ago), followed by a 100,000 year cycle in the mid- to late-Pleistocene. The most intensely studied glacial stage during the Pleistocene is the last glacial maximum (21,000 years ago).

Marine fossil material and isotopic proxies were used to simulate sea surface temperatures, sea ice, continental ice sheets, and albedo during the last glacial maximum, with results indicating that high latitudes in the northern hemisphere cooled by 7–11 degrees F (4–6 degrees C), while simulated sea temperatures increased by 2–5 degrees F (1–3 degrees C) in the Pacific and Indian oceans. Most recent evidence suggests that with the exception of Central America and the Indo-Pacific, the climate was much drier than today, due to the combination of reduced evaporation, greater coverage of land surfaces by ice sheets, and wind anomalies.

Glaciation was most extensive in the northern hemisphere, with 2–2.5 mi.- (3–4 km.-) thick ice sheets covering Canada and parts of the northern United States, Greenland, northern Europe, Russia, and perhaps to a lesser extent, the Tibetan Plateau. In the southern hemisphere, the glaciation of Antarctica that began in the Pliocene continued through to the last glacial maximum, the Andes were highly glaciated, the Patagonian Ice Sheet covered much of southern Chile, and small glaciers formed in Africa, the Middle East, and southeast Asia, where simultaneously, deserts were expanding. Sea levels may have been up to 426.5 ft. (130 m.) lower than today. The hydrologic and geological consequences of the last glacial maximum and other glacial stages are still evident, particularly at the higher latitudes of the northern hemisphere, where the abundance of fresh water is effectively the result of glacial retreat and runoff. Remnants of Pleistocene glaciers also remain in high-altitude tropical localities such as on Mount Kilimanjaro and the Peruvian Andes, but these glaciers are quickly retreating.

The causes of the Pliocene-Pleistocene glacial-interglacial cyclicity are largely attributed to climate forcing caused by variations in the Earth's orbital parameters (Milankovitch cycles), but the sequence of events is difficult to establish. However, there is strong evidence that greenhouse gas levels fell at the start of glacials and rose during the interglacial retreat of the ice sheets. So far, eight glacial cycles have been identified from cores in Antarctica dating back to 740,000 years ago, but currently, it is the Vostok ice core dating back to 420,000 years ago that provides the clearest perspective on the link between greenhouse gases and sea surface temperatures over the last four glacial-interglacial cycles. CO_2 concentrations fall between 180–200 ppm during the coldest glacial periods, and 280–300 ppm during full interglacials, while methane concentrations were approximately 350 ppb during glacials, and roughly twice that amount during interglacials. Current thinking is that Pleistocene changes in greenhouse gas levels were probably caused by disturbance to the sources of these gases, of which the oceanic and terrestrial sources were most significant.

During the last glacial maximum, the presence of large ice sheets over the high latitudes of the Northern Hemisphere significantly reduced the amount of exposed vegetation, and combined with low atmospheric CO_2 and other regional climatic changes, created biomes and vegetation assemblages that have no modern analogue. The Laurentide Ice Sheet completely covered Canada and the northern United States, with taiga, desert, and grassland ecotones dominating the mid-latitudes. At this time, woodland and shrub communities were also present, but highly fragmented. An exception to this is the Canadian and Alaskan Pacific coasts, where the continuity of woody flora remains largely unchanged from the last glacial maximum.

Substantial winter cooling reduced the global extent of tropics and subtropics and caused local extinctions, but equable areas may have acted as regional refuges for species that otherwise would have disappeared. The expansion of more arid ecosystems is well documented from pollen data showing that grasslands and shrub ecotones spread into previously tropical areas such as the Amazonian Basin, equatorial Africa and southern Asia. The persistence of rainforests in central North America and Indonesia during the last glacial maximum can be attributed to the consistently high rainfall in these regions. By contrast, over half of central Australia was desert, with tropical grasslands lying in the north, and scrub-woodland vegetation dominating the eastern and western regions.

Substantial evidence exists to support the hypotheses that Pleistocene fauna was dually affected by the climatic oscillations of the early-mid Quaternary, and the hunting activity of ancestral humans. The disappearance of species that had evolved in colder climates, such as the woolly mammoth, woolly rhinoceros, and musk ox, is most consistent with the appearance of humans in North America. By contrast, the Pleistocene extinction of Eurasian megafauna was likely due to climate. The disappearance of African and South American mammals is unresolved, but current evidence points to the arrival of humans as a key factor.

Pliocene Era

THE PLIOCENE EPOCH is the uppermost subdivision of the Tertiary period (65.5 to 2.588 million years ago), and represents a geological stage from about 1.806 to 5.332 million years ago. Although the Pliocene was generally warmer than the present, this epoch is characterized by pronounced climatic oscillations that ultimately led to the characteristic cooling of the late Quaternary glacial-interglacial cycles. Pliocene climate data are inferred from oxygen isotope, dust, microfossil, and in some cases pollen data from cores collected under the flag of the Ocean Drilling Program (ODP), as well as terrestrial deposits. These records have allowed climatologists to refine the absolute chronology of the Pliocene epoch, and provide a continuous climatic record of global ice volume, sea surface temperatures, aridity, and terrestrial vegetation patterns.

The first Pliocene cooling event is documented at 4.5 million years ago, and was followed by variable, but persistent reductions in temperature after 3.6 million years ago. A brief period of warmth followed until 3.5 million years ago, at which time a second cooling event took place. A well-characterized mid-Pliocene warm period dates to approximately 3.3 to 3.15 million years ago, and is followed by the return to progressive cooling that culminated in the arrival of early northern hemisphere glacial-interglacial cycles about 2.75 million years ago. Significant growth of ice sheets did not begin in Greenland and North America until approximately three million years ago, following the formation of the Isthmus of Panama. Many agree that this final Pliocene cooling period set the stage for strongly developed glacial events of the Pleistocene (1.8 million to 11,550 thousand years ago) and thus represents a climatic stage that is most relevant to the climates of late Tertiary and early Quaternary.

The contemporary significance of the mid-Pliocene warm period lies in its utility as a model for future scenarios of global warming. This is because continental distributions and climate-indicative plant taxa are thought to have been very similar to today. Members of the Goddard Institute for Space Studies (GISS) and the PRISM (Pliocene Research, Interpretations and Synoptic Mapping) group have exploited these paleofeatures in their efforts to model global Pliocene climate and vegetation distributions. Average mid-Pliocene global sea levels are modeled at 33 to 82 ft. (10 to 25 m.) higher than today, due to reduced Greenland and Antarctic ice cover, while sea surface temperatures were approximately 6.5 degrees F (3.6 degrees C) warmer than at present day. Mid-Pliocene climate simulations generally indicated increased surface air temperatures, particularly during the winter, and increased annual rainfall, evaporation, and soil moisture. Pollen records from land-based cores are less chronologically accurate, but consistent with a 7–18 degrees F (4–10 degree C) warmer northern hemisphere climate, coupled with higher continental moisture levels. This is especially evident in high latitude regions such as the Arctic.

The PRISM group has used fossil and pollen data to document vegetation patterns across the globe during the mid-Pliocene warm period. Their work indicates extensive conifer and mixed forests in the mid-Pliocene Arctic, and generally more northerly distributions of the mixed deciduous forests of eastern North America. Interior North America was likely to be moister, and warmer than today, with evidence of lakes in southeastern California, Arizona, and Utah. Northern Europe was warmer and wetter, with a greater abundance of swamps and wetland areas. Little information exists about Central and South America, but the limited numbers of pollen studies are consistent with GISS climate models suggesting a warmer, wetter climate, with a greater abundance of steppe and prairie vegetation. The Australian mid-Pliocene warm period is poorly documented, but it is thought to be wetter than today, with broader distributions of forest flora. Regions of Antarctica were significantly warmer than today, so increased exposure of soils supported the presence of mixed beech forests.

The cause of the mid-Pliocene warming is uncertain, but some combination of CO_2 increase and change in ocean heat transport may have been responsible. Carbon isotopic data from deep-sea microfossils, coupled with GISS climate models, support the increased strength of thermohaline circulation during the mid-Pliocene, particularly with respect to North Atlantic deep water production. However, simulations where CO_2 is the single variable show that the proposed, realistic patterns of mid-Pliocene oceanic heat transports would only have been possible at CO_2 levels greater than 1,200 ppm. There is no evidence supporting such elevated CO_2 excursions, but some workers suggest that even the predicted minor increases up to 380 ppm, in combination with altered ocean heat transport, may have been enough to catalyze mid-Pliocene warming.

Early Pliocene fauna was transitional, favoring grazers over browsers, as grasslands and savannas expanded in central North America and Africa, thereby replacing woodlands and their associated fauna. Charismatic Pliocene fauna included mammoths, mastodons, camels, and hippopotamus in the mid-Northern Hemisphere latitudes, while large turtles and marsupials were found in the southern hemisphere. Pliocene high-Arctic fauna was primarily Eurasian, characterized by now extinct species of beavers, badgers, deer, and caniids, the presence of which is consistent with mixed-evergreen forest vegetation. The Pliocene deposits of eastern North America revealed mostly Eurasian fauna, most notably new species red panda.

Pliocene Africa, prior to 2.8 million years ago, was wetter than today, as evidenced by deposits of mangrove swamps and tropical forests, which retreated southward as desertification intensified. The western Sahara desert likely formed after 2.8 million years ago. The Pliocene is a particularly important time for the evolution and diversification of hominids. The aridity-humidity cycles that were related to the late Pliocene glacials-interglacials in the northern hemisphere in the Pliocene climate of Africa may have shaped hominid evolution by creating cyclic opportunities for species extinction and innovation.

Poland

LOCATED IN EASTERN Europe, Poland has a land area of 120,728 sq. mi. (312,679 sq. km.), with a population of 38,125,500 (2006 est.), and a population density of 320 people per sq. mi. (122 people per sq. km.). Some 47 percent of the country is arable, with a further 13 percent used as pastures and meadows, and 29 percent is forested.

Regarding electricity generation in the country, 98.1 percent comes from fossil fuels, mainly coal that is mined in many parts of the country, with 1.5 percent from hydropower. As a result of this, even though Poland is less industrialized than many other European countries, it has a high per capita rate of carbon dioxide emissions—9.1 metric tons in 1990, falling slowly to 8.0 metric tons per person by 2004. Some 57 percent of all carbon dioxide emissions in the country come from the production of electricity, with 17 percent from manufacturing and construction, 11 percent from transportation, and 11 percent for residential purposes. The reliance on coal has meant that 76 percent of Poland's carbon dioxide emissions have been from solid fuels, with 15 percent from liquid fuels, and 7 percent from gaseous fuels.

The rising average temperatures in Poland as a result of global warming and climate change have caused hot summers in Lesser Poland, a region in the south of the country. Poland has been actively involved in various schemes to introduce carbon trading, and has even managed to reduce its own emissions rate, although it is hoping to cut back further. As a result, Poland has tried to follow a project that was developed by the Global Environment Facility, by which Mexico and Norway managed to reduce their power use through widespread introduction of compact fluorescent lamps in two major cities. In the case of Poland, this would also involve the conversion of coal-fired boilers to use gas. The main problem with this has been the political power of the coal-mining areas, which has hindered many attempts to reduce the dependence on coal.

The Polish government took part in the UN Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. It signed the Kyoto Protocol to the UN Framework Convention on Climate Change on July 15, 1998, committing to a 3 percent reduction prior to ratification, which took place on December 13, 2002, with it entering into force on February 16, 2005.

Polar Bears

THE POLAR BEAR (order Carnivora, family Ursidae) is the largest bear species and is thought to have evolved from brown bears, *Ursus arctos*, approximately one million years ago. There are 19 recognized populations, distributed in Canada, the United States (Alaska), Norway (Svalbard Islands), Denmark (Greenland), and Russia. The current estimated worldwide population is 20,000–25,000.

Polar bear territories can cover tens of thousands of sq. km. They live solitarily, but often congregate around food sources. Their diet consists primarily of ringed seals, but includes other seals, walruses, and beluga whales. They get the majority of their nutritional intake in the spring and summer from seal pups, which can be as much as 50 percent fat. Polar bears can swim for 37 mi. (60 km.) without resting, at speeds up to 6.2 mi. per hour (10 km. per hour). They possess several adaptations for a semi-aquatic existence, including partially webbed front paws, eyes adapted to see underwater, and a thick fat layer (eight to 12 cm.) that provides buoyancy and insulation in water.

Polar bears are also highly adapted to the Arctic climate. Arctic temperatures can drop to minus 49 degrees F (minus 45 degrees C) for days or weeks, but polar bears can withstand this due to their thick fat layer, a dense undercoat of fur with longer guard hairs, and black skin (which absorbs heat from sunlight). Other Arctic adaptations include white-seeming fur for camouflage (the hairs are actually colourless and hollow), small ears and tail (which reduce heat loss), large furry feet (which act like snowshoes), and a digestive system very effective at absorbing and storing fat.

Females become sexually mature at four to five years of age. Males may not mate successfully until they are 8 to 10 years old. Mating occurs from April to June and each male may mate with more than one female. The females have induced ovulation, mating multiple times causes the release of an egg. The implantation of the blastula (the fertilized egg after several cell divisions) is delayed until September/October, and in November/December the female excavates a den in the snow. She eventually gives birth in December or January. One to three cubs are born (two-thirds of cubs are twins) and they are nursed in the den until March/April, when they emerge. Cubs are weaned at the age of two or three years. During

A reduction of sea ice would result in the loss of polar bear habitat. It would also affect their access to food and to mates, and disrupt their migration routes. Many drowned polar bears have been reported, the result of larger areas of open water between ice floes.

this period, they learn important hunting skills from their mother. Occasionally, cubs are attacked and killed by males, so mothers are fiercely protective. Females breed after they wean the current cub(s), but will not reproduce at all if conditions are unfavorable. Cub mortality rates are high.

The most common cause of death for subadult bears is starvation, as they do not yet have a territory and must compete with larger bears, pushing many into marginal habitats. In adulthood, mortality drops sharply (to less than 5 percent annually); the most common natural cause of death in adults is attacks by other bears. Human activities and impacts that pose the greatest risk to polar bears include hunting, pollution, industrial development, and climate change.

HUMAN EFFECTS ON POLAR BEARS

Humans kill polar bears for aboriginal subsistence, sport, and defense of human life and property. In some areas, monitoring of polar bear kills is effective (in Norway and the United States), but in other areas there is little reliable information (Russia and Greenland). Concerns have recently been expressed about the threat posed by trophy hunting (currently allowed only in Canada and Greenland). Quotas are often based on poor population data. Approximately 80 trophies are imported into the United States each year from Canada.

Arctic marine mammals can accumulate high concentrations of pollutants in their blubber. As top predators, polar bears accumulate the highest concentrations, and in some areas there is concern about pollution effects on the bears' health. Polar bears with abnormal genitalia and other defects have been recorded, and there have been suggestions that these are caused by exposure to certain contaminants. Development in the Arctic is also an issue. The Arctic is rich in natural resources, especially oil and gas. Exploration for and extraction of these resources involve construction that could potentially reduce habitat, produce pollution, or cause disturbance.

Because of their exclusively Arctic habitat and their charismatic nature, polar bears have become the "poster child" for the impacts of climate change. The primary concern is the loss of sea ice. This would remove essential habitat, for both the bears and their marine mammal prey. Increasing numbers of drowned polar bears have been reported, the result of increasing areas of open water between ice floes, presumably leading to overexertion during swimming. The loss of ice cover could also reduce the ability to access prey and mates, disrupt migration routes, and increase distances animals have to travel to find food (exacting an energetic cost). Many females also construct their birthing dens on ice. In the past 20 years, the proportion of dens located on sea ice has halved.

Habitat loss and prey reduction may force bears closer to human habitation to find food. Sightings of animals near Arctic towns and villages are occurring with greater frequency. This increases the likelihood of negative human/polar bear interactions. In addition, researchers have reported a significant decrease in polar bear body condition over the past 20 years, and such a decline is likely to have impacts on reproduction and survival.

Climate change may also cause chronic overheating in the highly cold-adapted bear. Finally, rising temperatures are likely to cause a shift in the distributions of other bear species; for example, brown bear populations may shift farther north and could compete, or hybridize, with polar bears.

CONSERVATION OF POLAR BEARS

In 1965, the "polar bear" nations met and agreed that each country should take whatever steps were necessary to conserve the species. Cubs, and females accompanied by cubs, should be protected throughout the year; each nation should, to the best of its ability, conduct research on polar bears within its territory; and each nation should exchange information on polar bears freely. This eventually led to the signing of the International Agreement on the Conservation of Polar Bears in May 1973 in Oslo, Norway. This agreement is currently the major international polar bear treaty.

In 1982, largely due to declines resulting from hunting pressure, the World Conservation Union (IUCN) listed the polar bear as Vulnerable. This rating was reduced to Lower Risk in 1996. However, in May 2006, polar bears were relisted as Vulnerable due to a predicted population reduction of more than 30 percent within three generations (45 years), and a decline in area of occupancy, extent of occurrence, and habitat quality resulting from climate change.

In the United States, polar bears are managed by the Fish and Wildlife Service and are protected by the Marine Mammal Protection Act (MMPA), which prohibits harassment, hunting, capture, or killing, or attempts to do any of these. There are exemptions for Alaska Native subsistence hunting, as well as scientific research and "incidental harassment" from activities such as oil and gas exploration. However, a controversial amendment in 1994 permitted the import of sport-hunted polar bear trophies into the United States from some Canadian populations. A legislative attempt is ongoing to repeal this amendment.

In February 2005, the Center for Biological Diversity and Greenpeace USA petitioned the U.S. government to list polar bears as threatened (that is, likely to become endangered within the foreseeable future throughout all or a significant portion of its range) under the U.S. Endangered Species Act. Such a listing would obligate the U.S. government to reduce anthropogenic impacts on polar bears and to devise a plan to aid their recovery. In December 2006, the U.S. Secretary of the Interior announced a proposal to list the polar bear as threatened. The deadline for deciding on the listing was January 2008.

Policy, International

INTERNATIONAL POLICY IS complex because of the necessity to consider the needs of each sovereign nation against economies, global environmental impact, and contributions to human-induced climate change. Much of the work toward international cooperation is done through the United Nations (an international organization with nearly all countries as members). The United Nations facilitates discussion and commitment, though it has limited authority or power. Members agree that something most be done about climate change and the environment; however, getting member nations to agree on solutions is harder. Conflicts and disagreements usually include protection of national interests by not turning authority over to the United Nations, wording of agreements that appears to not protect the interest of private industry or national interest, and economic differences between developing and developed countries.

CURRENT INTERNATIONAL POLICY

The UN Environment Programme (UNEP) was formed in 1972 with the specific purpose of encouraging collaboration on conservation and development. In 1977, the international community adopted a Plan of Action to Combat Desertification due to impacts on economy, society, and environment. In 1991, the UNEP concluded that even with some successes, land degradation due to desertification had increased, and at a 1992 conference proposed sustainable development and for the UN General Assembly to establish an Intergovernmental Negotiating Committee (INCD) to prepare a Convention to Combat Desertification, which was adopted in 1994, with entry into force on December 26, 1996. Over 179 countries were parties to the convention as of March 2002.

The Montreal Protocol on Substances that Deplete the Ozone Layer was agreed on September 16, 1987, and entered into force on January 1, 1989, and has been ratified by 191 countries. In meetings for the Montreal Protocol, the parties established adjustments and reductions of production and consumption of the controlled substances.

At the 1992 UN Conference on Environment and Development, member nations agreed to work together to formulate solutions. The Convention on Biological Diversity (CBD) was adopted at the conference for commitments to maintaining ecology balanced with economic development, though the United States disagreed with some document wording as not protecting biotechnology firms.

The Intergovernmental Panel on Climate Change (IPCC) was formed in 1988 by partnership with the World Meteorological Organization (WMO) and the UN Environment Programme to assess the risk of human-induced climate change, possible impacts of climate change, and provide options to deal with climate change. The First IPCC Assessment Report completed in 1990 provided the impetus for the formation of the UN Framework Convention on Climate Change (UNFCCC) by the UN General Assembly.

The UNFCCC is an international treaty joined by most countries and adopted in 1992, and entering into force in 1994. The UNFCCC provides the overall policy framework for addressing climate change and for coping with the impacts from inevitable temperature increases. From initial discussions, the idea came about of incorporating policy-based commitments into the international climate negotiations. The variety of options considered by the Intergovernmental Negotiating Committee was a system incorporating national assessment, along with implementation strategies and programs for reducing greenhouse gas emissions by considering their country's needs and responsibilities within the scope of international, regional, and local circumstances to determine what agenda items would be a priority and for the setting of objectives.

Developed countries committed under the initial negotiations to take the majority of responsibility for creating policy and actions to mitigate climate change and limit/reduce their output of emissions of greenhouse gases to 1990 levels by the year 2000. In debating further commitments, the participants discussed a variety of options, including policies and measures, as well as quantified emission targets. The 1995 Berlin Mandate, under negotiation, requested more significant quantification of emissions and stricter policy to enforce reduction objectives in a certain period of time. The various participants presented and supported policy approaches including across-the-board standards and taxation as well as options to choose from. Some proposals blended mandatory strict policy standards and taxation, along with a variety of options for reaching those goals.

Proposals from the European Union, the primary proponent of common and coordinated policy, listed specific actions including mandatory commitments, highly recommended commitments, and voluntary commitments. The United States and other participants favored target-based approaches to allow countries complete autonomy in choosing policies and measures.

By the late 1990s, working in voluntary partnerships was leading to reductions in conflict among stakeholders, new ideas on sustainable economic development and poverty alleviation, new thinking about the relationship between conservation areas and the communities in and around them, and more focused application of existing resources. An addition to the UNFCCC treaty is the Kyoto Protocol, drafted in 1997 by 160 nations, calling for the 38 industrialized countries releasing the most greenhouse gases to cut their emissions to levels five percent of 1990 levels by 2012 to achieve a worldwide reduction of greenhouse gases.

THE KYOTO PROTOCOL

The Kyoto Protocol entered into force on February16, 2005, and is legally binding on countries that ratify the agreement. In initial negotiations, the United States voluntarily accepted a more ambitious target, promising to reduce emissions to 7 percent below 1990 levels; the European Union, which had wanted a much tougher treaty, committed to 8 percent; and Japan, to 6 percent. Since the adoption of the Kyoto Protocol, 175 parties have ratified it. The protocol sketched out the basic features of its mechanisms and compliance system, for example, but did not explain the all-important rules of how they would operate. The United States has not ratified the agreement because of wording and exclusions of developing countries from emissions reduction.

Though the United States has not ratified the Kyoto Protocol, the government has established a comprehensive policy to slow the growth of emissions with voluntary and incentive-based programs, strengthen institutional advancement of climate technologies and climate science, and enhance international cooperation. In February 2002, the U.S. government announced a comprehensive strategy to reduce the greenhouse gas intensity of the American economy by 18 percent 2002–12, preventing the release of more than 100 million metric tons of carbon-equivalent emissions to the atmosphere (annually) by 2012 and more than 500 million metric tons (cumulatively) 2002–12.

A core challenge in addressing global climate change is arriving at multilateral arrangements ensuring adequate effort by all major economies to moderate and reduce their greenhouse gas (GHG) emissions. Thus far, the multilateral effort has relied most heavily on a particular form of commitment-economy-wide emission targets. Developed countries agreed to voluntary targets under the UNFCCC, and most later agreed to binding targets under the Kyoto Protocol. Most developing countries, however, view quantified emission limits as a potential cap on their growth and are unlikely to accept binding targets in a post-2012 climate agreement.

At the World Conference on Disaster Reduction, The Hyogo Framework for action signed in January 2005 by 168 countries details steps to reduce the impact of natural hazards on populations. It assesses disaster capabilities and needs and incorporates risk reduction strategies and adaptations associated with existing climate variability and future climate change, including risks from geological hazards such as earthquakes and landslides. The result has been 40 countries adjusting national policies to give priority to disaster risk reduction.

The mission of the Millennium Development Goals is to alleviate poverty by integrating sustainable development into national policies and prevent the loss of natural resources. These goals allow countries to determine their own priorities. One way this is being done is with the creation of model forests to show how sustainability practices can have a positive impact on human life and to reverse environmental degradation with conservation and reforestation.

FUTURE OUTLOOK FOR INTERNATIONAL POLICY

Some international policies retain support over the long term, like the Montreal Protocol on Substances that Deplete the Ozone Layer and the Convention to Combat Desertification. The reduction in greenhouse gas emissions measures agreed to in the Kyoto Protocol end in 2012.

In determining future policy, the success of the target-based approach to reducing greenhouse gas emissions and its enforceability must be examined. The commitment is based on outcome, and coupled with emissions trading, provides economic benefits as well as freedom to apply reduction strategies in the most cost-effective manner. This works for industrialized nations, with already established economies. Developing countries may not accept imposed limits on emissions, because those same limits may limit the potential for growth. Developing countries already have multiple concerns to improve first, including environmental issues like water quality, air quality, poverty, and health issues like access to sanitation, nutritious food, and health services.

Ongoing negotiation and commitment will be needed to continue international cooperation on climate change policy. As discussed at the Climate Dialogue at Pocantico, flexibility seems to be the most important factor in gaining support by perhaps allowing countries to develop national policies in developing countries to reduce emissions on a more individual basis, instead of being limited to strict limits set by an economy-wide emission limit. Within this framework, nations would need to establish quantifiable measurements of emission impacts.

Since the Kyoto Protocol applied emission reduction levels to industrialized nations, gaining agreement to emission standards from developing countries may require some incentive-based policies. Researchers have made a variety of proposals, including the trading of carbon/emission credits as long as emissions can be quantified, control of conventional air pollutants, or improvement of agricultural productivity. Taking measures for limiting the extent of global warming from the greenhouse effect includes preventive measures (reducing emissions, enhancing carbon sequestration) and adaptive measures (construction to protect against the effects of climate change, improving water resources, and improving cultivation practices, or shifting crops to match the plants' ideal weather conditions for maximum production).

Also to be considered is a shift to previously underutilized or unused commodities like carbon taxes on all fossil fuels, such as gas, oil, coal, and the electricity generated from these sources. These taxes would shift the burden of emissions reduction to the consumer by inflating the price of using carbon-based energy and making the use of energy conservation measures and alternative resources more attractive and cost-effective, as well as increasing the demand for alternative sources. The trading of carbon credits (with each nation allocated a certain permissible level of carbon emissions and the ability to sell leftover allocations to nations who have exceeded their allocation limits), subsidizing non-carbon-based fuel providers instead of fossil fuel providers, and research and development expenditures promoting the commercialization of alternative technologies and promoting the transfer of technology to developing nations could also help.

Any measures taken to prevent global climate change will have economic effects, both positive and negative, on the economy, including production, employment, and investment. Continued scientific research on climate and atmosphere, as well as environmental education and continued voluntary dialogue between countries on the future of global environment and economic policies, can help lead to action and global policy development to overcome the limitations of determining economic policies.

Policy must also take into account the damages caused by the impacts of climate change. While climate models vary on temperature increase for each region, depending on the already present climate, potential risks include rising sea levels causing flooding, loss of coastal wetlands, beach erosion, saltwater contamination of drinking water, and damage/decreasing stability of low-lying property and infrastructure; possible increase in frequency and intensity of storms make flooding a possibility in many areas made worse by difficult drainage and causing other damage. Flooding and runoff could contaminate water supplies (with eroded soils and agricultural chemicals containing high concentrations of nitrates, pesticides, and soil nutrients); other damages could include decreased water supplies, population (both human and animal) displacement, changes in agriculture (with benefit to colder climates and loss to warmer climates), forest loss with persistent drought, and loss of trees unsuited to higher temperatures.

Changes within established ecosystems would affect wildlife, including breeding grounds of waterfowl and migratory birds. Human health risks include contracting certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents. Warmer temperatures would increase the incidence of heat-related illnesses and lead to higher concentrations of ground-level ozone pollution, causing respiratory illnesses (diminished lung function, asthma, and respiratory inflammation). In addition, psychological factors related to higher stress could be prevalent. All of these potential impacts will also have an impact on the economy, and policy, international, national, or local, must take these possibilities into account, as some areas are more vulnerable than others; those with high emissions may not be the ones who suffer from the consequences.

Groundwork for emissions crediting is being demonstrated through the Clean Development Mechanism of the Kyoto Protocol. The projects already approved could generate 870 million tons of emission credits with the current estimated value of between $6 and $9 billion. This monetary value makes carbon crediting a viable source of income, especially for developing countries and those with carbon sequestration in forests and agricultural areas. This type of market enterprise would require independent verification. The limitation to this program might be creating disincentives for industrialized nations to reduce emissions with the option to purchase carbon credits or to not agree to the program at all if they will not be able to benefit from the income produced.

The quantification of standards thus far has been based on present levels and emissions assessments. For developing countries that have not had access to the vast amounts of energy used by industrialized nations, the strategy is not reduction of emissions, but limiting emissions to standards for consumption of energy against the development of renewable energy and improved social structures. The effectiveness of a policy is only as good as the results; other variables may be in action instead of just the policy.

As environmental awareness grows and more individuals choose climate-preserving strategies, those will have a cumulative effect on emissions. Options for telecommuting reduce driving, an economic downturn affects production, and service industries consume less energy than industrial production. Improved agricultural practices remove carbon from the air. In some cases, the effectiveness of the emissions reduction policy will be difficult to determine. The most vital part of international policy is raising awareness of the environment and what can be done to combat climate change and the effects of climate change.

Policy, U.S.

U.S. GLOBAL WARMING and climate change policy is a hotly contested issue, one fraught with partisan bickering throughout the course of at least the last three presidential administrations. The official U.S. position has vacillated considerably over the last two decades, swinging from initial global leadership displayed during the very first climate change hearings in the U.S. Congress during summer 1988, to a mixed bag of sorts during the tenures of President George H.W. Bush and President Bill Clinton, to periods of obstruction and outright suppression of scientific studies during the early 21st century under President George W. Bush.

Despite this checkered past, though, a previously politically hamstrung United States is now making considerable advances in climate change policy. Thanks in large part to the federalist model of a national government that shares some power with its individual states, as well as local municipalities, and a fundamental separation of powers among executive, legislative, and judicial branches at the national level, notable changes are underway.

Many analysts now believe that the United States has reached a tipping point in terms of public awareness of climate change. Scientific consensus on both the rising global temperatures and anthropocentric roots of that shift, combined with concerns about energy insecurity and its ties to international terrorism, have pushed climate change discourse to the forefront, particularly in the context of what some now label the post–Hurricane Katrina effect, the growing recognition among Americans that they too are vulnerable to the vagaries of climate change.

No longer is this a problem just for their children or grandchildren to consider, or a problem that threatens primarily the developing world or small island states. According to a survey commissioned by the Yale Center for Environmental Law and Policy in March 2007, 83 percent of Americans believe global warming is a serious problem. Analysts increasingly believe that a reasonable debate about the regulation necessary to reduce greenhouse gas emissions is possible in the United States and that this regulation makes good economic sense, much in the model of the 1987 Montreal Protocol on Substances that Deplete the Ozone Layer.

Yet, when the Kyoto Protocol, the only global treaty with binding measures to address climate change, finally entered into force on February 16, 2005, the United States was one of only two Annex I industrialized countries (Australia being the other) that did not ratify the protocol. In total, 175 states of the world joined together without the world's leading economic engine, and its biggest polluter. United States resistance to the Kyoto Protocol rests firmly on this division between Annex I and Annex II countries, the developed and developing world, and the fact that Kyoto exempted Annex II states from any reductions in greenhouse gas emissions, at least until 2012.

While India is also a concern, American diplomats fear China most. China is the world's largest and most populous country, one that has ranked among the world's fastest-growing economies for two decades. China is also heavily coal-dependent and becoming ever more so, building an average of one new coal-fired plant a week. Its total energy-related carbon emissions have more than doubled since 1980, and it is widely regarded as on pace to pass the United States as the leading greenhouse gas emitter before 2020. Nevertheless, per capita emissions of carbon dioxide in China are still seven times less than that of the United States, according to the Sierra Club. With only 4 percent of the global population, Americans account for roughly 22 percent of the planet's greenhouse gases. Because China was such a late entry into an industrialization process that has created the climate change problem, the ethics of reducing greenhouse gas emission there are spotty. However, the country's economy and greenhouse gas emissions are growing at such a fast pace, reductions seem necessary.

The globalization argument as to dirty industry being able to relocate to China if it continues to be exempt from any global agreement is essentially a red herring. According to the nonpartisan Pew Center on Global Climate Change, the vast majority of U.S. greenhouse gases come from transportation, commercial, residential, and agricultural sectors that cannot leave the country. Only industry itself could potentially do so, which in 2004 accounted for 30 percent of U.S. greenhouse gases.

HISTORY OF CLIMATE CHANGE IN THE U.S.

The United States was an early leader in the field, dating at least to the aforementioned congressional climate change hearings during summer 1988. Experts such as National Aeronautics and Space Administration's (NASA) Jim Hansen first sounded alarms as to the severity of the climate change problem. Four years later, at the 1992 UN Conference on Environment and Development (UNCED) in Rio de Janeiro, Brazil, the United States continued to actively participate in climate deliberations on the international stage. President George H.W. Bush attended what was at the time the largest gathering of world leaders in history, signing the UN Framework Convention on Climate Change (UNFCCC), one of the five major agreements reached at what has since been referred to popularly as the Earth Summit.

But both President Bush's presence and signature were couched within political compromise. Bush feared mandatory limits on greenhouse gas emissions would severely hamper the U.S. economy, and only agreed to attend if the final document would go no further than suggesting voluntary limits by each country. His famous saying was that America's way of life was not up for negotiation. Popular opinion in the United States had yet to grasp the concept of sustainable development, the idea that economic development and environmental resource protection can go hand in hand.

Thus, the great irony of Rio is that a conference that was intended to firmly establish the 1987 Brundtland Report's definition of sustainable development, outlined in their publication *Our Common Future* as development that meets the needs of the present generation without sacrificing the needs of future generations, actually did the exact opposite. An entire cohort of American diplomats handcuffed themselves by bowing to the popular connotation that a tension existed between economic and environmental health. For the next decade and a half, American climate change politics would be shaped primarily by President Bush's language, one that insinuated a trade-off between environmental protection and economic development and completely ignored the underlying foundation of economic health, namely a healthy environment.

The following year, President Bill Clinton, after defeating President Bush in his reelection bid, was faced with precisely this type of obstacle in public sentiment. Despite placing perhaps the most qualified environmental politician of his generation in the number two slot of the Democratic ticket in 1992, President Clinton was unable to generate much political traction when it came to the climate change debate during the eight years in office with Vice President Al Gore, Jr. Two key examples bear out this point. The first is the attempt early in Clinton's first administration to institute a British thermal unit (BTU) tax, one that would raise taxes for a family income of $40,000 by approximately $17 a month and those making under $30,000 by none at all. This proposal failed in short order and reinforced the perception in American politics that the public will not pay to solve a long-forming, distant problem with uncertain consequences. There are simply too many more immediate concerns the average American faces on a day-to-day basis.

The second major example rests squarely upon the foundation of the international climate change debate, the Kyoto Protocol. In the lead-up to the United States signing that international treaty in December 1997, Clinton Administration officials took a central international role. With the preceding April 1995 Berlin Mandate, for instance, the United States was a passionate supporter of the argument for differentiated responsibilities, where the industrialized world would agree to restrict its emissions on the average of 5 percent below its 1990 levels before the developing world would do so, much like the Montreal Protocol had divided the world between developed and developing world.

But well before Vice President Gore left for Kyoto in late 1997 to join the U.S. delegation led by former senator Tim Wirth (D-CO), the U.S. Senate passed the bipartisan Byrd-Hagel Resolution, which stated that body would only support a treaty that included all countries of the world. Touting what would come to be labeled global apartheid, the Byrd-Hagel Resolution demonstrated an overwhelming sentiment, passing by a vote of 95–0. Thus, despite signing Kyoto, Clinton never submitted the treaty for ratification in the Senate, a constitutional requirement that dictates any international treaty must receive two-thirds Senate support before becoming force of law.

THE GEORGE W. BUSH ADMINISTRATION

Such failures pale in comparison to the politicization of climate change during the successor administration of President George W. Bush. Over his two terms, borrowing in large part from the tobacco industry playbook, President Bush has overseen a White House that first vociferously discounted the science of climate change, and then turned to outright suppression of its evidence. Thus, while President Bush has developed a combination of modest bilateral and regional initiatives such as the Asia-Pacific Partnership on Clean Development and Climate, International Partnership for a Hydrogen Economy, and the Carbon Sequestration Leadership Forum, the lasting legacy of President Bush in terms of climate change will be a decidedly negative one.

He has ignored scientific consensus on climate change and its human-induced links in the form of the widely regarded assessments by the Intergovernmental Panel on Climate Change (IPCC). He has withdrawn the United States from Kyoto, citing the familiar refrain on lack of participation by China. And most egregious of all, he has obstructed and even deleted the dissemination of information from his own Environmental Protection Agency (EPA) and other governmental scientists. The most publicized of these was reported by the *New York Times* in its coverage of e-mails obtained by Greenpeace under the Freedom of Information Act, which depict the White House Council on Environmental Quality chief of staff Phil Cooney, a former oil industry lobbyist, as actually doctoring science by editing climate scientist reports to render them innocuous in 2002.

Despite these actions by the Bush Administration, separation of powers in the United States has allowed both the legislative and judicial branches to weigh in regarding climate change. In April 2007, for example, the U.S. Supreme Court, in the landmark 5–4 decision of *Massachusetts et al. v. EPA et al.*, sided with the Commonwealth of Massachusetts in its suit of an EPA that had heretofore ignored whether greenhouse gas emissions cause or contribute to climate change. The Court declared Massachusetts, as well as the supporting states of Connecticut, Illinois, Maine, New Jersey, New Mexico, New York, Rhode Island, Vermont, and California, had every right to request the EPA to regulate greenhouse gases.

Six months prior, the sweeping midterm elections of November 2006 saw a redistribution of party lines in the U.S. Congress, with Democrats gaining advantages in both the House and Senate (with the two Senate independents in Vermont and Connecticut, respectively, agreeing to caucus with the Democrats) for the first time since 1994. While that election was primarily driven by sentiment over the war in Iraq (and climate change debate in Congress is by no means divided solely along partisan lines, with western coal interests and mid-western automobile labor interests often influencing Democrats more than Republicans), the tangible results within congressional committees were nearly immediate, as at least five different greenhouse cap and trade bills began circulating in Congress when it returned to session in January 2007.

Most notably, the newly minted chairwoman of the Senate's Environment and Public Works Committee, Sen. Barbara Boxer (D-CA) replaced James Inhofe (R-OK), who held a grand total of five hearings on climate change in four years as head of that committee, including science-fiction writer Michael Crichton as his star witness. Senator Inhofe was also well known for labeling global warming as the greatest hoax ever perpetrated on the American people. Senator Boxer promptly held five hearings on climate change in her first three months at the helm and proposed what will likely become the centerpiece of a renewed national debate with Sen. Bernie Sanders (I-VT). This bill, formerly known as S-309 but more popularly referred to as the Global Warming Pollution Reduction Act, requires emissions reductions in the United States to the 1990 level by 2020, 27 percent below 1990 by 2030, 53 percent below 1990 by 2040, and 80 percent below 1990 by 2050.

CLIMATE POLICY: STATE AND REGIONAL LEVELS

The most significant advances in U.S. climate policy to date have actually occurred at the state level. It is in these laboratories of democracy where federalism has allowed a number of enlightened governors and their respective legislatures to forge ahead where the federal government has floundered. Where the United States is flexing its muscle most is in California under Republican governor Arnold Schwarzenegger. As the eighth-largest industrial engine on the planet, California's 2006 law targeting a 25 percent cut in carbon dioxide by 2020 is more than mere lip service to climate change.

Furthermore, as the first U.S. law imposing mandatory caps on carbon dioxide, it turned heads all the way up to the Potomac and beyond. This was not California's first foray into the climate change debate. Four years prior, in 2002, the state passed legislation creating vehicle emissions standards that required reductions of 22 percent in tailpipe greenhouse gas emissions from new vehicles by the 2012 model year and 30 percent by the 2016 model year. Governor Schwarzenegger and California are responding to the increasing loss of Sierra mountains snowpack, their primary source of drinking water, and believe they must compensate for a federal government that has dragged its heels on the issue of climate change for far too long. They also believe their economy is large enough to force others to sit up and take notice.

That logic appears to be on target. In February 2007, governors of Arizona, New Mexico, Oregon, and Washington joined California in signing an agreement establishing the Western Regional Climate Action Initiative, a joint effort to tackle climate change by reducing greenhouse gas emissions with a market-based system. This set-up mimics that of the Regional Greenhouse Gas Initiative (RGGI), which became the first mandatory U.S. cap-and-trade program for carbon dioxide in December 2005. Negotiated by the governors of seven northeastern and mid-Atlantic states (Connecticut, Delaware, Maine, New Hampshire, New Jersey, New York, and Vermont) with Maryland joining in April 2007, RGGI sets a cap on emissions of carbon dioxide from power plants at current levels in 2009, and then reducing emissions 10 percent by 2019.

U.S. BUSINESS INTERESTS

Aside from state and regional initiatives, the business community is making perhaps the most significant inroads regarding climate change policy. Echoing the logic and business acumen that drove DuPont Chemical from its position as a stiff opponent of domestic regulation of chlorofluorocarbons (CFCs) in the late 1970s to that of a staunch supporter of the globally-reaching Montreal Protocol in the mid-1980s, an incredibly diverse cross-section of corporations now stands in favor of mandatory limits on carbon dioxide emissions.

A business-NGO alliance, the U.S. Climate Change Action Partnership (USCAP), which touted 33 different members in September 2007, six of which are environmental non-governmental organizations (NGOs) and 27 of which are corporations, is a prime example. These businesses cover a broad spectrum of the economy, including several from the fossil-fuel industry and transportation sector as well as energy and electric power interests, including BP America Inc., Chrysler LLC, ConocoPhillips, Duke Energy, Ford Motor Company, General Electric, General Motors Corp., and Shell.

As Pacific Gas & Electric (PG&E) CEO Peter Darby explained in his congressional testimony in February 2007, these companies worry that a motley collection of different U.S. state regulations will emerge if no national direction is given, making their day-to-day operations much more complicated and expensive than they need to be. And they fear a United States that has abdicated its global leadership in this area risks handicapping their financial interests even further in the global marketplace. This is the driving rationale of USCAP and the reason its January 2007 publication, *A Call for Action*, calls for mandatory, market-driven cap and trade programs in carbon dioxide emissions. In short, USCAP outlines a proposal to first slow, then stop, and ultimately reverse emissions on the order of 60 to 80 percent below the current level by 2050.

CONCLUSION

Thus, on numerous levels, from both the governmental to the business sector, climate change policy in the United States has enjoyed a rebirth of late. The IPCC first noted a discernible human impact on climate change in 1995. In the 2005 aftermath of a devastating Hurricane Katrina and its utter destruction of the truly unique American city of New Orleans, Americans finally concurred. And according to NASA's chief climatologist Jim Hansen, this public opinion tipping point is about to encounter its scientific brethren. Hansen believes there are only 10 more years to act before it is too late, before the phenomenon of irreversibility enters the complex climate models. Others hope the time horizon to be a bit longer, but concur that we are talking about only a two degree C rise before the threat of irreversibility arises.

It is here that a third sector of democratic policymaking, that of civil society, becomes all the more relevant. Since the Frenchman Alexis de Tocqueville first visited the United States in the 1830s, democracy scholars have singled out the United States as a unique bastion of civil society. De Tocqueville's *De la démocratie en Amerique* (1835, 1840) found American individualism and its dominant moneymaking ethic supported the unusually high level of civic interactions outside official government structures. This is part of what handicapped the Bush and Clinton administrations in the 1990s and their efforts to face climate change policy seriously: Americans do not like to be told what they can and cannot do, especially when it limits earnings potential. But it is also what explains the burst of grassroots activity now underway regarding climate change. Americans see great financial loss if action is not taken soon.

Al Gore's 2007 Academy Award–winning film *An Inconvenient Truth* is but one piece in the puzzle galvanizing action. Environmental NGOs from the Sierra Club and Environmental Defense to the National Wildlife Federation and Natural Resources Defense Council to The Nature Conservancy and World Resources Center continue to beat their advocacy drums, and are now showing results. American public opinion surveys over the past decade show a decided maturation of understanding that climate change is real, is in large part human-induced, and, perhaps most notably, actually impacts their own lives in the United States.

Pollution, Air

THE ATMOSPHERE IS an important resource for the survival of all species on the planet, as a source of fresh air for breathing and as a protective layer against direct solar radiation. The Earth's atmosphere is composed of 78.084 percent nitrogen, 20.948 percent oxygen, 0.934 percent argon, 0.031 percent carbon dioxide, and 0.003 percent trace gases such as water vapor and air pollutants. The analysis of air bubbles trapped in ice cores provides evidence that the contents of so-called greenhouse gases, such as carbon dioxide, methane, nitrous oxide, ozone, sulfate, and carbonaceous aerosols, have significantly increased over the past 200 years. This historic change of the atmospheric composition is not fully understood, but it has roots in natural processes and human activity. As a result, both roles of the atmosphere are affected. First, the increase of greenhouse gases contributes to the increase in the amount of solar radiative energy trapped at the Earth's boundaries, which directly affects the planetary climate. Second, the composition of atmospheric air, particularly the air pollutants, strongly affects the human and environmental health.

The air pollutants are defined as substances that adversely affect humans, animals, plants and/or damage property. The air pollutant substances are gases, liquids, or solids, which are suspended in the atmosphere and emitted from different stationary or mobile sources. The pollution sources can be located in outdoor or indoor environments, and as a result the pollution levels are location dependent. Typical outdoor pollutants are particulate matter resulting from different combustion processes, including transportation. The gaseous pollutants include nitrogen oxides (NO_X), sulfur oxides (SO_X), and carbon monoxide (CO), also resulting from combustion processes. These primary pollutants can have chemical reactions in the atmosphere and create secondary air pollutants such as chemical substances forming smog. An example of naturally occurring pollutant is radon (Ra), a radioactive gas, which is released from the soil, and can be dangerous when trapped in poorly ventilated building basements. Indoor air quality is also becoming important because symptoms called sick building syndrome were correlated to the high levels of indoor air pollutants such as volatile organic compounds emitted from common building materials.

Many countries have established their regulations and standards for air pollution. The so-called first class standards define the maximum concentration levels of target pollutants, which are then attained through regulations passed by environmental protection agencies. The second-class standards provide the scales that define risk levels associated with outdoor activity, which are provided as advisory information to the public.

Pollution, Land

LAND POLLUTION IS the degradation of the land surface through misuse of the soil by poor agricultural practices, mineral exploitation, industrial waste dumping, and indiscriminate disposal of urban wastes. It includes visible waste and litter, as well as pollution of the soil. The contamination of land usually results from its commercial and industrial uses or from the spillage and dumping of waste, including landfill. These activities leave behind levels of trace metals, hydrocarbons and other compounds on the land, which have the potential to cause harm to people or the environment. The main human contributors to pollution are landfills. About half of the waste is disposed of in landfills. The gradual decomposition of landfill wastes over several decades also generates new environmental problems in the form of air pollutants. Trace organic gases are emitted from landfills, along with significant amounts of methane and carbon (IV) oxide, both of which are greenhouse gases. Garbage and other forms of waste arising from homes, municipalities, industries, and agricultural practices are the major sources of pollution on the land environment. The indiscriminate discharge of these wastes into the environment creates a filthy environment.

Unlike contaminated air and water, which directly affect human health, pollution of the land from the dumping or burial of solid wastes affects people less directly. The primary environmental concern is that a waste material in the soil may migrate into surface water or groundwater where it can be ingested and harm living organisms. Soil pollution is mainly due to chemicals in pesticides. Soil erosion and degradation are some of the problems facing the state of the land. The causes are losing six hectares of land every year, and losing 24 billion tons of topsoil. Globally, a minimum of 15 million acres of prime agricultural land is lost to overuse and mismanagement every year. Desertification is threatening about one-third of the world's land surface.

TYPES OF WASTE

Litter is waste material dumped in public places such as streets, parks, picnic areas, bus stops, and near shops. The accumulation of waste threatens the health of people in residential areas. Waste decays, encourages household pests, and turns urban areas into unsightly, dirty, and unhealthy places to live in. The following measures can be used to control land pollution. Anti-litter campaigns can educate people against littering, organic waste can be dumped in places far from residential areas, and inorganic materials such as metals, glass, paper, and plastic can be reclaimed and recycled. One of the main factors influencing fast generation of municipal sewage and garbage and agricultural, commercial, and industrial wastes is population growth. The world human population has increased tremendously, and there has been phenomenal urban growth due to the migration of rural-area dwellers to urban areas. The larger the population, the larger the wastes generated and the greater the pollution. Pollution becomes even more pronounced when the population is crowded into a smaller space.

The sources of domestic wastes are garbage, rubbish, and ashes. Municipal wastes emanate from bulky wastes, street refuse, and dead animals. Municipal solid wastes are wastes collected by private or public authorities from domestic, commercial, and industrial sources. No two wastes are the same. The wastes generated within a municipality vary widely depending on the community and its level of commercial venture. The data on waste will depend on the level of sophistication of the waste management operation. Domestic waste from a house will vary from week to week and from season to season. Waste varies from socioeconomic groups and from country to country. In most cases, the number of refuse dumps decreases with increasing distance from the city center. Other factors that influence the distribution of solid waste dumps in cities are distance from main markets, positions of residential houses, commercial and industrial centers, and topographic characteristics of the city that determine accessibility by vehicles.

Commercial wastes are traceable to markets, stores, and shops, while industrial wastes are from factories, power plants, and treatment plants. Commercial, domestic, agricultural, and industrial activities generate vast amount of wastes, which include paper, food, metals, glass, wood, plastics, and dust. Effluents from domestic and industrial sources are also potential land pollutants. Many commercial houses and industries, especially in developing countries, do not have an organized method of disposing of their wastes. They are dumped indiscriminately, thus constituting a menace, and if they are toxic or in any way harmful, they become hazardous to the health of the public. Spillage of oil on land is a source of pollution. Land can also be polluted by the introduction of pesticides. Acid deposition also changes the integrity of the land. Contamination of land gives rise to impairment of the quality of groundwater, and impoverishment of soil to the

Land pollution occurs in many forms. Some of the sources of land pollution are agricultural, commercial, industrial, military, and from the general public. About half of the waste is disposed of in landfills.

extent of not supporting plant and animal life. Land pollution leads to the uptake of pollutants by plants, thereby introducing the pollutant to the food chain.

Garbage or trash is a component of municipal solid waste, which includes all of the wastes commonly generated in residences, commercial buildings, and institutional buildings. Municipal solid wastes consist of such things as paper, packaging, plastics, food wastes, glass, wood, and discarded appliances. Similar kinds of wastes generated by industrial facilities also are part of municipal solid wastes. The additional wastes generated by manufacturing processes, construction activities, mining and drilling operations, agriculture, and electric power production are referred to as industrial wastes. The environmental threats posed by municipal and industrial wastes are varied. Though defined as nonhazardous wastes, many of these wastes are capable of harming human health and the viability of other living species. They contain discarded hazardous wastes like batteries, paints, solvents, and waste motor oil, items that add trace metals and organic compounds to the inventory of potential contaminants in soil.

Environmental pollution by industrial wastes has become a threat to the continued existence of plants, animals, and humans. Industrial pollution contains traces of quantities of raw materials, intermediate products, final products, coproducts, and by-products, and of any ancillary or processing chemicals used. They include detergents, solvents, cyanide, trace metals, mineral and organic acids, nitrogenous substances, fats, salts, bleaching agents, dyes, pigments, phenolic compounds, tanning agents, sulfide, and ammonia. Many of these substances are toxic. Because of the larger volumes of waste materials, landfills are the preferred method of waste disposal. The pollutants arising from a particular industry are different from those arising from another industry. The waste generated differs from industry to industry. The level of pollution arising from the industry depends on the nature and magnitude of its wastes.

Pollution by trace metals occurs largely from industries, trade wastes, agricultural wastes, and automobile exhausts. These wastes are large in magnitude and varied in types. They include large quantities of raw materials, by-products, coproducts, and final products. Mining is a major area where metal pollution occurs. Apart from natural occurrence such as erosion, metal pollution on land is a direct result of anthropogenic activities. The dumping of old or damaged vehicles on land occurs especially in developing countries. Also, the dumping of obsolete or dangerous military wastes on sites is another source of pollution. Apart from trace metals, the wastes contain organic materials, biological and chemical warfare explosives, pesticides, solid objects, and other materials peculiar to military operations. Trace metals in soil also can enter the food chain via uptake by plants and vegetation that are subsequently consumed by animals and humans, with deleterious consequences. Land disposal sites serve as breeding grounds for disease-carrying organisms.

Pollution from agricultural practices is due to animal wastes, materials eroded from farmlands, plant nutrients, vegetation, inorganic salts, and minerals resulting from irrigation and pesticides that farmers use on their farms to increase agricultural yield and fight pests and weeds. Agricultural wastes are made up of unwanted parts of crops during harvesting season. Examples are maize sheaves and cobs, maize stalks of guinea corn, millet and rice and their chaffs, yam vines, cassava stems, and yam and cassava peelings. Studies have shown that groundwater can be contaminated through seepage by leachate arising from solid wastes dumped on the ground. Land application of wastes is the most economical, practical, and environmentally sustainable method for managing agriculture wastes, especially animal wastes. Application of agricultural wastes to the land recycles valuable nutrients and organic matter into the system from which they originated. Land application can also be an effective component of management strategies for other organic wastes like food processing wastes.

Radioactive wastes are peculiar and dangerous. Their harmful effects on living organisms are induced by radiation, rather than by chemical mechanisms. They also remain dangerous for several years. Radioactive wastes are products of usage of nuclear energy. An example is the mining of uranium ore and its processing into nuclear fuel, which is used for electric power production. Power plants may also be radioactive. The environmental impacts of nuclear waste vary with the nature and form of the waste material. The most dangerous of these include the spent fuel from nuclear reactors, as well as the radioactive liquids and solids produced from any reprocessing of spent fuel. This high-level waste is characterized by the intensity of its radioactivity and long half-life. Death from exposure to intense radiation can occur, depending on the intensity and duration of the exposure. Human exposure can occur through inhalation of radioactive substances and ingestion of food containing radioactive materials.

WAYS TO MINIMIZE WASTE

The best way to avoid the environmental problems of solid waste disposal is to desist from generating wastes in the first instance. Pollution prevention programs aimed at this objective have become widespread. Recycling and reuse of materials are ways to avoid waste generation. At the residential level, recycling programs for newspapers, glass, and metal containers have been implemented. However, some municipal programs have been criticized for increasing environmental emissions of air pollutants from the fuel combustion.

The ultimate land disposal methods used for municipal solid wastes are land filling, land farming, and deep well injection. Land filling of solid wastes involves the controlled disposal of solid wastes on or in the upper layer of the Earth's mantle, which has been excavated to a depth of about 13 ft. (4 m.). When solid wastes are placed in sanitary landfills, biological, chemical, and physical processes occur. Biological decay of organic materials occurs by either aerobic or anaerobic processes, resulting in the evolution of gases or liquids. The chemical oxidation of waste materials occurs, dissolving and leaching of organic and inorganic materials by water and leachate moving through the fill also occur.

Land filling in moist climates produces large quantities of leachate that are toxic and of high organic strength and require treatment in wastewater plants. Land filling in dry climates produces localized air pollution problems. There is also movement of dissolved material by concentration gradients and osmosis. Initially, the organic material in the landfill undergoes aerobic decomposition due to some oxygen amount obtained in air trapped in the landfill. Within a few days, the oxygen content is exhausted and long-term decomposition occurs under aerobic conditions. The anaerobic conversion of organic compounds occurs in the transformation of high molecular weight compounds catalyzed by enzymes in soil bacteria into compounds suitable for use as a source. However, landfill sites cause soil and groundwater contamination if not properly operated. Additional environmental problems with landfill are odors, litter, scavengers, and rat infestation.

Solid wastes are those wastes from human and animal activities. In the domestic environment, the solid wastes include paper, plastics, food wastes, and ash. Improper management of solid wastes has direct adverse effects on health. Solid wastes may contain human pathogens, animal pathogens, and soil pathogens. Inadequate storage of such wastes provides a breeding ground for vermin, flies, and cockroaches, which may act as passive vectors in disease transmission. The pathogens that can cause fecal-related diseases are viruses, bacteria, protozoa, and helminths. As proper waste management involves recycling, reuse, transformation, and disposal, it is relevant to know the physical, chemical, energy, and biological properties of wastes. The physical properties that are relevant include density, moisture content, particle size distribution, field capacity, hydraulic conductivity, and shear strength. Chemical analyses required are proximate analysis, ultimate analysis, and energy content analysis. The important elements in waste energy transformation are carbon, hydrogen, oxygen, nitrogen, and sulfur.

Only 2 percent of waste is actually recycled. Solid waste recycling implies recovery of a component of waste for use in a manner different from its initial function. Recycling consists of recovering from waste the matter of which a product was made and reintroducing it into the production cycle for reproduction of the same item. Composting after decomposition by aerobic bacteria mostly readily recycles garbage, grass, and organic matter. Composting may be defined as the decomposition of moist, solid, organic matter by the use of aerobic microorganisms under controlled conditions. The end product of the decomposition is a sanitary, nuisance-free, humus-like material that can be used as soil conditioner and as partial replacement for fertilizer. In a typical operation, the municipal wastes are presorted to remove noncombustible materials and those that might have salvage value such as paper, cardboard, rags, metals, and glass. Refuse is then shredded and stacked in long piles where it degrades to humus much as it would in soil. Usually, the decomposed material contains less than 1 percent of each of the three primary fertilizer nutrients. The final step is grinding and bagging for ultimate sale as soil conditioner.

Plants die because of land pollution. Crops are affected, as they do not mature and grow well. There are three ways that people pollute the land: littering all over the land, improper garbage disposal, and dumping of chemical fluids on the land. It is not uncommon to see people throw the trash on the road while in the car. Every day, people are polluting the land. Because of pollution, people do not only affect the cleanliness of the land, but also destroy the beauty and increase avenues of contracting diseases. These negative tendencies have effects on tourism potentials of nations as tourists are turned off. Tourists won't like to take risks in an unsafe environment because of pollution. Mosquitoes live in littered empty cans. Thus, the threat of mosquito bite is imminent in a polluted land. A greater proportion of land pollution is instigated and carried out by man. Governments of nations should be alive to their responsibilities of providing a safe and secured world environment to its people.

Pollution, Water

WATER POLLUTION USUALLY describes the introduction or presence of harmful or objectionable substance in water in magnitude sufficient to alter the quality indices of natural water. It also connotes the presence of polluting substances in rivers, lakes, bays, seas, streams, underground water, or oceans in levels capable of resulting in measurable degradation of the water quality or usefulness. For example, if water contains too much contamination as a result of certain harmful chemical compounds or microorganisms, it could be rendered unsafe in its existing state for an intended purpose. This could be described as water pollution. In most cases, water pollution may arise from the use to which the water has been put. Although some kind of water pollution can occur through natural processes, it is mostly caused by human activities.

Water pollution has many sources and characteristics. These sources can be categorized into point and nonpoint sources. Point sources of water pollution are direct discharges to a single point, or simply stationary location discharges. Examples include discharges from sewage treatment plants, power plants, factories, ships, injection wells, and some manufacturing or industrial sources. Nonpoint sources of water pollution are more diffused across a broad area and their contamination is traceable to a single discharge point. Examples of nonpoint sources include mining activities and agricultural and urban runoffs. Water pollution arising from nonpoint sources accounts for the majority of contaminants in streams, rivers, bays, underground water, and seas.

A water pollutant is any biological, chemical, or physical substance if when present in water at excessive concentrations has the capability of altering the chemical, physical, biological, and radiological integrity of water, thereby reducing its usefulness to living organisms, including man. Although there are many sources of pollutants in our waters, the primary sources of water-polluting substances come from sewage, agricultural runoffs, oil spills, industrial wastewaters, land drainage, and domestic wastes. The major categories of common water pollutants include heavy metals, pathogens, nutrients, acids, organic chemicals, and radioactivity. Many of these substances are toxic and are capable of interacting additively or synergistically or antagonistically to give varying responses in aquatic ecosystems and in humans. However, the influence of a pollutant in natural waters varies according to the polluting substance, the local environmental conditions, and the organism involved.

MAJOR TYPES OF WATER POLLUTANTS

Heavy metals are toxic and include many metal pollutants that could have potentially harmful effects on human health and aquatic ecosystems. Common examples include cadmium, nickel, arsenic, lead, vanadium, mercury, and selenium. Typical sources of metal pollutants include wastes from domestic, industry, agriculture, urban, and mining drains. Acids are inorganic water pollutants caused by industrial discharges, especially sulfur dioxide from industrial power plants, drainage from mines, wastes from industry, and aerial acid deposition. Acids have the potential of causing harm to aquatic ecosystems via the mobilization of toxic heavy metal pollutants.

Organic chemicals such as insecticides, herbicides, petroleum hydrocarbons, detergents, and a range of volatile organic compounds such as solvents discharged into aquatic ecosystems have the potential of altering the integrity of natural waters. This variety of chemicals regarded as water pollutants arises from agricultural use of pesticides, especially insecticides and herbicides, industrial wastes, marine oil spillage, and domestic wastes. They are potentially harmful to human health and aquatic organisms. Nutrients arising from sewage and agricultural use of fertilizers may cause eutrophication in aquatic ecosystems.

Although nutrients are elements essential for the growth of living organisms, human-caused contaminations can greatly enhance the presence of nutrients (especially nitrogen and phosphorus compounds), leading to anthropogenic or cultural eutrophication. Continuous nutrient loading to aquatic systems could ultimately increase the phytoplankton population, resulting in algal bloom, by providing more food for the algae than is normally available. Nutrients may affect human health. Excessive algal population in water has the potential of unbalancing the food chain, discoloration of water, and reduction in the quantity of light radiation that is available to aquatic life. However, when the algae dies, the rotting algae could produce a strong, unpleasant smell and the remains could be toxic to aquatic fauna and flora. This process could also result in depletion of dissolved oxygen in water.

There are several sources of water pollutants, and these are domestic and industrial wastewaters, agricultural runoff water, and other nonpoint sources. Domestic wastes commonly carry organic matter, microbiological contaminants, and sometimes physical and chemical pollutants. Industrial wastes contain mostly chemical and radioactive pollutants, while agricultural run-off water may carry mainly nutrients, pesticides, and heavy metals. Moreover, water pollution can be broadly classified into different types and these include microbiological, chemical, physical, and thermal water pollution.

Biological hazards associated with water pollution include disease-causing (pathogenic) microorganisms, like parasites, bacteria, and viruses. People exposed to biologically contaminated waters can become sick from drinking, washing, or swimming. Disease-causing pathogens commonly associated with fecal contamination of water include *Shigella dysenteriae, Salmonella typhi, Salmonella paratyphi, Vibrio cholerae, Entamoeba histolytica* and poliomyelitis virus responsible for causing bacterial dysentery, typhoid fever, paratyphoid fever, cholera, amoebic dysentery, and infantile paralysis, respectively. Also, the consumption of microbe-contaminated seafood, especially shellfish, could lead to outbreaks of food poisoning.

CHEMICAL WATER POLLUTION

Chemical form of water pollution includes the presence of a wide range of chemicals from industry, such as lead, arsenic, nitrates, radioactive substances, metals and solvents, and even chemicals which are formed from the breakdown of natural wastes (ammonia, for instance). Effluents from chemical industries and oil pollution from accidental crude spillage are categorized under chemical form of water pollution. In aquatic systems, these chemicals are poisonous to fish and other aquatic life. Chemical pollutants can be generally categorized into persistent (degrade slowly) and nonpersistent (degradable) substances.

Nonpersistent pollutants include domestic wastes, fertilizers, and some classes of industrial wastes. These polluting substances can be broken down into simple nonpolluting molecules or compounds such as carbon dioxide, and nitrogen by chemical or biological processes. Persistent water pollution is the most rapidly growing type of pollution, and includes polluting substances that degrade or do not grade or cannot be broken down at all. These pollutants tend to remain in aquatic environments for a long period of time. Common persistent chemical pollutants include some pesticides (such as dieldrin, heptachlor, and DDT), petroleum products, polychlorinated biphenyls (PCBs), chlorophenols, dioxins, polycyclic aromatic hydrocarbons (PAHs), radionuclides, and heavy metals. Toxic metals discharged in effluent can be accumulated in seafood, especially fish and shellfish such as prawns, cockles, mussels, and oysters, to levels in excess of public health limiting levels, therefore posing serious health concerns to people who eat them.

Pesticides used in agriculture and around the home, especially those used for controlling insects (insecticides) and weeds (herbicides), are another type of toxic chemical. These chemicals are used to kill unwanted animals and plants, and may be collected by rainwater runoff and carried into streams, lakes, bays, rivers, and seas, especially if these substances are applied in excessive quantities. Some of these chemicals are biodegradable and may quickly decay into harmless or less harmful forms, while others are nonbiodegradable and can persist in the environment for a long time. When animals consume plants that have been treated with certain nonbiodegradable toxicants (NBTs), such as dichlorodiphenyltrichloroethane (DDT) and chlordane, these chemicals are absorbed into the tissues or organs of the animals and can accumulate over time. When other animals feed on these contaminated animals, the chemicals are passed up the food chain. Some of these can accumulate in fish and shellfish and poison people, animals, and birds that eat them. Materials like detergents and oils float and spoil the appearance of a water body, as well as being toxic; and many chemical pollutants have unpleasant odors.

PHYSICAL WATER POLLUTION

A common form of physical water pollution is thermal pollution. This includes warm water from cooling towers, floating debris, foam, and garbage. In highly industrialized areas of the world, power plants are used in generating electricity, where warmer water generated in the process is generally released back to the environment. In nuclear plants, water is used in large quantity to cool reactors. The discharge of high-temperature water into a natural body of water can affect the downstream habitats, therefore altering the ecological balance. It can lead to cultural eutrophication, thereby promoting algal bloom. This development has the potential of threatening certain fish species, as well as disturbing the chemistry of the receiving water body.

Heat may also affect man's legitimate use of water for fishing. Another common and widespread type of thermal pollution is the unsafe removal of vegetations that should naturally keep streams and small lakes cool. Natural vegetations, mainly trees and other tall plants, are usually seen around streams and sizable water bodies and they block direct sunlight from heating and thereby increasing the surface temperatures of these waters. People often remove this shading vegetation in order to harvest wood from the trees, to make room for crops, or to construct buildings, roads, and other structures. When these vegetations are removed and the aquatic ecosystems are left uncovered, the water temperature could increase by as much as 18 degrees F (10 degrees C).

Many wastes are biodegradable, that is, they can be broken down and used as food by microorganisms like bacteria. Biodegradable wastes may be preferable to nonbiodegradable ones, because they will be broken down and not remain in the environment for a very long time. However, too much biodegradable material can cause the serious problem of oxygen depletion in receiving waters. Like fish, aerobic bacteria that live in water use oxygen gas, which is dissolved in the water when they feed. Invariably, the oxygen is not very soluble in water. Even when the water is saturated with dissolved oxygen, it contains only about 1/25 the concentration that is present in air. So if there are too many nutrients in the water, the bacteria that are consuming it can easily use up all of the dissolved oxygen, leaving none for the fish, which will die of suffocation. Once the oxygen is depleted, other bacteria that do not need dissolved oxygen take over. But while aerobic microorganisms convert the nitrogen, sulfur, and carbon compounds that are present in the wastewater into odorless, oxygenated forms like nitrates, sulfates, and carbonates, these anaerobic microorganisms produce toxic and smelly ammonia, amines, and sulfides, and flammable methane.

Nutrients are major chemical pollutants and they include nitrates and phosphates found in sewage, fertilizers, and detergents. Although phosphorus and nitrogen are essential elements necessary for plant growth, in excess levels nutrients overstimulate the growth of aquatic plants and algae. When discharged into rivers, streams, lakes, and estuaries, they cause nuisance growth of aquatic weeds, as well as blooms of algae, which are microscopic plants. Excessive growth of these organisms can clog navigable waters, deplete dissolved oxygen as they decompose, and block light from penetrating deeper waters. Weeds can make a lake unsuitable for swimming and boating. Algae and weeds die and become biodegradable material. If the water is used as a drinking-water source, algae can clog filters and impart unpleasant tastes and odors to the finished water. It can also impair respiration by fish and aquatic invertebrates, which could lead to a decrease in animal and plant diversity.

Suspended solids originate from eroded stream banks, construction, and logging sites. They are a form of physical water pollution. These pollutants are also referred to as particulate matter because they contain particles of much larger size which remain suspended in the water column. Although they may be kept in suspension by turbulence, once in the receiving water, they will eventually settle out and form silt or mud at the bottom. As these sediments enter the rivers, lakes, and streams, they tend to decrease the depth of the body of water. If there is a lot of biodegradable organic material in the sediment, it will become anaerobic and contribute to the formation of algal bloom. Toxic materials can also accumulate in the sediment and affect the organisms that live there, and can build up in fish that feed on them, and so be passed up the food chain, causing problems along the food web. Also, some of the particulate matter may be coated with grease, which is lighter than water, and float to the top, creating an aesthetic nuisance.

CONCLUSION

The pollution of water resources can have serious and wide-ranging effects on the environment and human health. The immediate effects of water pollution can be seen in water bodies and the animal and plant life that inhabits them. Pollution poisons and deforms fish and other animals, unbalances ecosystems, and causes a reduction in biodiversity. Ultimately, these effects take their toll on human life. Drinking-water sources become contaminated, causing sickness and disease. Pollutants accumulate in food, making it dangerous or inedible. The presence of these toxic substances in food and water can also lead to reproductive problems and neurological disorders. The effects of water pollution are varied. They include poisonous drinking water, poisonous food animals (due to these organisms having accumulated toxins from the environment over their life spans), unbalanced river and lake ecosystems that can no longer support full biological diversity, deforestation from acid rain, and many other effects. These effects are, of course, specific to the various contaminants.

Population

CLIMATIC EVENTS HAVE had an important impact on the geographical distribution of human populations in the past. Nowadays, the growing consensus among the scientific community on the reality of human-induced global warming has raised concern that millions of people could be displaced.

A LONG HISTORY OF LINKAGE BETWEEN CLIMATE AND POPULATIONS

Population geography has acknowledged for many years the role played by climatic factors in explaining the history of population and the emergence of cities. Thus, for mankind, the passage across the Bering Strait to America 13,000 years ago was possible due to the low sea levels of the Ice Age, while the Medieval Climate Optimum which lasted between the 8th and 13th centuries stimulated the population of Polynesia by making navigation relatively easy, thanks to regular winds and clear skies. The desertification of the Sahara and the Arabian Peninsula also played an important part in the densification of the population on the banks of the Nile and consequently contributed to the birth of ancient Egyptian civilization.

More recently, the droughts of the 1930s in the plains of the American Dust Bowl (parts of Kansas, Oklahoma, Texas, New Mexico, and Colorado) forced thousands of migrants toward California, and those that struck the Sahel between 1969 and 1974 displaced millions of African farmers and nomads.

Notwithstanding the present media focus on global warming, the amount of systematic research on climate and populations remains limited. There is much vagueness surrounding the concepts employed, the underlying mechanisms involved, the number of persons affected, and the geographical zones concerned. Climatic factors are rarely the sole cause of migration, and the economic, social, and political situation of the zone under threat can, depending on the case, increase or decrease the flow of migrants.

The use by numerous authors of the term "climate refugee" has also led to confusion, because it evokes the juridical status recognized by the UN Convention of 1951 to political refugees. The High Commissioner for Refugees, aware of a risk of confusion between political and nonpolitical refugees, has always treated with the utmost prudence the idea of including environmental motivations in the international definition of refugees, even if this category of the population is deemed a part of the protective mandate toward displaced persons.

THE CONSEQUENCES OF GLOBAL WARMING

Alarming predictions of greater resource scarcity, desertification, risks of droughts and floods, and rising sea levels that could drive many millions of people to migrate appeared in the review on the economic consequences of global warming delivered to the British government by Sir Nicholas Stern at the end of November 2006. While it is extremely difficult to elaborate scientific predictions by combining climate and migration models, the expected consequences of climate change can be compared to past experiences so as to establish a list of the populations most at risk and the possible resulting emigration flows. Three consequences of climate warming forecast in the latest report of the Intergovernmental Panel on Climate Change (IPCC) for the end of the 21st century appear to be the most threatening potential causes of migrations:

1. The increase in strength of tropical hurricanes and in the frequency of heavy rains and flooding due

to the augmentation of evaporation correlative to temperature increase.
2. The growth in the number of droughts, with evaporation contributing to a decrease in soil humidity, often associated with food shortages.
3. The increase in sea levels resulting from both water expansion and melting ice.

While the first two consequences are the direct result of sudden natural disasters, the third is a long-term process, which has very different possible implications in terms of migrations.

HURRICANES, TORRENTIAL RAINS, AND FLOODS

The consequences of hurricanes and floods on population displacement are among the easiest to identify in that they manifest themselves in a brutal and direct manner. While the number of persons affected by flooding worldwide (106 million yearly between 2000 and 2005 according to the International Disaster Database) and by hurricanes (38 million) is known, the total number of people threatened by an eventual increase of this kind of disaster is, however, very difficult to estimate. No climate model is able to predict with accuracy whether or not the affected zones will be densely populated and whether the damage wrought will have tragic consequences.

Apart from this difficulty of forecasting, the studies carried out after such events tend to relativize their effects in terms of migration in general, and long-term migration in particular. Living mainly in poor countries, the victims have little mobility, and the majority of the displaced return as soon as possible to reconstruct their homes in the disaster zone. The results from numerous researches conducted worldwide on the subject tend to confirm this point with remarkable regularity. On a global level, the general conclusion therefore is that the potential of hurricanes and torrential rains to provoke long-term and long-distance migrations remains limited.

DROUGHT AND DESERTIFICATION

The latest report of the Intergovernmental Panel on Climate Change predicts increased water shortages in Africa (74 to 250 million people affected in 2020) and Asia. Case studies, however, bring to light a contrasting picture of the consequences for migrations of these kinds of evolutions. The effect of a lack of drinking and irrigation water on migration is actually less sudden than that of hurricanes and floods, and it only generates progressive departures. On one hand, there are many well-known cases of mass population departures following droughts, in particular in Africa (Sahel, Ethiopia) with an impressive figure of one million displaced persons during the drought in Niger in 1985, but also in South America (Argentina, Brazil), in the Middle East (Syria, Iran), in central Asia, and in southern Asia.

On the other hand, many researchers strongly relativize the possible direct link existing between drought and emigration by highlighting the fact that the latter, in general, is the last resort when all other survival strategies have been exhausted. For example, during the 1994 drought in Bangladesh, only 0.4 percent of households had to resort to emigration. Other researchers hold views similar to that of Nobel Prize winner for Economics, Amartya Sen, in remarking that famines are, in general, only marginally the direct result of environmental factors, but much rather political ones and add that this also holds for migrations. In certain contexts, the effect can even be inversed. This was the case in Mali during the drought of the mid-1980s: a reduction in international emigration was observed due to the lack of available means to finance the journey. Forecasts of increased migrations linked to drought-related phenomena remain hazardous. Consequently, it would be difficult to put a figure on the magnitude of populations at risk and the eventual migrations arising from global warming–induced droughts.

RISING SEA LEVELS

While the first two climatic hazards mentioned do not foreshadow massive population displacements due to climate change, the potential for migration when linked to an increase in sea level is considerable. Contrary to hurricanes, rain, and drought, this phenomenon is virtually irreversible and manifests itself over a long period of time. This could make migration the only possible option for the population affected. The localization of the consequences of rising sea levels is a relatively easy task because the configuration of coastlines, their altitude, and population are well known and thus easy to map. Hence, it is possible to calculate, on a global scale, the number of persons living in low-elevation coastal zones and threatened by either rising water levels, higher tides, or farther-reaching waves. Low-elevation coastal zones are defined as situated at an altitude of less than 33 ft. (10 m.). Even though these zones account for only 2.2 percent of dry land, they are presently home for 10.5 percent of the world's population, some 600 million people, of whom more than two-thirds live in Asia, and nearly a half in the poorest countries of the world.

It would be an exaggeration, however, to consider that these hundreds of millions of people are all potential migrants in a near future. The latest report of the IPCC evokes, of course, the possible melting of Greenland ice cover and the consequent 23 ft. (7 m.) rise in sea level, but this would occur over several thousand years. Of more concern is the scenario of thermic expansion of the oceans. According to a future CO_2 emission estimate based on continuing economic growth, but with a moderation of fossil fuel use, there would be an increase of 1 to 2.6 ft. (0.3 to 0.8 m.) of the oceans by 2300. On this basis, it seems reasonable to consider populations living at an altitude of less than one meter as being directly vulnerable by the next century. A study commissioned within the framework of the Stern Report gives a considerable figure of 146 million people for this group. Mainly situated in the major rivers' deltas and estuaries, the flood zones are particularly populated in south Asia (Indus and Ganges-Brahmaputra) and east Asia (Mekong, Yangtze, Pearl River). These two regions account for 75 percent of the population at risk. Certain Pacific states such as Tuvalu or Kiribati are, in the shortterm, among the most threatened, as they are situated only centimeters above water. Although far less populated, they nevertheless have inhabitants numbering several thousand persons.

The increase in sea levels is the greatest direct threat for numerous populations. Contrary to hurricanes and droughts, the localization of potential victims is ascertainable. If no measure of moderation is taken and if no effort is made to protect the groups at risk, then they will have no alternative but to emigrate.

CONCLUSION

Climate changes can generate migration flows. Global warming could, in particular, lead to major forced displacements. The latter will result principally from rising sea levels, but will only progressively manifest themselves over the forthcoming centuries, with the exception of the flooding of certain islands. The increase in droughts and meteorological disasters predicted by climatic models will also have impacts in terms of migrations, but these will remain regional and shortterm, and are at present difficult to estimate.

Existing research shows that due to the number of factors involved, no climatic hazards inevitably result in migrations. Many authors note that even if disasters become more frequent in the future, political efforts and measures of protection will be able to lessen the need to emigrate, provided that the necessary financial means are made available. Even rising sea levels could be partially counteracted by the erection of dikes or the filling in of threatened zones. The question of what kind of international system of burden-sharing and protection to put in place to face these challenges remains unanswered, and is all the more important because of the clear responsibility of rich countries for global warming. Bangladesh, for example, contributes only 0.14 percent of global CO_2 emission, but counts hundreds of thousands of people at risk of increased flooding.

Portugal

AS REPORTED IN a major collaborative international research project, named SIAM II, Portugal is one of the European countries that are expected to suffer from the most extreme consequences of global warming and climatic change. These consequences are expected to entail three major geological effects in Portugal. First, due to the rise in sea levels, studies predict an increase in the erosion of Portugal's coastal areas. Second, scientists anticipate increased levels of rain precipitation and the concomitant occurrence of floods that will carry high social and economic costs. Finally, in dry areas of the country, studies point to a higher probability for the incidence of forest fires. Studies show that the tendency for increasingly hotter summers in Portugal has accelerated in the past few decades. Research and analysis based on data collected from 1931 to 2000 in Portugal demonstrates that the six hottest summers occurred in the last 12 years.

The Portuguese population is slowly becoming aware of the relationship between global warming and climate change within the borders of their nation, and this awareness is becoming stronger. One of the reasons for increased knowledge concerning the impact of global warming on Portugal has been the occurrence of major forest fires, as well as fluvial floods. In this context, the mass media and government officials have played a crucial role in sensitizing and educating the Portuguese population about the risks associated with global warming. Another reason is the fact that an increasingly large percentage of the Portuguese population is university educated and, in this context too, they are exposed to recent and important national as well as international research concerning the issue.

Due to Portugal's relatively late entry into the European Union in 1986, and its previous situation of economic isolation and considerable underdevelopment in terms of European standards, Portugal is still highly dependent on importing energy derived from nonrenewable sources. According to the Statistical Office of the European Union (Eurostat), Portugal is 99.4 percent dependent on such imported energy. Because of the economic weight that this carries, it is oftentimes difficult for enterprises to develop or invest in alternative and more ecological forms of energy supply. For this reason, it is feared that Portugal may face difficulties in reaching Kyoto established goals.

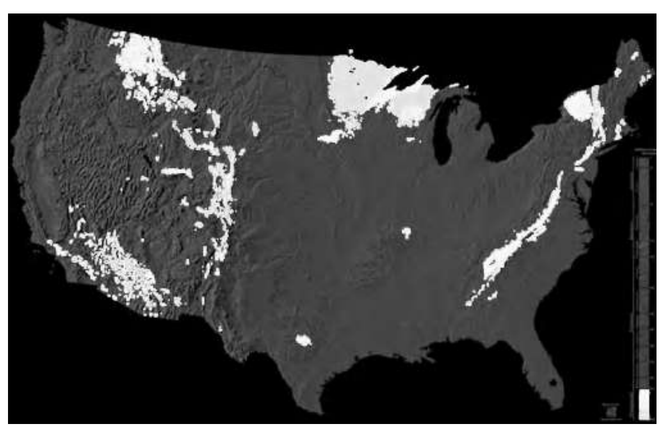
Precambrian Era

THE PRECAMBRIAN ERA, or Supereon, refers to the geological time comprising the eons that came before the Phanerozoic eon. This time spans from the formation of Earth around 4.5 billion years ago to the evolution of abundant macroscopic hard-shelled animals, which marked the beginning of the Cambrian era, the first period of the first era of the Phanerozoic eon. The Precambrian era encompasses 86 percent of the Earth's history, however very little is known about this time period. In fact, the few fossil discoveries from this period were recently made in the late 20th century. Precambrian time can be further divided into three large eons, the Hadean, Archean, and Proterozoic eons.

The Precambrian's oldest eon, the Hadean (4.5 to 3.9 billion years ago), predates most of the geologic record. During the Hadean, the solar system formed out of gas and dust, the sun began to emit light and heat, and Earth took shape. Meteors and other galactic debris showered the planet over the first half-billion years, making it entirely uninhabitable. Planet Earth was very hot during its initial formation. As the earth began to cool and its mass increased, its gravitational field strengthened. This attracted meteorites and other debris, which continued to bombard the planet for at least another 500 million years, producing enough energy and heat to vaporize any water or melt any rock that may be present. Iron continued to sink to form the Earth's core, while silicon, magnesium, and aluminum gradually rose toward the surface. Gases released from magma



Highlighted in light areas are Precambrian rocks. They formed between 560 million years and 2.6 billion years ago.

inside the Earth escaped through cracks in the surface and began to collect in the early atmosphere. The likely presence of methane and ammonia among the gases made for conditions that would be highly toxic to life as we know it. Because there was little to no free oxygen, no protective ozone layers existed and damaging ultraviolet rays showered the Earth at full strength. As the meteorite bombardment finally slowed, Earth was able to cool, and its surface harden as a crust, rocks and continental plates began to form. Water began to condense in the atmosphere, resulting in torrential rainfall. After several hundred million years of falling rain, great oceans were formed. By about 3,900 billion years ago, Earth's environment had been transformed from a highly unstable state into a more hospitable place. This marked the beginning of the Archean eon (3.9 to 2.5 billion years ago). It was early in the Archaean eon that life first appeared on Earth.

The climate of the late Precambrian time, the Proterozoic eon (2.5 billion years ago to 543 million years ago) was typically cold with glaciations spreading over much of the earth. One of the most important events of the Proterozoic was the gathering of oxygen in the Earth's atmosphere. Though oxygen was undoubtedly released by photosynthesis well back in Archean times, it could not build up to any significant degree until chemical sinks unoxidized sulfur and iron had been filled. The first advanced single-celled and multicellular life roughly coincides with the oxygen accumulation. It was also during this period that the first symbiotic relationships between mitochondria and chloroplasts and their hosts evolved. At this time the continents were bunched up in to a single supercontinent known as Rodinia. It broke up starting around 750 million years ago, and as continental fragments reached the North and South poles they likely contributed to the great Ice Ages. In the latest Proterozoic era a new supercontinent called Pannotia came together. A number of glacial periods have been identified going as far back as the Huronian epoch, roughly 2,200 million years ago. The best studied is the Sturtian-Varangian glaciation, around 600 million years ago, which may have brought glacial conditions all the way to the equator, resulting in a "Snowball Earth". This theory states that the continents and oceans were covered in ice approximately 600 million years ago. The Earth may have remained in this frozen form, but it was rescued by the release of volcanic gases. While the Earth was in a deep freeze, chemical cycles were halted; as a result, carbon dioxide accumulated in the atmosphere causing an extreme greenhouse effect. After 10 million years of deep freeze, the Earth thawed in only a few hundred years. These dramatic events may have caused the explosion of lifeforms seen in Cambrian fossils.

At this point, at the start of the Cambrian period, Earth had taken on its current form in the life-filled oceans and oxygenated atmosphere. Coevolution of biosphere and lithosphere over billions of years led to this point. Anaerobes and oxygen-breathers had evolved complementary chemical cycles, and biogenic carbonates entered the plate-tectonic cycle of the crust and upper mantle with new efficiency.

Precautionary Principle

THE UPSHOT OF precaution is that it is better to be safe than sorry when there are severe or irreversible consequences. It has been a very important notion in environmental and public health policy. It has been advocated in several issues ranging from climate change to genetic engineering to phase-out of persistent organic pollutants. The invocation of precaution has been particularly controversial when there are significant business interests at stake. The problem with simply asserting precaution whenever a technology, policy, or action involves possible negative outcomes is that it often poses significant challenges in evaluating the public versus private trade-offs involved.

This use of precaution is often invoked when outcomes are uncertain. The notion of uncertainty is used to characterize how well future events or scientific truths can be predicted or known. It is used in both social and natural science disciplines, from mathematics to philosophy, to risk assessment and public policy. If probability is a measure of likelihood, then uncertainty is a measure of how well the probability is known. Uncertainty can be classified into known and unknown probabilities. Events with known probabilities are referred to as events with statistical uncertainties. Events with unknown probabilities are often called events with true uncertainty.

Uncertainty in the context of the environment mainly refers to scientific uncertainty. Here, science generates truths through the testing of hypotheses. But often, the affirmation of hypotheses involves a certain degree of uncertainty due to the method or research design. Scientists often use the benchmark of 95 percent certainty when deciding whether or not cause and effect have been correctly identified. Scientists often report confidence limits based on research design and sampling error in their studies to account for uncertainty.

The precautionary principle is often invoked under uncertain circumstances, particularly when the consequences are irreversible or permanent. This differs from the choice that scientists make when deciding what to do under conditions of uncertainty. Typically, scientists are interested in avoiding false negatives, because science is epistemologically conservative. Scientists do not want to suggest something as truth when in fact it may not be. In public or environmental policy, however, because the consequences are not epistemological but are ethical, there is desire to avoid false positives and be ethically conservative.

In public and environmental policy, it is important to understand how to make decisions in the absence of perfect information. Knowing the degree of uncertainty is particularly important when questions about risk arise. Risk assessment is a policy approach that deals with uncertainty. Risk assessment is widely used by the Environmental Protection Agency (EPA), but mainly focuses on known probabilities. Because of difficulties with codifying the precautionary principle into policy, the EPA has yet to include true uncertainty in environmental policy.

CLASSES OF SCIENTIFIC UNCERTAINTY

Scientist Schrader-Frechette describes four classes of scientific uncertainty dealt with by scientists and policymakers: framing uncertainty, modeling uncertainty, statistical uncertainty, and decision-theoretic uncertainty. In framing uncertainty, scientists often use a two-value frame to accept or reject a hypothesis. Frechette argues that in public policy, it is more appropriate to adopt a three-value frame that creates a category to deal with situations where significant uncertainty and serious consequences suggest adopting the precautionary principle. Modeling uncertainties involve those involved in the prediction of future scenarios. These are highly speculative, despite claims to be verified and validated models.

In public and environmental policy, statistical uncertainty should be dealt with in such a way that highlights the difference between epistemological consequences and ethical ones. When faced with decision-theoretic uncertainty, scientists are forced to distinguish between using expected value rules and the minimax rule. The former argues that decisions should be based on the expected value, while the latter seeks to prevent the worst-case scenario. More recently, Bayesian statistics has been used to help evaluate data under conditions of uncertainty by updating the probabilities as new data come to view. A Bayesian approach involves the introduction of prior knowledge into statistical models.

There are many environmental policy debates where questions about uncertainty are raised. In debates about global climate change, for example, scientists typically agree that there is significant uncertainty in the projection of future climate change models. Climate change skeptics, to discredit climate change science, often highlight uncertainty. In debates about genetic engineering, uncertainty about the prediction of how transgenic organisms will behave in the environment, or uncertainty about how markets will react to the adoption of transgenic organisms, is cited as a reason to invoke the precautionary principle. In debates about nuclear waste disposal at Yucca Mountain, uncertainty about how the storage facility will perform in the long term is cited as reason to question the suitability of nuclear waste repository.

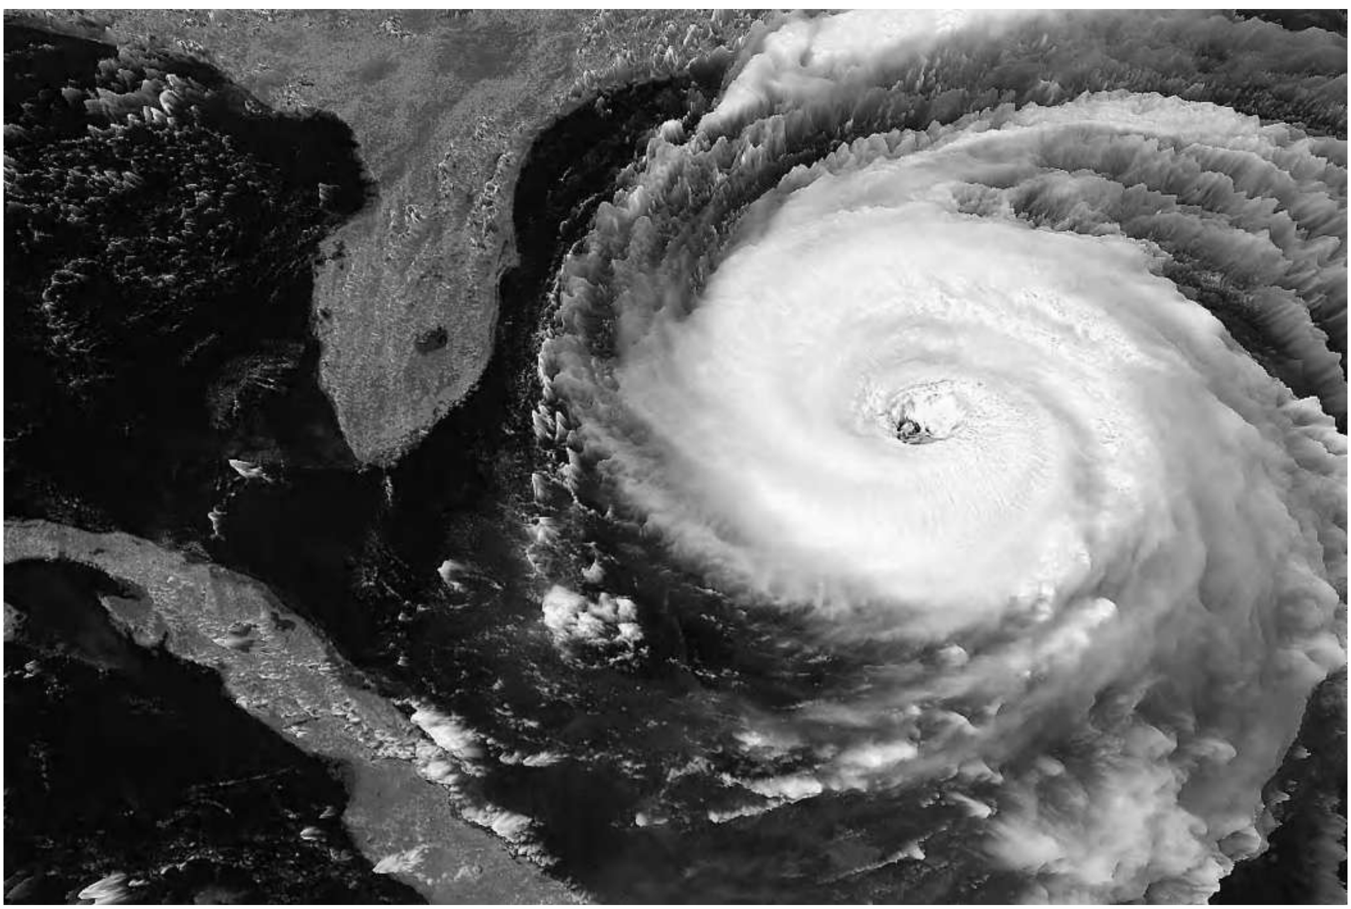
Precipitation

PRECIPITATION IS THE primary factor that controls the hydrologic cycle. It takes different forms, such as rain, snow, hail, sleet, drizzle, dew, and fog. It supplies most of the fresh water on the Earth. Most precipitation starts from space as snow, as the upper space is cooler. If the temperature of the surface closer to the ground is below 32 degrees F (0 degrees C), then the precipitation falls on the ground in the form of snow. If the ground and closer surface temperature is above 32 degrees F (0 degrees C), the precipitation takes the form of rain. When the air at the ground is below freezing, the raindrops can freeze while heating the ground, and that is known as freezing rain. When a dust particle in the atmosphere attracts a moisture drop, hail is formed. Drizzle consists of very small raindrops, 1/1000 of a normal raindrop size. Sleet is a type of precipitation between rain and snow, but very distinct from hail. Dew is another form of precipitation that can be seen in the early morning on colder days. Water vapor in the atmosphere condenses on the surface of exposed objects at a greater rate than that at which it can evaporate, developing dew. Fog as such is not precipitation, but is considered one because of its low-altitude occurrence. This consists of a cloud in contact with the ground, and produces water droplets when intercepted with vegetation or other exposed objects. If the precipitation evaporates before reaching the ground, it is then known as virga.



The 1996 Hurricane Fran, shown in a weather sattelite image, caused about $5 billion in damages in North Carolina alone. Greater precipitation, including hurricanes, typhoons, ocean depressions, and floods, are being experienced globally.

HOW PRECIPITATION OCCURS

Dynamic and adiabatic cooling causes precipitation. Due to this process, condensation of water vapor occurs and then falls to the Earth as rainfall, snowfall, or as other forms of precipitation. Vertical air motion is the leading factor of all rainfall from clouds after condensation. Rising air in the tropics and midlatitudes (40 to 60 degrees N and S latitudes) causes more precipitation and descending air patterns in the subtropics (20 to 30 degrees N and S latitudes) and in the poles causes less. Precipitation is classified into different categories based on the conditions that generate vertical air motion: convective, orographic, and cyclonic.

Convective precipitation is mostly seen in the tropics. Heating up of the air at groundlevel, then moving upward and mixing with the water vapor in the atmosphere, with dynamic cooling in space, causes precipitation to fall on Earth. This is called convective precipitation. Orographic precipitation occurs due to the interception of moisture-laden air or clouds by mountain ranges. Cyclonic precipitation is caused by movement of moist air masses from high-pressure regions to low-pressure regions. In the hydrologic cycle, the total volume of precipitation onto land is measured at 42,471 sq. mi. (110,000 sq. km.), while the total volume of precipitation on the ocean surface is 176,834 sq. mi. (458,000 sq. km).

Precipitation has greater ecological, geographical, and regional impact due to its characteristics, such as relative amount, seasonal timing, and most importantly the size and intensity. Low-intensity and well-distributed seasonal precipitation is good for agriculture. High-intensity, long-duration precipitation creates more problems than good. Precipitation is governed primarily by atmospheric water vapor, but its variation depends upon other climatic factors such as temperature, wind, and atmospheric pressure at different locations and season. The amount of water vapor is very high in the atmosphere closer to water bodies. Therefore, coastal areas always have heavier precipitation (high-intensity, long-duration) than inland areas. Thunderstorms, hurricanes, typhoons, cyclones, blizzards, and hailstorms are high-intensity precipitations with damaging ability.

It is essential to understand the precipitation distribution process and its temporal and spatial variation for water resources planning and management for the betterment of the society. Precipitation distribution mechanisms include interception by vegetation, filling in depression storage, infiltration to soil and ground water, surface detention, and overland or surface flow or runoff. Low-intensity, short-duration storms are good for land and vegetation because most of the water either stays in depression storage or infiltrates to soil and groundwater for groundwater recharge. But high-intensity, long-duration storms are detrimental because most of the precipitation (rainfall) is wasted as runoff. The excessive runoff erodes soil, creates floods, landslides, and other damaging effects. Blizzards are examples of such high-intensity, long-duration precipitation. A heavy amount of snowfall accompanied by high wind creates problems. Many high-intensity, long-duration storms are currently being encountered, believed to be due to global warming.

EFFECTS OF GLOBAL WARMING ON PRECIPITATION

Global warming is the effect of increasing atmospheric concentrations of greenhouse gases. The near surface of the Earth has warmed by nearly 1 degree F (0.6 degrees C) during the 20th century. It may continue in this century, warming the globe further, so that a warmer ocean surface would result. There would be increased evaporation rate and subsequent increase in the other components of the hydrologic cycle, like water vapor in the atmosphere and consequent higher precipitation amounts. Computer simulation models found that a global warming by 7.2 degrees F (4 degrees C) is expected to increase global precipitation by about 10 percent and that rainfall intensity will increase. Scientists using models found that the upper tropospheric water vapor amount will increase by 15 percent with each degree of atmospheric temperature rise. The global water vapor amount will increase by 7 percent with each degree of atmospheric temperature rise.

Another major downside of global warming is less snowfall throughout the world. As the surface temperature is rising, raindrops, in many parts of the Earth, cannot take the shape of snow before reaching the ground. Snow is better for the land than rain because it helps in water conservation. Rainfall becomes runoff to oceans and is a waste if not conserved artificially through dams, earthen embankments, and soil and water conservation structures, whereas snow remains on the ground and melts slowly to release water for agriculture and other consumption. Slow melting of snow also facilitates more accumulation of soil moisture and ground water recharging. Agriculture in the northern United States and southern Canada depends upon soil moisture conserved by snowpack on the agricultural land. With less snowfall, due to increase in surface temperature, there may be less snow deposition on agricultural land, and agriculture would suffer.

The irony of global warming is the occurence of more rain resulting in less water. Due to warmer temperatures in the spring, snowpacks in the mountains are melting unseasonably and at a rapid rate. Many perennial rivers in the world are experiencing shortages of flowing water in summer months and groundwater recharging has lessened. The water from a quick snowmelt cannot be arrested in reservoirs due to lack of space. Therefore, the systems failing to hold the entire season of runoff would face challenges to meet the water demand for agriculture and other purposes. Increased quick melting of snowpacks (due to a rise in surface temperature) in the northwestern United States and India causes spring and summer floods.

It is estimated that there could be a 15 to 30 percent reduction of water available for human consumption from California's Sierra Nevada mountains. Agriculture in the Canadian prairies could be the worst affected, due to spring water runoff. Sufficient water may not be available for subsequent crop seasons. Many rivers in the world will experience water shortages in dry seasons because during dry months, most of the perennial rivers get water from snow and glacier melting. Glacial retreats are clearly visible in the Poles, Greenland, and Antarctica. This occurs due to an insufficient supply of water to glaciers from precipitation as compared to the loss of water from melting and sublimation.

Global warming would cause more precipitation on the Earth, but would create more detrimental effects to agriculture, ecology, and, above all, society. The wetter areas of Earth would become wetter, and the drier areas may become even drier.

Preparedness

PREPAREDNESS FOR GLOBAL warming and climate change requires multilevel planning, at the international, national, local, and individual levels to deal with the direct effects of climate changes in temperature, precipitation, wind, storm patterns, sealevel, as well as the indirect strain on world resources leading to migration, famine, and conflicts.

While mitigation strategies like reducing greenhouse gas emissions are a start, they do not take precedence over readiness to respond to natural disaster emergencies associated with the impact of climate change (intense storms, flooding, wildfires, public health, or the necessity to deal with future environmental pressures, the decreasing longevity of infrastructure with roads, bridges, waterworks, buildings, and facilities requiring earlier replacement, repair or modifications to remain safe for use. Adaptive measures in the form of physiological, social, and cultural measures will allow people to live throughout the world.

ASSESSMENT OF IMPACT

In order to prepare for climate change, assessments must be completed and available for decision-making processes. On the international level, the International

Governmental Panel on Climate Change encourages collaboration among scientists, allied professionals, and policymakers, providing a forum for the collection of research material and posing questions to spur planning. The take-away message is evaluation to determine global policy toward a common goal while addressing implications and increasing cooperation between governments.

On the national and local levels, any assessment of the extent of impact climate changes (higher temperatures, rising sea levels, changing weather patterns will have on human health, ecosystem diversity and productivity, agricultural production, water supply, sanitation, infrastructure) must factor in the associated costs and benefits in developing sustainability plans, preparation for emergency situations, and adaptive measures.

Each area is different, with varying susceptibilities, policies, institutions, and social/cultural structures. National and local assessments to be most effective must evaluate the capacity to handle emergency measures associated with natural disasters and identifying susceptible areas of the environment and resources including agriculture, fisheries, forestry, fauna, human health, water supply and sanitation, infrastructure and construction, land use in hazard-prone areas (flood plain, islands), and disaster management.

Challenges to assessment for impact include factors not related to climate change that will impact the areas being considered at risk because of climate change include the dynamics of society and economy (demographic trends, agricultural management, improving and new technologies, cultural preferences, opportunities for employment, availability, and changes in transportation). Complex dynamics in human relationships with the environment, self-reliance, growing population, and increased urbanization may produce very different impacts between urban and rural areas.

IMPACTS TO CONSIDER

When making assessments, a variety of elements need to be considered that cross boundaries of social structures and practices as well as environmental conditions. Severe weather destruction has highlighted areas that lack preparedness. The current global situation for preparedness is still lacking. Severe weather causes great devastation. Even in a highly developed country, as seen in the aftermath of the 2005 Hurricane Katrina hitting New Orleans and other areas on the U.S. Gulf Coast, problems were experienced with infrastructure, the failure of levees to hold back storm surge water, and mobilizing emergency supplies.

Planning for impacts from rising global temperatures must take into account a wide range of factors including the impact on human health, comfort, lifestyle, food production, economic activity, and residential and migration patterns including tourism.

Housing or shelter must be sufficient to meet the needs of an emergency situation or for migration from an area no longer suitable for living or to meet expectations for increased tourism to climates that so far have not been inundated by travelers. In addition, supportive measures must be able to supply water, sanitation, communication, energy, transport, and industry; and social and cultural services including health services, education, police protection, recreational services, parks, and museums for areas with an increased population.

With rising temperatures, weather patterns could alter in frequency and seasonality of precipitation, weather-related events could increase, including droughts, floods, severe tropical storms with associated storm surge flooding and wildfires from increased temperatures and drought conditions. With a rise in evaporation and precipitation rates, water availability and quality could be affected, with lower groundwater levels, decreased surface area and water levels of many lakes or inland waterways, as well as altering natural habitats. Potential impacts range from loss of property, effects on housing and street/road conditions, effects on construction materials, stress on sewage systems and potential overflow from excess storm water and drainage failures.

Rising sea levels could displace residents of delta regions (Nile, Ganges, Yangtze, Mississippi) from homes and livelihoods. Island nations could become uninhabitable. Coastal erosion on gradually sloping coasts by encroaching water could affect densely populated cities (New York, London) and important seaports.

Cooler climates may see an increase in agriculture and warmer climates may see a decrease in agriculture. Feeding the world's population means an inherent dependence on agricultural production, which is highly sensitive to climate change. Land degradation may produce either abandonment of the land or require changes in cultivation practices to improve yields and restoration of soil. Possible changes in fertileness of the land could increase or decrease food production capability for the agricultural country and as an export to other world regions.

Health impacts include temperature stress from either extreme heat or cold, especially among high-risk groups (children, the elderly, and those with already compromised health); air pollution exposure with increased incidence of respiratory disease; chemical pollution; water quality or water shortages from precipitation changes, flooding, or in some areas already a lack of safe water; and vector-borne diseases; lack of physical or economic access to health services or insufficient capacity of health services. In the event of disaster refugees or migration, sanitary facilities and housing could become quickly overburdened, enhancing the spread of communicable diseases.

Climate change could modify supplies and consumption patterns. These impacts would vary by region based on cost of various types of food and fiber. Changing availability of resources might lead to changed diets, production patterns, and employment levels. Major impact could be felt by the energy, transport, and industrial sectors, with increasing need balanced against dwindling supply.

Impact on physical and social environment would also vary by region and could include loss of housing (from wildfires, flooding, mud slides); loss of living resources (water, energy supplies, food, or employment); loss of social and cultural resources (cultural properties, neighborhood or community networks); decline in living standards (conditions caused by mandatory evacuation, contamination of water supply); total loss of livelihood following land degradation (erosion of top-soil, over-cultivation or deforestation); or a major natural disaster like flooding or drought. In some areas, physical and social environments could improve. Communication technologies (cell phones, computers, and fax machines) could have a positive impact including increased potential for decentralization of the population by enabling many professional and technical people to perform work in homes far removed from major metropolitan areas.

POSSIBLE SOLUTIONS

The Hyogo Framework for Action signed in January 2005 by 168 countries details steps to reduce the impact of natural hazards on populations. The result has been 40 countries adjusting national policies to give priority to disaster risk reduction.

Examples of disaster planning paying off in action include Jamaica in 2004. A community disaster response team issued early warning by megaphone, and used risk maps and equipment assembled by the Red Cross for successful evacuation of all area residents. Hurricane awareness is taught in schools in Cuba along with practice drills. The Citizens' Disaster Response Center in the Philippines helps to create disaster management plans and provides emergency response. These examples indicate effectiveness and indicate the need for global, regional, national, and local early warning systems to alert populations of impending disasters.

While the previous examples are for disasters, the same ideas can be used to implement climate change preparedness, of which natural disasters are one element. One caveat for planning is the necessity to include feedback loops to allow for changes as new information becomes available or conditions are modified.

The challenge is the predictive factor (strategies planning far into the future, 10 years, 25 years, 50 years, or 100 years) in the presence of current needs of access to clean water management, production of energy allowing for cost-effectiveness and to allow developing countries to utilize cheap fossil fuels available to them, and supplying enough food for populations with limited agriculture due to already stressed conditions. To meet food supply needs far into the future, research to develop new varieties of wheat, corn, and soybeans for resistance to drought and heat and still produce good yields and strategies for future irrigation sources should begin now, building new wells and reservoirs instead of waiting until water shortages persist. Centralized stockpiles of grain could provide for increases in food needs or to supply areas with crop devastation.

With changing weather patterns, coastal areas should prepare for and be able to demonstrate effective evacuation procedures to deal with rising sea levels and more severe hurricanes, as well as to assess the risks of new construction in low-lying areas. Global, regional, national, and local early warning systems to alert populations of impending disasters should be developed, implemented, and tested.

Water supplies, both in rural areas and in municipal water infrastructure, should be set up for equitable availability and pricing. Some areas have no access to fresh water and must use desalinization systems to make clean water from seawater.

Environmental policy should strengthen institutional and legislative environmental framework at national and regional levels, including environmental authorities, and incorporating new laws, as well as implementing environmental control standards for air quality, including reduced emissions of greenhouse gases, reducing ground level ozone and particulates from stationary and transport sources, and more tightly enforcing pollution and land use regulations.

Emphasis should be placed on nature and biodiversity such as management of protected areas and a national biodiversity strategy and provide for better management of all natural resources, including forests, fishing, soils, water, air, wildlife. Altered habitats will cause animal migration. Barriers standing in their way could be removed by setting up migration corridors to connect natural areas and allow them to migrate safely. In the event these measures aren't enough, wildlife managers may have to capture and move certain species.

Reducing health impacts from climate change can be acted upon early by preventing the onset of disease from environmental disturbances, in an otherwise unaffected population (such as supply bed nets to all members of a population at risk of exposure to encroaching malaria, taking precautions against mosquito bites to prevent West Nile virus, early weather watch warning systems). Surveillance systems could be improved in sensitive geographic areas with the potential for epidemics under certain climatic conditions, including those bordering areas of current distribution of vector-borne diseases (plague from prairie dogs, hanta virus from rats, malaria from mosquitoes). Vaccination programs could be intensified and pesticides used for vector control. Drugs for prophylaxis and treatment could be stockpiled.

In certain areas of the world, irrespective of climate change, breakdowns in public health measures have been responsible for many recent outbreaks of disease. In those areas, climate change would add to the health burden; current and future health problems related to the environment share similar causes of economic factors and access issues. All areas must have sufficient trained staff to handle healthcare issues, as well as technology for diagnosing and treatment and medications or medical interventions required.

Construction practices and advancing technology make possible new building techniques, including floating houses to weather storm surge and flooding in hazard areas. Current building material (including roads) may not be able to withstand future climate change conditions and will require replacement or restoration. Public reconstruction to ensure safe bridges and other infrastructure is necessary. In some areas, drainage improvements will need to be made for water and sewage.

Adaptation refers to actions taken to lessen the impacts of the anticipated changes in climate. The ultimate goal of adaptation interventions is the reduction, with the least cost, of disruptions in living standards, of suffering from diseases, injuries, or disabilities, and of destruction of habitats, ecosystems, and species (both plant and animal).

AWARENESS RAISING

To make any plan for preparedness work, the information collected in assessments must reach all relevant stakeholders in the process of building and reaching a consensus on adaptation strategy. Providing environmental information to the public is essential to any preparedness method; if people don't know what to do in the event of an emergency or steps to take to prevent or adapt to changing conditions, the plan will fail. Awareness campaigns directed at the general public and to those persons who are directly affected should be made available through all forms of media and should be easily understood.

On the individual level, certain precautions can be taken to prepare for natural disasters, and some associated climate change, including extreme heat or winter weather, flooding, hurricanes, landslides and mudslides, tornadoes, tsunamis, and wildfires. Taking preparedness actions helps people deal with disasters in an effective manner. Having emergency supplies of water, food, and first aid prepared and easily available allows an individual or families to either evacuate quickly or shelter in place as appropriate. Having a plan of action for where to go, how to reconnect with family members, and dealing with finances lessens the stress involved with disasters.

Princeton University

PRINCETON UNIVERSITY IS a private coeducational research university located in Princeton, New Jersey. It is one of eight colleges and universities that belong to the Ivy League.

Originally founded at Elizabeth, New Jersey, in 1746 as the College of New Jersey, it relocated to Princeton in 1756 and was renamed "Princeton University" in 1896. Princeton was the fourth institution of higher education in the United States to conduct classes. Princeton has never had any official religious affiliation, rare among American universities of its age. At one time, it had close ties to the Presbyterian Church, but today it is nonsectarian and makes no religious demands on its students. The university has ties with the Institute for Advanced Study, Princeton Theological Seminary, and the Westminster Choir College of Rider University.

Princeton has traditionally focused on undergraduate education and academic research, though in recent decades it has increased its focus on graduate education and offers a large number of professional master's degrees and Ph.D. programs in a range of subjects. The Princeton University Library holds over six million books. Among many others, areas of research include anthropology, geophysics, entomology, and robotics, while the Forestall Campus has special facilities for the study of plasma physics and meteorology.

The Atmospheric and Oceanic Sciences Program is a unique collaboration between a renowned academic institution, Princeton University, and a world-class climate research laboratory, the Geophysical Fluid Dynamics Laboratory (GFDL) of the National Oceanic and Atmospheric Administration. The program hosts graduate students, postdoctoral researchers, and visiting senior researchers, as well as permanent research staff and faculty. The highly flexible graduate program offers students opportunities for research and courses in a wide variety of disciplines related to climate, including the physics and dynamics of the atmosphere and ocean, atmosphere and ocean chemistry and biological processes, global climate change, and paleoclimate. Through the in Science, Technology, and Environmental Policy (STEP) program at the Woodrow Wilson School of Public and International Affairs students can explore climate- [and air pollution] related policy. Students benefit from an unusually low student-to-faculty ratio and access to GFDL's supercomputing resources.

The Program in Atmospheric and Oceanic Sciences (AOS) offers graduate study under the sponsorship of the Department of Geosciences. An understanding of the complex behavior of the atmosphere and oceans requires a balanced effort in theoretical analysis, numerical modeling, laboratory experiments, and analysis of observations. The AOS program benefits from the research capabilities of the Geophysical Fluid Dynamics Laboratory (GFDL) of the National Oceanic and Atmospheric Administration, which is located on the Forrestal Campus. GFDL has a major in-house supercomputer facility to which students have direct access for their research. Many GFDL scientists are active in the AOS program as lecturers with the rank of assistant through full professor. The geosciences department, with its activities in physical and chemical oceanography, paleoceanography, and paleoclimatology, collaborates with GFDL in providing an academic program of courses and seminars.

The program is internationally recognized for its development of models of atmospheric and oceanic circulation and climate, particularly studies related to global warming. Additionally, it is world renowned for its development of earth system models, specifically as related to the global carbon cycle, and for its training of graduate students and postdocs. The student to postdoc to faculty ratio is typically about 1:1:1, which provides graduate students and postdocs with a highly stimulating environment for learning and carrying out their research.

Courses offered by the department which focus on climate change include:

Introduction to Physical Oceanography: Study of the oceans as a major influence on the atmosphere and the world environment. The theoretical and observational bases of our understanding of ocean circulation and the oceans' properties.

Introduction to Atmospheric Science: Atmospheric composition and thermodynamics including effects of water. Simple radiative transfer, elementary circulation models, phenomenological description of atmospheric motions, structure of the troposphere, stratosphere, mesosphere, and thermosphere, chemistry of ozone, and comparison with atmospheres on other planets.

Atmospheric Radiative Transfer: The structure and composition of terrestrial atmospheres. The fundamental aspects of electromagnetic radiation, absorption and emission by atmospheric gases, optical extinction by particles, the roles of atmospheric species in the Earth's radiative energy balance, the perturbation of climate due to natural and anthropogenic causes, and satellite observations of climate systems are also studied.

Atmospheric Chemistry: Natural gas phase and heterogeneous chemistry in the troposphere and stratosphere, with a focus on elementary chemical kinetics; photolysis processes; oxygen, hydrogen, and nitrogen chemistry; transport of atmospheric trace species; tropospheric hydrocarbon chemistry and stratospheric halogen chemistry; stratospheric ozone destruction; local and regional air pollution; and chemistry-climate interactions are studied.

Atmospheric Thermodynamics and Convection: The thermodynamics of water-air systems. The course gives an overview of atmospheric energy sources and sinks. Planetary boundary layers, closure theories for atmospheric turbulence, cumulus convection, interactions between cumulus convection and large-scale atmospheric flows, cloud-convection-radiation interactions and their role in the climate system, and parameterization of boundary layers and convection in atmospheric general circulation models are also studied.

Introduction to Geophysical Fluid Dynamics: Physical principles fundamental to the theoretical, observational, and experimental study of the atmosphere and oceans; the equations of motion for rotating fluids; hydrostatic and Boussinesq approximations; circulation theorem; and conservation of potential vorticity; scale analysis, geostrophic wind, thermal wind, quasigeostrophic system; and geophysical boundary layers.

Atmospheric and Oceanic Wave Dynamics: Observational evidence of atmospheric and oceanic waves; laboratory simulation; surface and internal gravity waves; dispersion characteristics; kinetic energy spectrum; critical layer; forced resonance; and instabilities.

Physical Oceanography: Response of the ocean to transient and steady winds and buoyancy forcing. A hierarchy of models from simple analytical to realistic numerical models is used to study the role of the waves, convection, instabilities, and other physical processes in the circulation of the oceans.

Numerical Prediction of the Atmosphere and Ocean: Barotropic and multilevel dynamic models; coordinate systems and boundary conditions; finite difference equations and their energetics; spectral methods; water vapor and its condensation processes; orography, cumulus convection, subgrid-scale transfer, and boundary layer processes; meteorological and oceanographic data assimilation; dynamic initialization; verification and predictability; and probabilistic forecasts.

Current Topics in Dynamic Meteorology: An introduction to topics of current interest in the dynamics of large-scale atmospheric flow. Possible topics include wave-mean flow interaction and nonacceleration theorems, critical levels, quasigeostrophic instabilities, topographically and thermally forced stationary waves, theories for stratospheric sudden warmings and the quasi-biennial oscillation of the equatorial stratosphere, and quasi-geostrophic turbulence.

Weather and Climate Dynamics: An examination of various components of the Earth's climate system. Dynamics and physical interpretation of principal tropospheric circulation systems, including stationary and transient phenomena observed in middle and low latitudes. Reviews of phenomena of topical interest, such as El Niño, seasonal climate anomalies, and natural and anthropogenic climate changes.

Public Awareness

PUBLIC AWARENESS IN the United States of the issue of global warming increased from about one-third in the early 1980s to near 100 percent 25 years later. By 2007, climate change was featured in the media almost daily. Awareness does not necessarily imply acceptance; although polls indicate that over half of Americans consider climate change to be real, there remains widespread public uncertainty about the degree to which human activities are involved, and to what extent CO_2 emissions need to be curtailed. There also remain widespread misconceptions about the meaning of global warming, and likely effects.

Public acceptance of human-induced climate change as a real phenomenon has lagged well behind the scientific consensus. In the mid-1970s, the popular media widely reported that the Earth was cooling and may be entering the next glacial interval, accelerated by light reflected off atmospheric particulates from pollution. The reports were based on the ideas of several scientists espoused primarily outside peer-reviewed literature. By the late 1970s, scientific consensus emerged from early generation global climate models that the warming influence of greenhouse gases was stronger than the cooling influence of particulates and insolation change. Scientific evidence that the climate was warming first received major coverage in a 1981 front-page article in the *New York Times*. Considerable advances in scientific understanding of current and past climate change occurred in the 1980s; this received enhanced public recognition with the 1988 congressional testimony by climatologists that coincided with a record hot summer.

As calls for government controls to reduce greenhouse gases increased, climate change discussions and media coverage of it grew politicized. In the 1990s, media, in efforts to offer "balanced" reporting, covered a small number of climate change skeptics in roughly equal proportion to the scientific consensus that climate is warming, which had grown to close to 100 percent in peer-reviewed scientific literature. The public was thereby given the impression that a considerable scientific controversy still existed. Debate about U.S. participation in the international Kyoto Accord in late 1997 and again in 2001 further increased politicization of the issue.

Several events in the mid-2000s swung U.S. public opinion from simple awareness of the issue to greater acceptance that global warming was happening. During this time, skeptics also changed stances, from whether climate change was happening to whether humans were causing observed changes. The severe hurricane season of 2005 (in particular, Hurricanes Katrina and Rita) centered U.S. public attention on potential domestic human and financial costs of climate change. Al Gore's 2006 documentary, *An Inconvenient Truth*, one of the most watched documentaries of all time, stimulated a groundswell of activity to further increase awareness, though to some degree maintaining the politicization of the issue. Several very warm years globally during the 2000s also helped give climate change greater reality to a broader geographic segment of U.S. citizens accustomed to hearing about warming in other areas of the world.

FACTORS THAT MAKE PUBLIC UNDERSTANDING OF CLIMATE CHANGE DIFFICULT

Scale: It is difficult for most people to grasp: scales of space the size of the Earth and its atmosphere; scales of time that include analyzing data from thousands of years in the past and up to decades or centuries into the future; and scales of human influence that involve billions of people, each contributing some quantity of CO_2 to the atmosphere.

Complexity: Climate is a complex system that is difficult for any one person, even specialists, to understand in total; in global warming, some places cool, which is why climate change is now the preferred term; spatial and temporal variability in weather systems means that even places that are warming on average may be occasionally unusually cold; in some places climate change is manifested more by precipitation change than temperature change.

Models and uncertainty: Computer models of climate are complex sets of mathematical equations that are "black boxes" for most of the public, and even many scientists; it can be confusing that different results occur for different researchers' models, as is evaluating the probability of events decades in the future, contingent on human actions in the meantime.

Personal reality: In many places climate change may not be readily evident from casual neighborhood observations; changes at the poles may seem personally irrelevant; warming may sound attractive in cooler climates.

Personal beliefs: Spiritual or philosophical beliefs may indicate that the Earth does not change, that humans need not concern themselves with personal influence on the Earth, or that near-term spiritual events on Earth will render changes to the Earth meaningless.

EDUCATION

Many efforts have developed in recent years to go beyond increasing public awareness, to educate the public on the nature of climate change and what can be done about it. The former is especially the purview of science education and the latter of personal and governmental action. Few K-12 school curricula have climate change as a major topic, though building block concepts such as greenhouse warming may be found in Earth and environmental courses at the high school level. Professional development for teachers at the state and national level may be needed in large numbers in the coming decades. Nonformal educational groups such as Scouts and 4-H are alternative settings for introducing climate education to youth. Major research partnerships such as Global Learning and Observations to Benefit the Environment (GLOBE) provide opportunities to collect data for scientific research that is relevant to climate change. Many colleges and universities are developing campus sustainability models and associated student action groups and courses.

Some organizations of informal education, such as museums and science centers, are in a good position to present public climate change education to a wide range of age groups. The International Polar Year (2007–09) provided an opportunity to present outreach associated with research on polar processes, including polar warming. Many grassroots groups have started in towns and cities across the United States to provide information on climate change to local citizens, particularly on how to take action to reduce CO_2 emissions. Among the most influential means of informal education remain radio and television documentaries on the topic.

Qatar

LOCATED IN THE Persian Gulf, the State of Qatar has a land area of 4,416 sq. mi. (11,437 sq. km.), with a population of 841,000 (2006 est.), and a population density of 192 people per sq. mi. (74 people per sq. km.). With massive prosperity from the petroleum industry and from the production of natural gas, some 90 percent of Qatar's population lives in urban areas. Only one percent of the country is arable, with a further five percent used for meadows and pasture, with the country having no forests or woodland.

Qatar has the highest rate of carbon dioxide emissions per capita, and one of the highest in the world as far back as 1950. In 1990, it was measured at 22.5 metric tons per person, rising dramatically to 37.4 metric tons per person, dramatically increasing to 55.3 metric tons in 1992. It rose steadily, reaching 69.2 percent in 2004, considerably more than the second highest per capita emitter, Kuwait, which reached a peak of 38 metric tons in 2004. This high level comes from the use of natural gas for electricity generation, all electricity coming from the use of fossil fuels. Electricity usage remains high, with heavy use of air conditioning, and also the running of a large desalination plant.

Gaseous fuels account for 80 percent of all carbon dioxide emissions, with liquid fuels making up a further 19 percent. The generation of electricity contributes 28 percent of all carbon dioxide emissions, with other energy industries making up 32 percent, and manufacturing and construction another 32 percent. In spite of its small size, transportation accounts for 8 percent of the emissions, a result of a wealthy economy that has a large private ownership of automobiles, and gasoline is cheap.

The Qatar government took part in the UN Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. They accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on January 11, 2005, with it entering into force on April 11, 2005.

Quaternary Era

THE QUATERNARY PERIOD, the most recent geologic interval, represents the last 1.8 million years of time. Its most striking feature is that the Earth had cold polar regions, which led to periodic development of continental glaciers. The prolonged Ice Ages, comprising the main part of the Quaternary interval, ended 10,000 years ago, when the continental glaciers had melted. Compared to the many cold periods (glacial intervals) of the Quaternary, the last 10,000 years of the present interglacial has been comparatively warm.

The changes in climate over the past 150 years have shown a varied history. The world endured a historic cool period during the late 1800s (the Little Ice Age), followed by a warm period of the 1930s (the Dust Bowl years), and since about 2000, the climate has been more variable, reaching extremes in warmth at high latitudes. Reports from Vikings show that 1,000 years ago the climate of Greenland and Iceland was warmer than today (the Medieval warming). While these historic shifts in temperature are relatively moderate, much larger changes in temperature on Earth have occurred in the geologic past.

PROXY DATA

Using the changing oxygen isotope ratios from ice cores and marine sediment cores, scientists have discovered global changes, recorded synchronously over a wide range of latitudes. One long climate proxy record was taken in the Antarctic, the Vostok core. From it, the inferred temperature over a long interval is based on the temperature-sensitive ratio of oxygen isotopes, ^{18}O to ^{16}O. In the Vostok core, isotopes of oxygen have been used to develop Earth temperature histories extending over 400,000 years. Trapped gas bubbles record the history of atmospheric CO_2 concentrations for over this period (data from the National Climatic Data Center, Asheville, North Carolina). Because the isotope ^{18}O is heavier than ^{16}O, the proportions of each vary depending on the climate region. In alpine areas such as in the Alps of Switzerland and in the polar regions, ^{18}O is more abundant, while in the lowlands of the middle and low latitudes ^{16}O prevails in the atmosphere. By calibrating these, scientists can use the proportions of oxygen isotopes taken from ancient sediments or ice cores as an index of average annual temperature.

The changing proportions of isotopes can be matched and dated with a geomagnetic signal of polar reversals (the Earth's poles changed in magnetic signals), a known time scale based on isotopically dated magnetic signals that are worldwide. Another source of long climate records are the deep-sea sediment cores from which oxygen isotopes can be extracted from calcareous plankton (foraminifera). These data carry the paleoclimatic records back through more than 60 million years through the Tertiary period and the time of the last dinosaurs.

The Ice Ages, which comprised the main part the last million years, was a globally cold period with increasingly variable swings of climate. The glacial pattern continued over long intervals, with only a few comparatively short warm or interglacial periods. The last major glaciation came in two parts; in the United States, these are called the early Wisconsin (80,000–28,000 years before present, oxygen isotope stage 4) and the Full Glacial or late Wisconsin (23,000–15,000 years ago, oxygen isotope stage 2); between these a somewhat warmer middle Wisconsin period occurred 28,000–23,000 years ago. The maximum of the last major glaciation occurred about 18,000–15,000 years ago (called the Full Glacial). After 15,000 years ago, a global warming began, and continental ice sheets melted by about 10,000 years ago. The period after 10,000 years ago, or postglacial, is called the Holocene or Recent period representing the present interglacial.

The period of the last glaciation (Full Glacial) brought continental ice down to the middle latitudes in both hemispheres. In Europe, ice from the Scandinavian highlands spread southward over the Netherlands and mountain glaciers covered the Alps. Ice stood over parts of northern Siberia, Greenland, and parts of Alaska. Permafrost ice developed underground in Siberia, northern Canada, and Alaska as much as 300 ft. (91 m.) thick. Equivalent ice expansions occurred in the Southern Hemisphere.

As temperatures warmed between 15,000 and 9,000 years ago, the average annual temperatures at mid-latitudes increased by about degrees 11 F (6 degrees C). At Lamont National Observatory, scientists estimated that the difference in solar insolation between the Full Glacial and the mid postglacial was about 8 percent.

An overall trend within the Quaternary is apparent. In the first half, the amount of variance from year to year was fairly low, while in the last half of

A glacier in New Zealand. The prolonged Ice Ages, comprising the main part of the Quaternary interval, ended 10,000 years ago. The continental glaciers melted during a comparatively warm cold period, but some have remained.

the Quaternary, variance became more and more extreme. Looking back over records of the past million years, geologists estimate that there were at least 40 cold or glacial intervals, and these were of varying length and were not regular in occurrence. In the last 400,000 years of the Ice Ages, proxy data indicate that there were four extreme cool periods (glacials) interspersed with five variable warm periods (interglacials). The last major interglacial (spanning the interval of about 80,000–122,000 years before present) was similar in warmth to the present interglacial climate, but the previous interglacials were definitely cooler that the present one.

CAUSES

The main climatic changes of the Quaternary are linked to the orbital position of Earth in relation to the sun. Astronomer Milutin Milankovitch proposed the orbital theory that is established by a variety of evidence, starting with tree ring variation. The precession of the equinox, the obliquity of the Earth's orbit around the sun, and the eccentricity of the Earth's orbit all contribute to the level of insolation received by Earth and are therefore the cause of geologic shifts in climate.

Before the Quaternary was the warm so-called Tertiary period that brought tropical conditions to the mid-latitudes, and extensive temperate forests grew in the Northern Hemisphere. The north and south polar areas were at least 36 degrees F (20 degrees C) warmer than today, perhaps around 41 degrees F (5 degrees C) average annual temperature. Orbital causes for this part of Earth's history have not been specified, but undoubtedly were important factors.

IMPACTS

Global changes in climate forced major changes in plant and animal distributions, especially in the high and mid-latitudes. During the Full Glacial, remains of trees that now grow in the northern boreal forest were found in Tennessee where their fossils were associated with deciduous hardwoods and even cypress-swamp types, creating strange mixtures of genera. Plants and animals that had dispersed to lower latitudes and in areas of southerly environments during glacials dispersed northward again during the postglacial warming. Thus, the Quaternary period records some of the more extreme climate changes known in Earth's history.

Radiation, Absorption

RADIATION IS ENERGY transmitted by electromagnetic waves. Electromagnetic waves travel at the speed of light (when passing through a vacuum) and have a characteristic wavelength, λ, which is inversely proportional to their frequency, ν, by

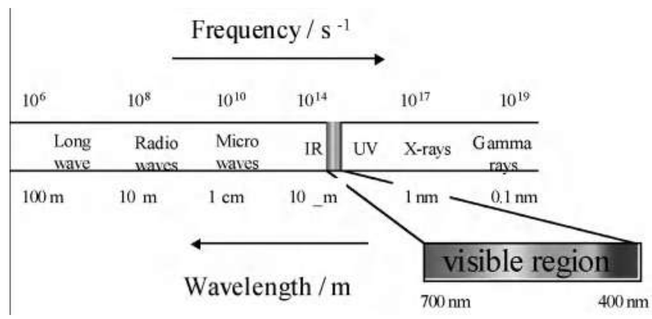
λ (m) = c (m s-1) / ν (s-1),

where c is the speed of light. Electromagnetic radiation is conceptualized in contemporary theory both as a wave and as a stream of particles called photons (this dual approach is referred to as wave-particle duality). The energy of any photon, E, of radiation is inversely proportional to the wavelength by

$E = h\nu$,

where h is Planck's constant. This relationship allows us to order electromagnetic waves from high energy/short wavelength (for example, x-rays), to low energy/long wavelength (for example, radio waves). The resulting progression is referred to as the electromagnetic spectrum (Figure 1). The visible region of the electromagnetic spectrum is bound by infrared (IR) radiation on the lower energy side of the visible region (around

Figure 1: The electromagnetic spectrum



1 µm to 1 mm in wavelength), and by UV radiation (UV) on the higher energy side (from 400 nm to 1 nm). Microwave radiation is slightly lower in energy than IR, with a wavelength of around 1 cm.

All objects both emit and absorb radiation. Although all objects emit radiation at all wavelengths, the frequency of maximum emission, λmax, is proportional to the temperature of the object by Wien's law

$\lambda max = \alpha / T$,

where α is a constant equal to 2897 µm K. This implies that hotter objects emit higher energy radiation, as would be expected from everyday experiences. From Wien's law, the surface temperature of the sun can be calculated based on its emission peak at ~0.5 μm (green light) to be around 5800 K. The average temperature of the Earth's surface is around 18 degrees C (290 K) which corresponds to a peak emission at around 10 μm, in the infrared to microwave region.

There are three basic modes of motion: translational (movement through space), rotational, and vibrational. These are important, because along with electronic energy, they are the ways in which gas molecules can store energy. Quantum theory dictates that energy levels are discrete, not continuous; this implies that molecules will only absorb discrete frequencies of radiation that correspond to the gap between a high and lower energy state. UV radiation corresponds to the gap in energy between electronic energy levels in a molecule. When a molecule absorbs UV radiation, it may be promoted to an electronically excited state. In the general, this will make the bonds holding the atoms together weaker and may help facilitate reactions or the breakup of molecules. For example, the reactions that complete the Chapman mechanism in the stratosphere:

(i) O2 + hν -> O + O (λ < 240 nm)
(ii) O+O2 + M -> O3 + M
(iii) O3 + hν -> O2 + O* (λ < 320 nm)
(iv) O* + M -> O + M

The Chapman mechanism is chemically a null cycle, but it is important in the context of life, as it prevents most of the high-energy radiation from below 320 nm reaching the Earth's surface. IR and microwave radiation, being lower in energy than UV, correspond to the gaps between rotational and vibrational energy levels, respectively. Quantum theory dictates that molecules interact with IR/microwave radiation only when two conditions (selection rules) are met:

1. The energy of the radiation corresponds to the energy gap between two of the discrete energy levels in the molecule and,
2. The resulting motion results in a change in the dipole moment (electron distribution) of the molecule.

This implies that atmospheric components that are symmetrical molecules, such as N_2 and O_2 that have an even electron distribution and cannot be rotated, bent, or stretched in such as way as to create one, do not absorb microwave and IR radiation. Molecules possessing a dipole, which can be altered by bending and stretching, absorb radiation. Atmospheric components that fill this requirement include CO_2, CH_4, H_2O and CFC's, for example, the asymmetric stretch of CO_2. These gases are collectively known as greenhouse gases. Radiation from the sun is received at the Earth's surface, mainly in the UV and visible region, with other frequencies cut out by the atmosphere and electromagnetic field.

Radiation, Infrared

INFRARED RADIATION IS the part of the electromagnetic spectrum popularly (but not entirely accurately) conceptualized as heat. The IR region covers wavelengths that span nearly three orders of magnitude; it is conventional therefore to break this down into further subgroups (Table 1).

Table 1: Conventional breakdown of IR radiation

Name	Wavelength	Comments
Near-infrared (NIR)	0.75 – 1.4 μm	Absorbed by water and commonly used in fiber-optic technology.
Short Wavelength Infrared (SWIR)	1.4 – 3 μm	Strongly absorbed by water and used in long-range telecommunications.
Mid wavelength Infrared (MWIR)	3-8 μm	Used in heat-seeking missile technology.
Long Wave Infrared / Far IR (LWIR)	8-1000 μm	Not absorbed by water, therefore used for thermal-image sensors.

The main application of IR radiation in relation to climate change is in the fields of meteorology and climatology. Satellite measurements of IR radiation received from the Earth can be used to derive cloud types and heights; these are used for weather forecasting, but knowledge of the number and type of clouds present is useful in calculating the Earth's radiative budget. It is possible to use the IR radiation returned to space from the earth to measure land and sea surface temperature, both of which are important parameters in calculating the Earth's heat budget and in monitoring global climate change. Satellite measurements of IR are also used to determine cloud height and rates of convection.

IR radiation also finds a variety of industrial, military, other scientific, and domestic applications, for example:

1. Night vision—Night vision devices use a photon muliplier to amplify the signal from the available ambient light which is then augmented with the IR radiation.
2. Thermal imaging—non-contact, non-destructive technique that generates a false-color thermal image of a subject finding a wide range of industries.
3. Heating—IR lamps can be used for heating; examples include for frozen aircraft wings and for patio heaters.
4. Spectroscopy—IR spectroscopy (also called rotational spectroscopy) is a technique used by chemists for the identification of molecules and for elution of chemical structure.

Radiation, Long Wave

LONG WAVE (OR longwave) radiation is the part of the electromagnetic spectrum emitted at spectral wavelengths generally greater than one micrometer (μm). Types of long wave radiation include infrared, microwave, and radio waves. Emittance of radiation is a function of temperature, and objects giving off long wave radiation are colder than those radiating at short wavelengths. For example, the sun (approximately 5800 K) radiates primarily in the short wave part of the spectrum (especially visible light from 0.4 to 0.7 micrometers), whereas the Earth (approximately 290 K) emits radiation at much larger wavelengths. Climatologically, long wave radiation generally refers to radiation emitted by the Earth-atmosphere system (also called terrestrial radiation), largely at wavelengths of 5–15 μm. Long wave radiation emitted by the Earth's surface and atmosphere falls primarily within the thermal infrared ("below the red") region of the electromagnetic spectrum. It can be sensed through the sensation of heat.

In the Earth-atmosphere system, short wave radiation from the sun is absorbed and converted to long wave radiation. Various components of the Earth-atmosphere system absorb the incoming short wave radiation; among those are the Earth's surface, gas and dust molecules in the atmosphere, and clouds. Long wave radiation is then reradiated from those components, after which it is referred to as outgoing long wave radiation or counterradiation. Counterradiation may be reabsorbed (and reradiated) by those very same components that initially absorbed short wave radiation. This process is behind the greenhouse effect.

Globally, the Earth's atmosphere is relatively transparent to radiation between 8 and 15 μm. This atmospheric window allows much long wave radiation to be lost to space. However, the window may be closed locally by the presence of large amounts of water vapor or clouds. Additionally, increasing amounts of greenhouse gases can also potentially close this window. Thus, the role of long wave radiation in the greenhouse effect is fundamental. In the absence of an atmosphere containing long wave–absorbing greenhouse gases (for example, water vapor, or carbon dioxide), the Earth's average temperature would be approximately 0 degrees F, (minus 18 degrees C or 255 K). However, due to the efficiency with which greenhouse gases reabsorb counterradiation, the Earth's average temperature is 59 degrees F (15 degrees C, or 288 K).

Water vapor and carbon dioxide are the most abundant greenhouse gases by volume. They are particularly effective at absorbing counterradiation. The amount of water vapor in the atmosphere is a direct response to temperature. Other long wave–absorbing gases can be produced by human activity. Carbon dioxide and certain other trace gases (such as methane, nitrous oxide, and chlorofluorocarbons) can potentially upset the long wave exchanges involved in the Earth's energy balance. Such deviations can lead to changes in the average global temperature. Potential consequences of an escalating amount of these atmospheric gases include a growing proportion of outgoing long wave radiation being "trapped" in the atmosphere, leading to an increase in the Earth's temperature.

Clouds serve as very effective absorbers of outgoing long wave radiation. This, in turn, affects surface and near-surface temperatures. The presence of clouds in a nighttime sky results in warmer temperatures than a cloudless one. In the absence of incoming short wave radiation, only long wave exchanges occur at night. With clouds trapping much of the outgoing long wave, substantial amounts are redirected back toward the surface. This increases the near-surface temperatures. Similarly, the lack of clouds leads to greater amounts of long wave radiation escaping the Earth-atmosphere system to space.

Radiation, Microwave

THE EXISTENCE OF microwaves was first postulated by James Clerk Maxwell in 1864 and confirmed by the experiments of Heinrich Hertz some 20 years later. Microwaves are subdivided into categories as listed in Table 1.

Table 1: Microwave frequency bands as defined by the Radio Association of Great Britain

Designation	Wavelength *
L band	15 cm – 30 cm
S band	8 cm – 15 cm
C band	3.75 cm – 8 cm
X band	2.50 cm – 3.76 cm
Ku band	1.7 cm – 2.50 cm
K band	1.1cm – 1.7 cm
Ka band	0.75 cm – 1.1 cm
Q band	0.6 cm – 1 cm
U band	0.5 cm – 0.75 cm
V band	0.4 cm – 0.6 cm
E band	0.33 cm – 0.5 cm
W band	0.3 cm – 0.4 cm
F band	0.2 cm – 0.33 cm
D band	0.27 cm – 0.18 cm

*Note the definition is originally in units of GHz and has been converted here to cm for comparison to the other measurements. This has inevitably led to some rounding.

Microwaves are most well known in popular culture for their role in heating food (in a microwave oven), and for their use in mobile telecommunications such as mobile phones and wireless networking. Microwave ovens work by passing S-band radiation though food, which excites water, sugar, and fat molecules. These molecules in turn reradiate in the infrared to heat the food. With the rapid expansion of mobile phone technology, many studies have been done to look at the effects of microwave radiation on human health. The studies show mixed results however, and the general conclusion is that only doses high enough to heat up tissue are likely to have negative impacts.

Radiation, Short Wave

RADIATION TRAVELING IN waves shorter than one micrometer (µm) is characterized as short wave, and includes gamma rays, x-rays, ultraviolet light, and visible light. Climatologically, short wave radiation commonly refers to the incoming radiation from the sun. There is an inverse relationship between the temperature of an object and the wavelengths at which it primarily emits. Because the sun is a hot object (approximately 5800 K), it emits radiation at short wavelengths. Since shorter wavelengths carry more energy than longer ones, they are more intense. Most of the short wave emitted by the sun is in the visible region of the electromagnetic spectrum, which spans from 0.4 µm (violet) to 0.7 µm (red). The sun's wavelength of maximum emission is found at 0.5 µm.

The amount of emitted solar radiation that reaches the Earth decreases inversely with the square of the distance between the Earth and sun, by the inverse square law. The total of short wave radiation that reaches the top of the Earth-atmosphere system is called the solar constant. Although the amount varies slightly throughout the year, due to the elliptical nature of the Earth's orbit around the sun, the solar constant averages around 1370 W m^{-2}.

Because the eccentricity of the Earth's orbit varies between nearly zero to five percent (with a periodicity of 110,000 years), the amount of short wave received increases or decreases over time from present values. The current orbit is nearly circular, leading to little seasonal variation of incoming short wave radiation. However, a more highly elliptical orbit would render a difference of up to 30 percent between aphelion (maximum Earth-sun distance) and perihelion (minimum Earth-sun distance). Incoming solar radiation can take several avenues once it enters the atmosphere. Over a year, 30 percent of total short wave radiation is reflected back to space, either by gas molecules or other particles in the atmosphere, by clouds, or by the Earth's surface; this is the Earth's albedo (the proportion of radiation that is reflected from a surface). The atmosphere and clouds absorb an additional 20 percent of short wave radiation. Approximately 50 percent strikes the surface, where it is absorbed. These values may vary locally and at shorter time scales.

Some of the short wave radiation reaching the Earth's surface arrives directly, unimpeded by clouds or atmospheric constituents; this is direct radiation. Some is scattered about the atmosphere and arrives at the surface indirectly. This is diffuse radiation. Diffuse radiation is a product of scattering, which occurs when short wave radiation strikes small particles in the atmosphere, including gas molecules. Upon impact, the radiation is scattered omnidirectionally. Some short wave radiation will be scattered toward the surface. Energy received at the Earth's surface is the total amount of direct and diffuse radiation.

The presence and type of clouds in the atmosphere reduces the amount of short wave radiation reaching the Earth's surface. Thin clouds, such as cirrus, have lower albedos than thick ones, such as cumulus. Once short wave solar radiation reaches the surface and is absorbed, it is converted to long wave forms of radiation.

Short wave radiation impacting the Earth also includes ultraviolet light. These wavelengths are shorter than visible radiation, so ultraviolet light carries more energy than visible light. Ultraviolet radiation is classed into three categories: UV-A (0.32–0.40 µm), UV-B (0.29–0.32 µm), and UV-C (0.20–0.29 µm). Excessive exposure to UV-A and UV-B radiation has been linked to skin cancers and skin damage. UV-C radiation is largely absorbed by stratospheric ozone. Absorption of ultraviolet radiation breaks ozone down into atomic and molecular oxygen. The presence of stratospheric ozone helps protect the Earth's surface from the damaging effects of this form of short wave radiation.

Radiation, Ultraviolet

ULTRAVIOLET RADIATION WAS discovered as a result of the observation that silver salts darken on exposure to sunlight. In 1801, the German physicist Johann Wilhelm Ritter first observed that invisible electromagnetic radiation was responsible for this darkening. These rays eventually became known collectively as UV, so named as this radiation is immediately beyond violet in the electromagnetic spectrum. This implies that UV is more energetic than the visible light. Conventionally, UV radiation is broken down into further subdivisions as shown in Table 1:

Table 1: Conventional subdivisions of UV radiation

Name	Wavelength	Comments
1. Near	400 nm – 200 nm	Referred to as 'Blacklight'
UV-A	400 nm – 320 nm	Strongly absorbed by O_3
UV-B	320 nm – 280 nm	Strongly absorbed by O_3
UV-C	290 nm – 200 nm	Strongly absorbed by O_2
2. Far	200 nm – 31 nm	Strongly absorbed by O_2
3. Extreme	31 nm – 1 nm	

In humans, UV radiation is important for health. UV-B has health benefits, as it is responsible for the production of vitamin D. A deficiency of vitamin D is thought to lead to a range of cancers and also to osteomalacia (the adult equivalent of rickets), with symptoms ranging from painful bones to brittleness and fractures.

Exposure to UV radiation also causes the skin to release a pigment (melanin), giving the skin a darker color that is regarded as healthy in most Western cultures. Melanin provides some protection again the more harmful effects of UV exposure.

Exposure to UV radiation also has a range of negative health effects. The most widely publicized of these is the link between exposure to UV and skin cancer. UV radiation is strongly absorbed by DNA, the cellular molecule responsibly for the transfer of hereditary information. The absorption of UV radiation causes chemical bonds in the DNA to be broken and reformed in the wrong order. This can lead to mutations and cancerous growths. UV radiation is also harmful to the eyes, leading to short-term uncomfortable conditions such as arc eye or to more serious conditions such as cataracts. There may also be a link between excessive UV exposure and poor immune response. UV radiation also finds a range of industrial and domestic applications; these include:

1. Astronomy: Many hot objects in the universe emit large amounts of UV radiation and are therefore better observed in the UV region. However, as the atmosphere absorbs a lot of this UV, these observations are generally only made from space.
2. Spectrophotometry: A widely used technique in analytical chemistry to determine chemical structure.
3. Analyzing minerals: Many minerals glow characteristic colors under a UV lamp, aiding identification.
4. Sterilization of surface and drinking water: UV radiation is effective at killing pathogens and is used to sterilize critical workspaces (such as biochemistry labs) as an alternative to chlorination. Methods to sterilize water based on using UV from sunlight may provide a carbon neutral solution to domestic water treatment.

Radiative Feedbacks

WHILE MOST OF the feedbacks at play in the Earth's ecosystem are subject to the closed system of matter, radiative feedbacks are those that deal with the open system in which the sun's energy is transferred to the Earth and then absorbed or reflected back, to varying degrees. Because the amount of absorbed or reflected solar energy is the principal component in the planet's temperature (the other factors then determine what happens to that heat, but the solar energy provides the initial quantity), these feedbacks are key to understanding and modeling global climate. Feedbacks are relationships found in complex systems, in which the output (or result) of the system is returned to the input. For instance, as the summers get hotter, people run their air conditioners longer, releasing more chlorofluorocarbons, accelerating global warming, and causing hotter summers. That is a simple example of a positive feedback often used in schools. The radiative feedbacks in question involve principally clouds, ice, and water vapor.

A critical feedback in global warming is the albedo-ice feedback. Though the melting of the polar ice caps is often associated with rising sea levels, it's only one of the important effects, and simply the most vivid to illustrate. The more complicated effect is in the change it enacts on how much solar energy is retained by the Earth. Ice is far more reflective than land or liquid water, and as the polar ice melts, the area of the surface that it occupied is replaced by one of those two things. As a result, more sunlight is absorbed by the surface instead of being reflected, which then warms the poles further, melting more ice.

Clouds are also critical. Clouds act as a sort of imperfect barrier, absorbing a limited amount of heat moving in either direction, heat emanating from the Earth into space, and sunlight shining on the Earth. Models disagree on whether their overall feedback effect on global warming will prove positive or negative. On the one hand, the evaporative feedback in general accelerates global warming: as the temperature increases, the capacity of the air to hold moisture increases exponentially, so as water evaporates into the warm air, it is able to stay there. Since water vapor is a greenhouse gas, as it accumulates, it causes the temperature to get warmer and warmer. On the other hand, sufficiently great cloud cover shields the Earth from solar radiation, and cloudy days aren't as hot. High-enough clouds can reflect sunlight back down on the Earth, however, more than balancing out the sunlight they have blocked. Water vapor also retains heat better than the atmosphere does; a wetter atmosphere loses heat more slowly. As more and more water evaporates, more and more heat from the sun can be retained, which makes for a warmer Earth, and greater evaporation.

It is possible that the effects of positive radiative feedbacks on global warming have been muted until recently by global dimming, the gradual reduction of the Earth's irradiance (emitted radiation, including heat and light) in the second half of the 20th century, which has reversed in the 21st century. Global dimming is probably caused by the coalescing of water vapor around anthropogenic particles in the air, the product of pollution and other industrial activities. The resulting water droplets form a little differently than they would otherwise, and make more highly reflective clouds. The Clean Air Act and other anti-pollution efforts are presumed to be responsible for ending global dimming. The apparent recent increase in global warming may be because that dimming had been reducing global warming's effects by limiting the amount of sunlight entering the system.

Rain

RAIN IS COMPOSED of water droplets formed from vapor that has condensed in the Earth's atmosphere. Regular rainfall is vital to the functioning of the biosphere, and even minor fluctuations in the amount of rain can have substantial impact on the ecosystem. Climatologists believe that rainfall patterns are going to change dramatically as the atmosphere heats up in the coming decades, with potentially damaging consequences.

HOW RAIN FORMS

Precipitation forms under three main types of conditions: convective uplift, frontal uplift, and orographic uplift. Convective uplift is common in the equatorial tropics and during the summer months. As the sun heats up the Earth's surface, the humid, warm air rises into the atmosphere, cools, forms tall, unstable cumulonimbus clouds, and then releases its moisture in a quick downpour.

Frontal uplifts are the result of cold and warm fronts colliding. This can take different forms. Fronts are transition zones between air masses of different temperatures. When warm air collides with cooler air along a warm front, the warm air gently rides up over the cooler air. If cold air collides with warm air along a cold front, the colder, denser air pushes up the warm air rapidly. Depending on the particular conditions, rains from frontal events can be a steady, soaking rain that last for several hours, or severe weather events that spawn quick downpours, high winds, and tornadoes. Orographic uplift, sometimes called "relief rain," occurs when a warm air mass meets a geographical barrier (usually a mountain range) that pushes the warm air up into the atmosphere, where it cools and condenses.

No matter what the type, the development of rain requires the presence of extremely small particles called condensation nuclei to form droplets. These particles, trapped in cloud formations, can be composed of anything from dust and soot to sea salt and phytoplankton, and at 0.02 mm. in diameter, are just 1/100th the size of a typical raindrop. Condensation nuclei give water vapor in the clouds something to coalesce around, thus increasing the size of the individual molecules of water vapor into droplets heavy enough to fall out of the clouds.

The speed with which raindrops fall depends primarily on their weight: for example, a 0.5 mm. raindrop would fall at around 6.5 ft. (2 m.) per second, while a five mm. drop would fall at 29.5 ft. (9 m.) per second. The average raindrop is around two mm. in diameter. The largest raindrop ever recorded was 10 mm. in diameter, but those are rare; drops larger than five mm. tend to be unstable, often breaking into smaller droplets as they fall. Raindrops are not shaped like teardrops: rather, they are spherical, or flattened on the top, with larger drops sometimes shaped liked parachutes.

RAINFALL AND GLOBAL WARMING

Rainfall is vital to the creation of food and water on Earth. With less than 1 percent of all the planet's fresh water available for human and animal consumption, the regular recharging of groundwater and reservoirs from rain and snow is critical to keep fresh water sources flowing, and all plant life requires at least some water to grow. Regular, moderate precipitation is critical to the production of most of the 2,000 food crops under cultivation. Because of the importance of rainfall to the environment, climate experts have been trying to determine the possible impact of global warming on rainfall distribution around the world.

In 2007, a group of researchers constructed a computer modeling program drawing on data collected 1925–99, and, taking into account potential future increases in levels of greenhouse gases and solar activities, made projections well into the next century. Their study found the precipitation in areas lying between 40 and 70 degrees N latitude is likely to increase at a rate of 2.44 in. (62 mm.) per decade, and in areas lying between zero and 30 degrees S latitude is likely to increase 3.23 in. (82 mm.) per decade. However, the area lying between zero and 30 degrees N latitude is likely to see precipitation decreases of 3.86 in. (98 mm.) per decade. This means that regions toward the poles, including Europe, Canada, and parts of Latin America, will become wetter, while already parched regions will become much dryer.

This could be catastrophic for the Sahel region in Africa. A 2,400-mi. (3862 km.) long belt stretching from Senegal on the west coast to Eritrea on the east, the Sahel is the boundary line between the Sahara Desert and the more fertile sub-Saharan region to the south. The area is home to an estimated 50 million people, 62 percent

A patch of rain moving through Tobago in the Caribbean. Climate models predict more heavy rain events, separated by prolonged periods of dry weather. In a global warming scenario, the warmer air in the atmosphere holds more water.

of whom live in poverty. Since the 1970s, the Sahel has been struck by longer and more frequent droughts, with overall precipitation decreasing by around 20 percent during the period. Modeling indicates that in the coming century, rainfall averages in this region could drop by another 30 percent. The death toll from previous droughts has numbered in the millions; in the future, the area may become uninhabitable.

Areas where rainfall is expected to increase will likely see new patterns of precipitation as well. The overall amounts of rain may not change dramatically from year to year, but climate models predict more heavy rain events, separated by prolonged periods of dry weather. Much of this will be due to the heating of the atmosphere: warmer air holds more water, raising the potential for a quick release of a large volume of water. Air pollution will also play a role, as more particulates in the atmosphere give this increased amount of water vapor more condensation nuclei around which to coalesce.

Heavy rains are a potential threat to human life and property, raising the probability of events such as flash floods and landslides. Research has also found that frequent heavy rains combined with long dry spells quickly erode the vitality of a region's biomass, and in the long term contribute to a loss of soil quality and overall biodiversity.

Climate experts predict there could be some initial benefits to plant life in areas of increased rainfall. Scientists have seen a rise in the amounts of reactive nitrogen in the atmosphere, which they believe stems from a combination of rising rates of nitrogen oxides from the burning of fossil fuels and ammonia (NH_3) from agricultural sources. This reactive nitrogen is carried to the ground by rain, where it stimulates plant growth, particularly in the forests. Increasing the vitality of the forest will increase the terrestrial carbon sink, as trees and plants absorb harmful carbon dioxide from the atmosphere as a process of photosynthesis. The amount of reactive nitrogen has increased fourfold since the beginning of the Industrial Revolution, and will likely to continue to grow in coming years. Scientists are not sure at what point there is too much of this substance available, when its risks to the environment begin to outweigh its benefits.

Rainfall Patterns

CHANGE IN RAINFALL pattern is a consequence of global warming. The world's agriculture, especially third world agriculture, depends upon the seasonal rainfall pattern. Recent erratic changes in rainfall pattern lead toward low agriculture production, thus creating food insecurity for an ever-increasing world population. Flood, drought, and famine are the consequences of these changing patterns.

Rainfall pattern means the distribution of rain geographically, temporally, and seasonally. The tropics receive more rainfall than deserts. Cooler places like the poles receive no rainfall, as it is converted to snow before it falls to the ground. Rainfall happens more in a particular time of a year, during a rainy season. In other seasons, rainfall is scant. Therefore, agriculture (rain-fed), worldwide, is planned based on rainfall's natural pattern. Water storages, irrigation networks, and urban water supply systems are designed according to the average annual rainfall. If it rains a lot on a continuous basis for a longer time, there is possibility of flood and subsequent disaster to the infrastructure. No rainfall or little rainfall for a longer period (years) in an inhabited area could lead to drought and famine.

Global warming leads to a near-term collapse of the ocean's thermohaline circulation. Thermohaline circulation is a global ocean circulation pattern that distributes water and heat both vertically, through the water column, and horizontally across the globe. Due to this collapse of thermohaline circulation, warm surface waters move from the tropics to the North Atlantic and extra-warm water surfaces in the Pacific Ocean surrounding the equator. Thus, Western Europe, some parts of Asia, and many parts of the Americas get warmer than normal, and some parts of Europe get cooler rapidly. El Niño and La Niña are examples of this. This latest deviant trend generates dramatic weather impacts, such as rapid cooling in some parts of the world, and greatly diminished rainfall in agricultural and urban areas. UNESCO and other studies found that changes in rainfall pattern could be attributed to the shifts in global wind pattern. These shifts are due to the changes in the ocean surface temperature. Effect of human activity on the surface vegetation is also causing rainfall pattern variation. Widespread deforestation in parts of Africa and Asia is causing scarce rainfall and subsequent drought.

The world's scientific community commonly accepts that global warming has affected rainfall patterns. More precipitation is happening in northern Europe, Canada, and northern Russia, but less in swaths of sub-Saharan Africa, southern India, and southeast Asia. A Canadian research team found with 75 years (1925–99) of rainfall data analyzed through 14 powerful computer models that the Northern Hemisphere's midlatitude (a region of 40 to 70 degrees N) received increased precipitation over the years. It corroborates with the change in thermohaline circulation. The models also showed that in contrast, the Northern Hemisphere's tropics and subtropics (a region between the equator and 30 degrees N) became drier, while the Southern Hemisphere's similar region became wetter. This study was conducted for rainfall patterns over land.

Researchers claim that a natural pattern of rainfall is good for plant growth, as variable rainfall patterns lead to lower amounts of water in the subsurface level of the soil (in the upper 30 cm.). Variable rainfall patterns also cause plant diversity in a particular land. That means that weeds grow rapidly with variable rainfall. The significance of these changes is evident from recent large-scale failure of the crops, rangelands, and water-supply systems in the world. Mass starvation in Sahelian Africa is the stark proof of this.

Some might argue that changes in rainfall patterns are unfounded due to lack of instrumental records for a large time period. However, studies using indirect methods have proved that global warming, in fact, is causing serious rainfall pattern variability. Tree-ring analysis for predicting rainfall amounts in previous years (hundreds of years back) is one study, which proved that rainfall pattern variability is extensive in recent years.

If this trend continues, environmental managers need to make new decisions about the management of water and land. They need to accurately understand the interannual variability of rainfall and a possibility of runs of dry and wet years, which may cause important changes in runoff, sedimentation, soil erosion, or changes in communities of vegetation and animals, and of the viability of large water resource developments. Rainfall pattern variability would certainly cause mass human migration.

Refugees, Environmental

IN THE LAST 10 years, the issue of environmental refugees has emerged as a pressing issue. Most refugees are fleeing from natural disasters such as the Asian tsunami in 2004, or as a result of the impacts of global climate change, such as sea level rise. As the executive director of the United Nations Environment Programme (UNEP) noted in 1989, "as many as 50 million people could become environmental refugees if the world does not support sustainable development." Since then, many studies have considered this topic, with Norman Myers (one of the leading thinkers in this field) estimating that environmental refugees will soon become the largest group of involuntary migrants.

One of the difficulties in managing the issue of environmental refugees is their classification. The 1951 Convention relating to the Status of Refugees classifies a refugee as a person who, "owing to a well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group, or political opinion, is outside the country of his nationality, and is unable to or, owing to such fear, is unwilling to avail himself of the protection of that country." Refugees who are outside their country for environmental reasons do not strictly speaking fit within this category. The first definition of environmental refugees came from UNEP researcher Essam El-Hinnawi in 1985: "environmental refugees are those people who have been forced to leave their traditional habitat, temporarily or permanently, because of a marked environmental disruption (natural and/or triggered by people) that jeopardized their existence and/or seriously affected the quality of their life [sic]. By 'environmental disruption' in this definition is meant any physical, chemical, and/or biological changes in the ecosystem (or resource base) that render it,

Many are still living as refugees from the 2002 eruption of the Mount Nyiragongo volcano in the Congo.

temporarily or permanently, unsuitable to support human life." Environmental refugees are different from environmental migrants, in that they do not have any choice about their situation.

Today, there are at least 25 million environmental refugees. There are 22 million people in the world that classify as refugees under the traditional definition. Environmental refugees number one person to every 225 worldwide. A further 900 million people may also become environmental refugees because they live in marginal environments, or are driven into marginal environments for political, economic, social, cultural, legal, and institutional reasons.

EXAMPLES OF ENVIRONMENTAL REFUGEES

There are a number of reasons to become an environmental refugee. First, it may happen as a result of a natural disaster. Natural disasters include floods, cyclones, earthquakes, tsunamis, or any other major event that will make the lived environment temporarily or permanently inhabitable. One example is the eruptions of the Soufriere Hills Volcano on the Caribbean Island of Montserrat in 1995–98. As a result of these eruptions, 7,000 residents were forced to evacuate. Second, individuals or whole groups of people might become environmental refugees due to the appropriation of habitat or land by external parties, hence dispossessing and permanently displacing people.

For example, the building of the Three Gorges Dam in China has displaced up to 850,000 people and overall has the potential to displace up to 1.3 million people by 2009. Third, people may become environmental refugees as a result of an ongoing deterioration of their land and seas. Desertification is a good example as is sea level rise of the type of activity that ultimately creates environmental refugees of people in their own homelands. Movement from one area to another occurs as families and settlements find it harder to sustain livelihoods. This is the group that most often finds it hard to get support, as it is hardest for this group to be recognized as having refugee status.

There are many examples of this situation across the world due to climate change. For example, water shortages caused by climate change will cause huge reductions in agriculture and people's way of life. Tropical forests are estimated to lose another 40 to 50 percent of their cover due to climate change, and in turn this will dispossess many millions of people living within and dependent upon it for survival. Up to 500 million people could experience absolute shortages in fuel wood supply as a result of climate change impacts. Other (preliminary) estimates highlight that the total of people at risk of sea level rise in Bangladesh could be 26 million, in Egypt 12 million, in China 73 million, in India 20 million, and elsewhere 31 million, making an aggregate total of 162 million. At least another 50 million people are at risk through increased droughts, desertification, and related climate disruptions.

RESPONSES

One response to the problem is to ensure that environmental refugees have a formal classification within the 1951 Convention relating to the Status of Refugees. Another is to address the root causes of the environmental problems motivating relocation of people across the world. Promoting policies of and achieving sustainable development programs is a good first step to help achieve this goal. Nations must also develop policy to address what support structures and frameworks they are going to put in place to deal with and acknowledge environmental refugees in their countries. Implementing specific projects in countries most affected is another pathway nations could take to support each other on this issue, including the relief of foreign debt and the granting of foreign aid that will help ameliorate this problem. For policymakers and governments, while the issue of how to deal with refugees is politically contentious, the plight of environmental refugees merits special attention because, due to climate change, any country may be vulnerable and need support in the future.

Regulation

IN THE CONTEXT of law, the United Nations Framework Convention on Climate Change (UNFCCC) and the complementary agreement of the Montreal Protocol on Substances That Deplete the Ozone Layer are legal regulatory instruments. The UNFCCC Article 4 section 1 governs scientific, technological, technical, socioeconomic initiatives in the research, observation, and development of data on anthropogenic emissions into the atmosphere. To effect the desired regulation of the amount of greenhouse gases released into the atmosphere requires both a legal rule of what is or is not permitted, and the inclusion of regulatory features in equipment and processes or activity to control the emissions of the relevant substances into the atmosphere.

The atmosphere and other planetary features operate according to laws that have been articulated in scientific terms. These scientific laws are anthropocentric in their perspective and can be used to describe the conditions under which human life continues on this planet. The dominant conditions of the laws according to which the planet dictates or regulates human life and activity are related to but distinct from the regulatory operations of neoclassical human law. Anthropocentric law is the law made by persons for persons and their property. It is the actions of persons and their property that have consequences for global warming and climate change. Alternatively, global warming and climate change occur at the intersection of the laws of the planet usually perceived in the context of scientific laws and the anthropocentric laws of human behavior.

LEGAL REGULATION

In a neoclassical utilitarian framework, the regulator is typically a natural or legal person or an entity with the power to regulate within its domain. The difficulty in the context of global issues such as planetary warming and climate change is the absence of a single regulator with the jurisdiction for the global atmosphere or the climate and hence no one with authority to regulate the global commons. Since local climate is not independent or separable from global atmosphere and does not observe legal jurisdictions, regulating local climate change or warming locally without some provision for the larger global dimensions would be an exercise in futility. Further, in the dominant utilitarian approach, the global physical features such as the atmosphere and the climate are a common resource beyond human or state jurisdiction and available for use by all who have access to it.

Within the context of law or legal systems, regulation can refer either to a regulatory regime being a set of laws about some action, or a subset of detailed technical rules that are to be applied in particular physical contexts. In the latter sense, regulations are a set of physical specifications that are to be applied to particular products or processes. Regulatory regimes as part of legal systems in particular jurisdictions differ in the international and the domestic national contexts. Details are particular to the applicable legal system, and may not have comparable features in other legal systems.

The recognition of national sovereignty results in the distinction between the international and the domestic state jurisdictions. In the international context, states may agree to be bound at their own discretion as sovereign entities and not to be compliant with the regulation of a global regulator. Thus, the climate or the atmosphere can only be legally regulated within the jurisdictions of the various sovereign states' legal systems and by agreement with each other. Agreements such as the UNFCCC and the more specific Kyoto Protocol are indispensable in achieving global action. Such agreements to regulate anthropogenic emissions into the atmosphere must be implemented within the jurisdiction of sovereign states by domestic actions and procedures.

In implementing an international agreement in the domestic realm, a state issues laws and enforces them in order to achieve compliance with the international and domestic objectives. In doing so, the state would typically rely on scientific opinion. For instance, a scientific opinion stating that emissions from automobiles include greenhouse gases that should be regulated could lead to applicable regulations. The legal regulation of vehicles may then include a legal rule or a law or legislation that requires the greenhouse gases in tailpipe emissions of an operating automobile to be within certain parameters. This rule could then be accompanied by related regulations that set out in detail the technical specifications as to how the determination of the emissions is to be made and the concentrations of such gases and other acceptable limits of the emissions and may further specify variations by type and model of automobile. The technology in the vehicle itself may then involve systems such as computers or other mechanical systems that adjust or regulate the operation of the equipment to obtain the desired result of compliance with the legal limits.

For the most part, legal regulations are formulated by taking into account the available technical capabilities as well as society's expectations. The Kyoto Protocol, for example, sets legally binding target limits to the emissions into the atmosphere. Some people find the targets inadequate for achieving the stated objective of the UNFCCC and expect further reductions, and others, citing technical and financial reasons, consider these targets unattainable.

FUTURE INTERESTS

A significant feature of the UNFCCC and the Kyoto Protocol is the attempt to regulate the present human behavior in view of the future. This forward concern contrasts with typical legal regimes that usually codify past practice by referring to existing technology and social expectations based on past experience. In the case of climate change, the legal regulation seeks to operate closely with the mechanical or technological aspects to influence future changes.

For those who prefer the typical legal regime, regulating the future is resisted, as the future is not predictable. For others, the scientific understanding of inertia in the trends of climate changes dictates that setting and meeting targets for the future is essential to prevent foreseeable results. To put it in the negative, waiting for the climate to change before regulating current conduct would be meaningless as it would be too late then to make a difference to the outcome.

In law, predictability and foreseeability are distinct and important, with significant implications in practice. Consider the requirement for safety features in a vehicle. One group may take the view that installing safety features would be an unacceptably expensive proposition to provide for an unpredictable future event such as that a particular vehicle will be involved in a particular collision, which may not occur. Another may prefer to consider that it is foreseeable that a vehicle could be involved in the same particular collision and prefer to install features that will enable the avoidance of that outcome. In the climate change context, for the latter, waiting until climate change is predictable before regulating contributing factors may be compared to installing and using safety features on a vehicle after it is predictably involved in a collision. Since the consequences of climate change have been compared second only to those of global nuclear war, waiting for predictability in outcomes of climate change is waiting for the nuclear weapons to detonate before doing something to stop it.

PROBABILITY AND UNCERTAINTY

Predictability and foreseeability also involve different roles for the concepts of probability and risk in technological and scientific and legal regulation. In formulating laws, scientific probability may be characterized as uncertainty, and without sufficient foundation for concern about the atmospheric conditions. Here, scientific uncertainty leads to an absence of regulation.

On the other hand, science can and does operate on probabilities or risk and in that sense does include scientific uncertainty without diminishing the development of appropriate regulatory regimes. For instance, in economic and business decision-making context, risk management is an established approach in many segments of society. Insurance and investment products in the marketplace are examples of socially valued items that are designed specifically by reference to uncertainty and are foundational features of a market economy and have been legally regulated since the last century.

INFORMATION AND REGULATION

Since regulation is a result of social and political actions based on information in which perception is a key component, changing perceptions correspond to changing behavior and regulatory activities. For instance, there is a perceived shift in the discussion from global warming to a broader concern for climate change as including issues other than increases in temperature. Responding to this shift in perception, the U.S. Environmental Protection Agency (EPA) has renamed its website, which also indicates its self-understanding of its regulatory function.

Changing perceptions involve social and political changes and may also lead more directly to changes in regulatory regimes. In a democratic state, legislation is made by acts of a corresponding legislature and its authorized bodies that together formulate the regulatory regime being the law and its regulations.

MODELS AND REGULATION

The perception of the complexity of the atmosphere and climate change has grown over time. Scientific models used to study these phenomena have evolved with a corresponding increasing rapidity as research continues. Weather has played a strategic role in conflict throughout history. The value of information about the weather was appreciated when it was critical in the success of the Allied Forces D-Day invasion of Europe in 1944. After that, meteorology gained in its value as a matter of strategic interest to security forces. It was the incidental observations of meteorologists that led to the development of climate change as a research topic in its own right.

Since meteorologists observed a correspondence between atmospheric CO_2 levels and mean global temperatures, scientific information has been critical in the modeling and understanding of the interaction between human activities and the climate. That the climate does change has always been observed, as has the impact of human activities on the atmosphere, if only at a local scale. The issue now is that of scale in the question of global human activities and global atmosphere and climate changes. It is the position of the Nobel Peace Prize–winning institution known as the Intergovernmental Panel on Climate Change (IPCC), which provides peer-reviewed scientific information on climate change, that anthropogenic emissions are having an impact on global climate patterns.

Established in 1988 prior to the Toronto Conference, the IPCC provides peer-reviewed scientific information to the public which may be used in formulating policies and regulations. Emerging regulations rely on the acceptance of scientific opinions such as that expressed by the IPCC. The IPCC has concluded that without any change in practices, and based on current models, the current trend of increasing greenhouse gas emissions may increase the mean global temperature by 1.4 to 5.8 degrees C by 2100 compared to the temperature in 1990.

In its 1989 *Report to Congress: The Potential Effects of Global Climate Change on the United States,* the U.S. EPA Office of Policy, Planning and Evaluation notes that its report relies on scenarios that are based on information at a certain point in time, and assumes that carbon dioxide levels will have doubled and the climate will have stopped changing, neither of which are realities. This increasing rate of change has already appeared in the complexity of scientific modeling. The capability of regulating such increasing rates of change in the traditional manner has been limited. At the same time, some debate the desirability of regulating changes.

The variety of chemicals now produced and used and the resulting atmospheric emissions add to the complexity of atmospheric models. Contributors to the greenhouse effect include emissions of atmospheric CO_2, methane, CFC/NO_X, and SO_2. Increasing amounts of these gases and particulate matter in the atmosphere is linked to the warming trend in mean global temperatures. The links are still being researched, as the effect of each of the atmospheric components is different. For instance, CFCs and CO_2 remain in the atmosphere up to 100 years, while methane breaks down in 10 years, and SO_2 in a week. They also occur in different proportions and the chemical reactions they induce are different.

Commercial usage of CFCs has declined, and so has SO_2, which also causes acid rain. Each of these emissions and related products and processes are all susceptible to regulation.

THE UNFCCC AND KYOTO

The UNFCCC and the Kyoto Protocol is the principal international agreement relevant to climate change to which more than 140 countries forming a substantial proportion of the global community have signed on. The consensus expressed in the Kyoto Protocol includes the agreement to legally binding obligations on the signatories. Domestic acceptability of this international agreement is an ongoing concern in some states.

Article 1 of the UNFCCC provides definitions of terms and phrases. These definitions indicate some of the complexity and scope of the discussions and indicate the difficulty of regulating the activities necessary to achieve the objective. For instance, "Climate system" means the totality of the atmosphere, hydrosphere, biosphere, and geosphere and their interactions would include most if not the entire human environment on the planet. "Climate change" is similarly comprehensive in referring to climatic change attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods. "Emissions" means the release of greenhouse gases and/or their precursors into the atmosphere over a specified area and period of time. All of which would require regulatory systems in law as well as in the applicable science, technology, and economics of human activities.

The convention's reference to the climate system as a shared resource indicates the continuing dominance of the utilitarian approach to the planet and recognizes the anthropogenic source of changes to the system. The observation of historically unprecedented anthropogenic changes to the system as a whole then also raises corresponding requirements for unprecedented solutions and strategies. In this endeavor, information and cooperation at the same global scale become critical. The Kyoto Protocol established legally binding levels of greenhouse gas emissions on the signatory nations. In doing so, the protocol's regulatory features advance the stated objective of the UNFCCC.

SOVEREIGNTY AND REGULATION

The format of the UNFCCC as a framework convention with protocols provides a foundation for a diversity of regulatory contexts and a variety of rates of change. This design relies on implementing regulatory regimes in sovereign states. Depending on the form and structure of each nation, the regulatory regime within a country will also vary. For example, in the context of the United States, which is a system of federated states, federal law, state law, and more local jurisdictions, all become pertinent to the implementation of international agreements.

Within each sovereign state, the specific form of the regulatory regime will also vary according to the state's legal system and internal rules. In a federal system, the implementation will require the appropriate jurisdiction to enact relevant laws. In a common law jurisdiction such as Canada, the federal and provincial jurisdictions are a constitutionally defined matter. Within each such jurisdiction, there can be further delegated authority that may need to act. For example, it would not be unusual to establish and authorize municipal authorities and regional organizations to fulfill obligations.

The legal regulatory regimes that are applicable to climate change are as complex and diverse as the human activities that influence climate change. These human activities may be broadly differentiated into social, technological, and economic spheres. The range of these activities was reflected in the development of the Kyoto Protocol, where delegates represented every organization with a vested interest in the outcome of the agreement. These included governmental and nongovernmental entities.

The divergent interests in this type of global agreement make discussions complex and differences more apparent. The motivation to achieve the desired objective and the capability of delivering the commitments vary. The use of a trading system to meet commitments was a significant victory for the United States and the overall effective commitment was to a reduction of greenhouse gas emissions to 5.2 percent below 1990 levels. The scientific consensus in contrast recommends a stabilization of the composition of the atmosphere. To achieve this scientifically recommended stabilization would require a reduction of about 50 percent below 1990 levels and an immediate stop to deforestation.

The emerging understanding of the complexity of the climate system and changing human behavior has led to a corresponding shift in the priority of various issues. For example, previous concern for the stratospheric ozone layer has declined while that for particulate matter has increased. Previously unperceived activities such as contrails from aviation activities have gained attention as possible anthropogenic contributors to the changes.

Complexity also results from the variety in the matters subject to regulation and the capacity of previous legal categories to accommodate emerging issues. For instance, in federal systems of national jurisdiction like Canada, transboundary transport of energy supplies would be federal jurisdiction, with the registration of vehicles and local deployment of the energy within the local jurisdiction. A single issue of the supply and use of energy then spans multiple jurisdictions even within a single sovereign state.

Again, if energy is considered as including electricity or gas and their use in commercial or domestic buildings, the related issue of the energy efficiency of building structures becomes relevant. To achieve the regulation of the buildings then involves the formulation of building codes which may depend on the materials used in construction and thereby involve international supplies, federal, and local jurisdictions, including land use regulations.

Land use provisions also relate to the preservation of habitats, which then determine the continuity of species. Changing species distributions impacts emissions to the atmosphere and human activities and therefore also become relevant to regulating climate change. Regulating the activities impacting on migratory species such as birds, energy transmission, and land use that usually modifies species habitat is all relevant to climate change.

Valuation of species is also related to consumer products and services. Consumer behavior and its modification through regulation and appropriately targeted municipal and private market services become imperative. Taxation systems can and do influence choices and have an effect on anthropogenic emissions. Other means of contributing to the amelioration of the climate change problem would be through actual regulatory measures coupled with market mechanisms. The product design and inventories and other similar information may be critically associated with the development of market mechanisms that include cap and trade systems.

Non-state entities also generate rules that are not typically included in the legal sense of the term regulation, but would be regulatory within the entity. For example, a business may take note of international and state laws or lack thereof in formulating its own internal rules and procedures. Where such entities are multinational, these internal rules may also be applicable in multiple state jurisdictions. Trade or industry groups and other associations can also formulate rules and regulations. Independent industry associations have also formulated rules or standards for environmental management systems along with procedures to certify those that comply with such standards.

The enterprise of modifying the climate changes has been inadvertent until recently, and the shift toward regulating the change intentionally has been growing in strength. Early attempts at regulating the climate involved the use of chemicals such as silver iodide to seed clouds to induce rainfall. For some, the ability to regulate the climate was also conceivably a strategic weapon that could be deployed in conflict.

In the United Kingdom, early air pollution issues arose with the regulation of the alkali industry with the Alkali Act of 1863, 1874, and consolidated in the Alkali Works Regulation Act of 1906. The Alkali Inspectorate later became Her Majesty's Inspectorate of Pollution and now amalgamated into the Environmental Agency. With separate legislation for smoke abatement in 1926 and the Clean Air Act in 1956 enacted following the death of 12,000 people from the London smog, regulating atmospheric gases and particulate emissions is not new. However, it was only in 1974 that a coherent regulatory structure was set up with the Health and Safety at Work Act and the Control of Pollution Act.

In the United States, regulation has proceeded unevenly between the federal and state levels and between states. For instance, California has taken a much more aggressive approach to regulating greenhouse gases than the federal government and some other states. Regional cooperation has also resulted in some cooperative regulatory regimes. The unevenness of the regulations regionally and globally has begun to have impacts also on the economic context with flows of products and processes being modified with differing features and specifications in response to local regulatory circumstances.

With the consumption of energy a dominant feature of human activity that results in the emission of greenhouse gases, the regulation of such usage has gained prominence. The installation of smart meters, which provide detailed information on the usage patterns for electricity consumption, along with the possibility of controlling energy distribution patterns by time of day, geographic location, and land use has begun to appear in places like Toronto, Canada. Thus, climate change-related concerns are beginning to be included in urban and regional planning regulations.

Additionally, the emergence of new viable renewable energy alternatives with reduced atmospheric impacts is also part of the trend to new regulations. In some jurisdictions, it is now possible for locally generated wind and solar power to be sold to the statewide grid operated by the usual utility companies. The tax regimes are also being considered legitimate means of regulating greenhouse gas emissions. From taxing the products that lead to the emissions to industries that directly emit the greenhouse gases, the complexity of the human response to climate change is growing.

CONCLUSION

In the context of climate change, regulation proceeds from an anthropogenic understanding and utilizes sociopolitical actions to implement technological and legal regulations as they occur in the totality of the climate system. From the understanding of the climate system as defined in Article 1 of the UNFCCC, very little human activity is irrelevant to the climate change and regulating the changes in the climate system is critical to the future of this planet.

Religion

RELIGION IS A universal and varied phenomenon. While there have been those who have rejected all religion and espouse atheism, they have been for practical purposes a very small minority until recently. The attempts since the Enlightenment in Western Europe in the 1700s to foster a belief in atheism has met with little success, except among educated elites in the more advanced industrialized countries. During the time of Communist domination in the Soviet Union or in Communist China, as well as other Communist countries, the attempts to suppress religion have almost completely failed.

ANCIENT RELIGIONS

For much of humanity, especially among tribal peoples, spirits are viewed as the animating part of nature. There are believed to be spirits in rocks, trees, plants, animals, or the forces of nature. Placating these spirits, which can be deadly, is a part of the acts of worship of many different groups of people. This may involve sacrifices to quiet a volcano, or the sacrifice of young men and women to the water god at the bottom of a well in order to bring the rains. Many of the religions of the Middle East in ancient times were fertility religions. Baal worship was done with cultic sexual practices that were believed to affect nature with fertility.

Among many peoples around the world, shamans, witch doctors, or medicine men have been the chief spiritual leaders. Shamans, who would beat drums and were transformed into a dancing bear or a seal or some other totemic animal, led the Inuit of northern Canada. The shaman, in a transformed and trance-like state, would then go on a spiritual journey where he would meet spirits in the spirit world who would be able to give him (or sometimes her) knowledge of the causes of sickness, the absence of the fish, or the failure of crops among people living in more temperate societies. The shaman might also wrestle with evil spirits that were causing nature to war on humans.

Other ancient religions, such as those of the Greeks, Romans, and Chinese, believed that dramatic events in nature were messages from the gods or spirit ancestors. For the Chinese, natural events could be signs that the ruling dynasty had lost the mandate of heaven. Signs such as droughts, floods, earthquakes, fires, or other natural disasters, especially if accompanied by events such as an unexpected arrival of a comet, were among the signs that said the ruling dynasty should be replaced. Virtually all of the movements that changed dynasties in Chinese history were religiously inspired.

The Chinese philosophy of Daoism (Taoism) founded by Lao Tzu, author of the Tao Te Ching, taught a philosophy of living in accord with nature. The sage, or just the common man who sought wisdom, would live wisely if he or even she went with the flow of nature. There was therefore a rhythm to life that led people to live according to nature.

CONTEMPORARY RELIGIONS

The Europeans who came to North America were farmers and settlers, rather than adventurers or traders, like many of the other Europeans who settled in what became Latin America. Their theology was based upon the Bible, which taught in Genesis that people should multiply and fill the Earth. In addition, they were to subdue the Earth and make a garden of it. Obedience to these commands may have been fulfilled too well. However, the land and water practices of Europeans had developed independently of Christian influences for centuries before their conversion. The Europeans had effectively deforested much of Europe and killed off a variety of species before the arrival of Christianity. What Christianity taught was stewardship.

It was like the stewardship practiced in ancient Israel. The religion of the Israelites included farming land owned by a family that would be handed down to the succeeding generations. This meant that the owners needed to practice careful husbandry that preserved the land and its resources for continued use over the generations. The idea of "development" by commercial developers common in the United States today would have been completely alien. In the modern State of Israel, there has been an ongoing project of afforestation, of identifying ancient practices and using them to make the Negev region, which is very arid, to bloom. The religious beliefs of earlier times have pushed the greening of the land since the beginning of the Zionist movement to return to the land of Israel. Oddly enough, those Christians who are most supportive of the return of the Jews to Israel are often not inclined to conservation.

Those groups that are usually evangelicals and fundamentalists who accept the end of history with the return of Jesus Christ in his Second Coming are those who believe that this divine event will happen very soon. To them, it is important to use Earth's resources before Christ returns, or else they will be wasted. The theological doctrine they commonly subscribe to is premillennialist. This, however, has historically been a minority view. Most Christians have been amillennialists, who believe that the Second Coming will be a complete surprise.

Therefore, the appropriate ethic for the eschaton (the period of waiting or the period of the last days) is to practice good stewardship of the resources of nature. The remaining theological position is postmillennialism. It is a very optimistic teaching about the unfolding of the events of the last days. The belief is that most people will become Christians and that the world will make steady progress until virtually near the end of the age. Most adherents discarded this optimistic view after the two world wars.

Religion has a powerful effect on people in a variety of ways. It can satisfy spiritual needs and organize energies to accomplish grand projects. The building of the pyramids, and other numerous architectural monuments in the ancient and medieval world, were driven by religious faith. Today, most of the peoples of the world belong to one of the major religions of Hinduism, Buddhism, Jainism, Sikhism, Judaism, Islam, or Christianity. Those who still follow Confucianism or Daoism are mostly confined to Taiwan or to other overseas Chinese communities. Among these and many smaller religious groups, there is developing a great concern for the present state of the globe.

Jainism has since its beginnings over 2,500 years ago practiced reverence for life or *ahimsa*. For the Jains, all living things are not to be harmed, because this will add karma to the soul of those who kill other living creatures, such as animals or even insects. This has made merchants of Jains, rather than butchers or farmers. Their ethic is one that requires urban living tolerance of wildlife if it invades the urban area.

For example, there are both Christian ethicists who teach in seminaries and lay people who work with environmental issues who are seeking to develop principles of a Christian environmental ethic. The goal is then to apply the Christian ethical principles to agriculture, to natural resources, and to the environment that go beyond traditional principles of stewardship. Ethical debates about environmental issues such as global warming are about problems that are current or that are likely to arise. The problems are likely to be caused by technological advances that allow for exploitation of resources in ways that are very productive, but also destructive of future utilization. The issues that arise concern agreement over what are the environmental facts, the nature of the problem, and the appropriate solution(s).

At the core of these disagreements are different values and beliefs related to nature itself, and the use and management of nature by people. A growing number of scholars in the humanities, social sciences, and physical and biological sciences are emphasizing that the problems causing environmental issues are fundamentally interrelated with ethical issues.

Renewable Energy Policy Project (REPP)

FOUNDED IN 1995, the Renewable Energy Policy Project (REPP) is based in Washington, D.C. The organization researches strategies to make renewable sources competitive in energy markets and to stabilize carbon emissions. REPP supports reindustrialization through the use of renewable technologies. It demonstrates that solar, wind, biomass, and other renewable sources can provide energy services at or below the cost of nonrenewables when structural barriers are removed. REPP works directly with states and firms to help them develop their renewable portfolio. The organization also provides expert information to consumers to improve energy efficiency and guide their transition to alternative energy options. To promote sales of renewable energy products and services, REPP created a buyer's guide and consumer directory for approximately 5,000 businesses.

REPP was initiated with support from the Energy Foundation and the U.S. Department of Energy. While financial support is determined on an annual or project-by-project basis, major donors have included the Oak Foundation, SURDNA Foundation, Turner Foundation, Bancker-Willimas Foundation, Joyce-Mertz-Gilmore Foundation, National Renewable Energy Lab, and the U.S. Environmental Protection Agency. REPP's board of directors includes leaders from renewable energy businesses, the financial sector, environmental advocacy groups, regulators, government officials, and multilateral development institutions.

A core issue for REPP is assisting the United States to stabilize its carbon emissions using renewable energies. This goal would have a significant impact on the world's carbon balance given that the United States produces approximately two-sevenths of global carbon emissions. Half of this, or one of seven total global wedges, comes from electricity. REPP's use of the wedge concept builds from the work of Stephen Pacala and Robert Socolow. Based on REPP's research, they suggest that mitigation of one wedge can be implemented with the annual production of 18,500 Megawatts of electricity from renewables.

REPP works with the renewable energy–component manufacturing sector to make it more transparent, facilitate entry, improve production, and promote growth. For example, wind energy requires rotors, towers, and generators. All the components for wind turbines can be produced domestically, and 25 states already have firms active in this manufacturing. REPP attempts to refine the supply chain to determine the exact specifications and avoid any potential bottlenecks as the use of wind power rapidly expands. This type of expertise has been underdeveloped and has slowed domestic manufacturing of renewable technologies. REPP also advocates for production tax credits for renewable energy projects.

REPP recently completed a state analysis for California, Michigan, Ohio, Wisconsin, Pennsylvania, Nevada, and Arizona. The REPP state reports provide an explanation of how manufacturing potential is calculated, and offer detailed analysis showing for a state, region, and county the potential for each of the 43 industrial codes (NAICS codes) that comprise the major component parts for the major renewable energy technologies. REPP provides states with a web-based product to present analysis in a graphical manner.

A total of 16 states have created Renewable Portfolio Standards that mandate that they generate a percent of their electricity from renewable sources. REPP analyzes the experience of these states and tracks industries to determine whether costs have declined. In addition to stimulating demand for renewables, REPP state reports identify the specific firms that could benefit from an existing or proposed national program.

REPP has linked social and economic development to ecological concerns. The staff argues that renewables take advantage of resources, such as biomass or wind, that are currently underutilized or wasted. This can provide local economic support, labor benefits, and job creation. As REPP promotes wind energy development in North Carolina, the organization advocates for a variety of direct and indirect benefits to local communities. An important element of REPP's work is promoting public awareness of success stories, such as a Nevada bill in 2003 that provided economic incentive to participants using photovoltaics. The first Solar Energy Systems Demonstration Program resulting from the bill was created in conjunction with the Washoe Tribe. REPP acquired the Center for Renewable Energy and Sustainable Technology (CREST) in 1999. CREST circulates policy briefs, fact sheets, and testimonials from

The Renewable Energy Policy Project researches strategies to make renewable sources competitive in energy markets. Solar, wind, biomass, and other renewable sources can provide energy services at or below the cost of nonrenewable sources.

public officials. It hosts popular renewable energy discussion groups with topics such as green building, stoves, photovoltaic use, and bioenergy.

Resources

A RESOURCE IS any item or substance that is in scarce supply and has some value. Resources are normally considered to be physical items, such as oil and natural gas. However, it is also possible to consider humans resources, since they are finite in number and are perishable under current technological conditions. Resources, when used in the context of computer or virtual environments, meanwhile, are inherently intangible in nature, although the hardware that produces them is not.

It is customary, when considering resources, to distinguish between those that are renewable and those that are nonrenewable. Resources such as oil are consumed in use and are, therefore, nonrenewable. However, in a number of other cases, it is possible to recreate or recycle some resources either in the original form or, at least, some components of the original. Glass and plastic bottles may, to some extent, be recycled into different forms and so value is created from spent resources that appear to be valueless. Considerable effort has been expended in determining which resources may be recycled or recreated in this way and, in some countries, it has led to significant social change as people become accustomed to considering the issues involved and sorting out recyclable household waste. The process is mirrored at the industrial level, too, especially when economic incentives are provided to encourage this behavior.

Improved technology has also provided two other means of increasing the stock of resources, or at least minimizing their depletion. The first is to employ more commonly occurring resources for more rare ones. This substitution may be seen in the prevalence of plastic bags, which are dispensed with alacrity at many retail outlets. More recently, the negative impact of those plastic bags has prompted the search for other materials that would be more environmentally friendly (more biodegradable). The process of beneficiation, on the other hand, is one in which technology enables the gathering or exploitation of resources which were previously considered to be too difficult or expensive to obtain. The search for coal deeper underground or in mines located underwater is an example of this, while the continuing demand for oil and the ability to extract it means that sources previously ignored have become of considerable strategic importance.

For example, water is considered a renewable resource, because once used, it can be returned to the circulatory system that returns it to use via evaporation and precipitation. However, the modern world has seen a growth in populations and demand for water, together with climate change, that has demonstrated the extent to which water resources are in fact insufficient for future use, given current trends for demand. It is possible to characterize the Middle Eastern wars between Israel and neighbors as the result of fighting for scarce water resources, while the conflict in Darfur in Sudan has been characterized as resulting from nomadic movements of people searching for water.

MORAL AUTHORITY TO USE AND DEPLETE RESOURCES

Most human societies have developed with a religious basis that justifies mankind's prerogative to use the resources of the Earth for its own benefit. Christianity, Judaism, and Islam, for example, have similar roots in a tradition that states a divine provenance for the world and the entire universe and the passing of responsibility to shepherding the world to humanity. Certain variations in scripture explain dietary rules for the different religions, and these have led to different uses of the land and the resources of the world. The same is true of those now rare religions that are believed to offer stewardship of the world to one specific group of people. The animism of the Mongols, for example, in common with that of certain other steppe peoples, was used to help justify the destruction of resources, including people, not immediately wanted or needed by khans and other leaders.

Buddhism stresses the endless cycle of birth, rebirth, and suffering in which souls are reincarnated in a variety of forms through the ages. Since souls could inhabit not only animate but inanimate objects, then it benefits people to take care of those items appropriately. They may be used in moderation, but not abused and used excessively. Other religious beliefs also confer upon humanity the right to use natural resources, but with certain limitations. The same is true of some moral creeds that have an environmental basis. Proponents of the Gaia hypothesis, for example, hold the resources of the Earth to be central to the successful existence of nature; consequently, husbanding of those resources is a central part of the successful functioning of society.

Belief systems based on nonreligious bases have not always been so favorable to the environment. Communism, for example, appropriates the resources of the Earth for the betterment of society, and has little to say about conservation of those resources. The impact on the environment by the Russian and Chinese Communist parties has been among the most severe in the world. Similar levels of exploitation of resources, such as pollution and overlogging, for example, are also witnessed when private-sector, free-market interests have been able to gain access to resources. The *Tragedy of the Commons* by William Foster Lloyd framed the potential problem of a laissez-faire approach to the management of nature. The presence of democracy in a country, accompanied by fair and transparent policing of the laws, is one of the best means of ensuring that overexploitation of resources does not take place. The Indian economist Amartya Sen, who observed that no famine had ever occurred in a functioning democracy, originally noted this concept.

THE DIMINUTION OF NATURAL RESOURCES

The history of cod fishing in the Atlantic Ocean is a graphic example of the abundance of resources available in past centuries and the way in which those resources have been enormously diminished within the last century. For hundreds and in some cases thousands of years, the ability of man to harvest resources, renewable resources in any case, was exceeded by the fertility of nature in replacing them. The development of industrialized harvesting techniques succeeded not only in depleting the stocks of the fish, but also seriously damaged the environment, including the ecology, in which the cod thrived. The diminution of this resource, in common with so many others, has been so severe that it is not possible to recreate a satisfactory understanding of the amount of the resource previously available. This makes it extremely difficult to identify means of returning to the status quo before overexploitation and, hence, it is not very likely that such a state could ever be attained. It would take an event as severe in its impact as World War II, which effectively prevented deep sea fishing in the Atlantic Ocean altogether for several years, for fish stocks to be replenished to any meaningful degree.

Overfishing has probably already destroyed ocean ecologies beyond repair, and the same is true of the logging of hardwood trees in the former rainforests of Thailand and Burma. Arguments persist over whether the production of oil and natural gas has yet peaked, or is at its maximum now, but the existing oil is not going to be replenished. Human society must prepare to live in a world in which many of the resources on which it had previously relied are no longer available.

RESOURCE ALLOCATION

Given that resources are, by definition, finite and scarce in nature, then there must be some mechanism to allocate different shares to different sets of people. Allowing everyone who has an interest in resource exploitation to do so as freely as desired will lead to disastrous depletion of the resource. Consequently, the basis of allocation must be determined.

In mature, democratic societies, coalitions of interests will help to set the agenda by which resources are allocated. This can be quite efficient in determining the share that each set of interests will gain, but has proved to be less successful in setting the amount of resource that may be allocated on a sustainable basis. Democratic debate must, consequently, be supplemented with a technical limitation determining overall exploitation in order to be viable. This is a superior approach to those that rely on market power (where resources go to those who can afford them and are denied to the poor), since these suffer from equity issues and, more relevantly, from the stress inflicted by inequality and the high probability that it will lead to social unrest and ultimately rebellion.

Systems that reward the rich at the expense of the poor rely, therefore, on the ability and willingness of the former to mobilize the threat of armed violence against the latter. Even so, social systems of this sort still rely upon the labor of the masses to produce goods and services to facilitate the lifestyle of the rich. Sequestering oxygen or water, therefore, which are essential for life, will provide short and possibly medium-term gains for the rich, but the system is not sustainable over the long term because it will lead to the deaths of so many of the poor. This in itself might not threaten the survival of the system, but the reduction in production capacity will do so.

Irrespective of the means by which resource allocation is managed, it must be supplemented by attempts to determine the presence or creation of substitutes. Resource scarcity inevitably leads to inequality, and this reduces social stability. The promise of suitable substitutes at some stage in the future helps to alleviate the pressures that this builds.

Resources for the Future (RFF)

RESOURCES FOR THE Future (RFF) is a nonprofit, nonpartisan organization with headquarters in Washington, D.C. Founded in 1952 under the Truman Administration, RFF initially had a domestic focus, but has since shifted to include international affairs. With a variety of outlets for data dissemination, RFF provides intellectual leadership in environmental economics. Research methods are based in the social sciences and quantitative economic analysis, including cost-benefit trade-offs, valuations, and risk assessments. RFF scholars compile core knowledge on a range of environmental topics, with the goal of contributing to scholarship, teaching, debate, and decision making. One major division of research is energy, electricity, and climate change.

RFF was the first think tank in the United States devoted exclusively to environmental issues. The impetus for RFF came from William Paley, who had formerly chaired a presidential commission charged with examining whether the United States was becoming overly dependent on foreign natural resources and commodities. Today, the RFF board of directors consists of members of the business community, former state officials, academics, and leaders of environmental advocacy organizations. It is increasingly inclusive in terms of nationality, race, and gender.

By 2006, RFF had operating revenue of $10.6 million, of which nearly 70 percent came from individual contributions and private foundations, as well as the 25 percent that is generated from government grants. The rest was withdrawn from a reserve fund valued at over $35 million that was created to support the organization's operations.

RFF has approximately 40 staff researchers composed of senior fellows, fellows, resident scholars, research assistants, and associates. In addition, RFF hosts visiting scholars from academia and the policy community. RFF scholars share their findings through seminars and conferences, congressional testimony, and global media. They publish in external peer-reviewed journals and several RFF publications, including discussion papers, reports, issue briefs, and *Resources* magazine. The online *Weathervane* is a guide to global climate policy. *RFF Connection* is an electronic newsletter that provides updates on events, research, and publications. RFF Press offers hundreds of titles on environmental issues written by the organization's staff and outside experts.

The focus of RFF's research has shifted to include global concerns, although U.S. policy innovation and implementation maintain importance. International research topics include environmental governance in the European Union, the UN-based negotiations that produced the UNFCCC and the Kyoto Protocol, and the U.S. proposal for a technology transfer agreement. RFF scholars also examine the related topics of climate stabilization and air pollution control in rapidly developing countries such as China and India.

RFF's Climate and Technology Program analyzes and critiques options for U.S. policy and the role of technology development and deployment in combating carbon emissions. In 2007, RFF scholars authored a series of background reports related to the design of federal climate policy. They provide stakeholders and policymakers with an understanding of policy options, from which effective mandatory federal policy might be crafted. Researchers have estimated the costs of emissions abatement, calculated the benefits of mitigating climate change impacts, assessed the effect of the choice of discount rate for long-term policies, and characterized uncertainty in such analyses.

RFF is certified as a U.S. General Services Administration (GSA) Management, Organizational and Business Improvement Services (MOBIS) contractor for consulting, survey, and facilitation services. MOBIS contractors assist the federal government to respond to new mandates and evolving practices. RFF researchers are also analyzing proposed actions and evaluating current efforts of state and local governments as well as the business sector.

RFF provides ongoing support to many state and nongovernmental organizations, including the Intergovernmental Panel on Climate Change. For decades, the RFF Seminar Series has provided the Washington community with a weekly forum in which scholars, journalists, advocates, and policymakers interact. RFF internships and doctoral and postdoctoral fellowships train and support future leaders and scientists.

Revelle, Roger (1909–91)

AN EARLY PREDICTOR of global warming, Roger Revelle helped to start the scientific debate on the issue in the late 1950s. He challenged the accepted notion that global warming was countered by the absorption of carbon dioxide from the oceans. Revelle discovered that the particular chemistry of sea water hinders such absorption. Because of the respect that he earned among the scientific community, Revelle was regarded as a spokesperson for science whose advice on as diverse matters as world population, agricultural policies, education, and the preservation of the environment were held in high esteem.

Born in Seattle, Washington, on March 7, 1909, Revelle was raised in Pasadena, California, and soon stood out as a gifted student during his academic career. In 1925, Revelle enrolled at Pomona College with an interest in journalism, but later switched to geology as his major field of study. In 1928, Revelle met Ellen Virginia Clark, a student at the neighboring Scripps College and a grandniece of Scripps College founder Ellen Browning Scripps. The couple married in 1931.

Revelle obtained his bachelor's degree from Pomona in 1929, and then entered the University of California–Berkley to pursue his studies in geology. In 1931, his professor George Davis Louderback recommended him for a research assistantship in oceanography at the Scripps Institute of Oceanography in

Roger Revelle lead navy research in oceanography. His carbon dioxide research led to his predictions of global warming.

La Jolla, California. While at Scripps, Revelle took part in several expeditions on the *Scripps*, the institute's small research vessel. He was also a guest on ships of the U.S. Coast and Geodetic Survey and the U.S. Navy. In 1936, Revelle completed his dissertation, "Marine Bottom Samples Collected in the Pacific Ocean by the *Carnegie* on its Seventh Cruise," and was awarded his Ph.D. He was immediately hired as an oceanography instructor at Scripps, under the directorship of Harald Sverdrup.

During World War II, Revelle served in the U.S. Navy as the commander of the oceanographic section of the Bureau of Ships and became head of their geophysics branch in 1946. His reputation and influence in the navy quickly grew during the war and enabled him to substantially influence the navy research program in oceanography. Revelle received an official commendation for this work from Secretary of the Navy James Forrestal after the war. After the conflict, he returned to Scripps in 1948 and directed it from 1951 to 1964. The scientist was involved in supervision of the first postwar atomic test on Bikini Atoll, Operation Crossroads. He led the oceanographic and geophysical components of the operation. His task was to study the diffusion of radioactive wastes and the environmental effects of the bomb at Bikini.

During his directorship at Scripps, Revelle was also appointed to other prestigious positions such as chairman of the Panel on Oceanography of the U.S. National Committee on the International Geophysical Year (IGY). Scripps, which Revelle was constantly expanding thanks to his administrative skills, was initially designated as a participant in the IGY, but was later promoted to the main center in the Atmospheric Carbon Dioxide Program. As a result, Revelle's interest in the general carbon cycle and the solubility of calcium carbonate grew and he began a systematic research which engaged him for the rest of his life. The result of this interest was a famous 1957 article published in *Tellus*, a European meteorology and oceanography journal, which Revelle coauthored with Hans Suess, one of the founders of radiocarbon dating. The article demonstrated that carbon dioxide had increased in the air as a result of the use of fossil fuels.

Following this discovery, in 1963, Revelle took a leave of absence from Scripps and committed himself to public policy. Revelle was among the first in the scientific community to bring the subject of rising levels of carbon dioxide to the attention of the public as a member of the President's Science Advisory Committee Panel on Environmental Pollution in 1965. The committee, chaired by Revelle, published the first authoritative U.S. government report which officially stated that carbon dioxide from fossil fuels was a potential global threat. Revelle also founded the Center for Population Studies at Harvard University, and spent more than a decade as director. His primary interests were applications of science and technology to world hunger. In 1976, Revelle returned to the University of California–San Diego where he received the title of Professor of Science and Public Policy and joined the Department of Political Science.

As the chair of the National Academy of Sciences Energy and Climate Panel in 1977, Revelle concluded that about 40 percent of the anthropogenic carbon dioxide has remained in the atmosphere. It was produced two-thirds from fossil fuel, and one-third from the clearing of forests. In his role of spokesperson against the dangers of global warming, Revelle influenced public opinion on the carbon dioxide issue thanks to a widely read article published in *Scientific American* in August 1982. His research emphasized the rise in global sea level and the melting of glaciers and ice sheets caused by the thermal increase of the warming surface waters. Through his international scientific contacts, Revelle circulated his research findings and fostered debates about his findings and the threatening environmental and social effects of increased atmospheric carbon dioxide. The scientist was an early advocate of governmental policy and action.

Revelle was a respected member of many academic, scientific, and government committees. He was science adviser to the secretary of the interior, president of the American Association for the Advancement of Science, and a member of the NASA Advisory Council. In November 1990, Roger Revelle received the National Medal of Science from President George Bush.

Luca Prono
University of Nottingham

Rhode Island

RHODE ISLAND HAS an area of 1,545 sq. mi. (4,001 sq. m.) with an average elevation of 200 ft. (61 m.) above sea level. The land is divided into two regions: the coastal lowlands (made up of sandy beaches, rocky cliffs, lagoons, saltwater ponds and low plains) covering more than half of Rhode Island; and the Eastern New England Uplands, a region of small valleys, rolling hills, lakes, reservoirs and ponds.

Rhode Island's humid continental climate is a little milder than in most of New England, with the extremes of winter cold and summer heat moderated by the Atlantic Ocean and Narragansett Bay. Providence's annual average temperature is 51 degrees F (11 degrees C), with January temperatures averaging 29 degrees F (minus 1.5 degrees C), and July temperatures averaging 73 degrees F (23 degrees C), with an annual precipitation of 46 in (117 cm.). Temperatures are moderated by warm winds off Narragansett Bay, but extremes do occur. The highest temperature recorded in the state was 104 degrees F (40 degrees C) on August 2, 1975, and the lowest temperature recorded in the state was minus 23 degrees F (minus 31 degrees C) on January 11, 1942. Rhode Island's soil is fertile, but very rocky, and about 60 percent of Rhode Island's land is covered by forest.

In 1969, massive storm surges from Hurricane Carol raged through the Rhode Island Yacht Club.

IMPACT OF CLIMATE CHANGE

Beaches do not stay put, waves and current move the sand and change the coastline, and this damage will likely increase as sea levels rise and the intensity of storms increases. The average temperature in Providence has risen about 3.3 degrees F (1.8 degrees C) over the last century. Coastal erosion and storm surges have already damaged many of the state's tidal flats and dunes, including those on Block Island and throughout the Rhode Island Refuge Complex. Rhode Island's 400 mi. (644 km.) of coastline is home to the bulk of the state's residents. The beaches along the south shore have already been severely damaged by hurricanes and storm surges. Many of Rhode Island's lakes and waterways are freezing for shorter periods of time, reducing traditional outdoor recreation opportunities such as hockey and ice-skating. Rhode Island's current ozone levels exceed national health standards, and the entire state is rated as having a "serious" problem attaining safe levels. Warmer weather could increase concentrations of ground-level ozone, which is known to aggravate respiratory problems.

Based on energy consumption data from the Energy Information Administration, Rhode Island's total CO_2 emissions from fossil fuel combustion in million metric tons for 2004 was 10.95, made up of contributions by source from commercial, 1.20; industrial, 0.62; residential, 2.80; transportation, 4.38; and electric power, 1.96.

Rhode Island adopted a "renewable portfolio standard" that calls for 16 percent of the state's energy to come from clean, renewable sources like solar and wind by 2020, and a greenhouse gas reduction target is to meet 1990 levels of six greenhouse gases by 2010 and below 1990 levels by 2020. Rhode Island joined the Climate Registry, a voluntary national initiative to track, verify, and report greenhouse gas emissions, with acceptance of data from state agencies, corporations, and educational institutions beginning in January

2008 and joined all the states in New England (as well as others in the mid-Atlantic area) in the Regional Greenhouse Gas Initiative (RGGI), the first multiple-states, market-based mandatory cap-and-trade program to reduce heat-trapping emissions from power plants. The Environmental Council of Rhode Island and more than 70 other state groups and businesses are part of the Rhode Island Climate Coalition, which is working to support the state's climate action plan.

Independent Scholar

Richardson, Lewis Fry (1881–1953)

LEWIS FRY RICHARDSON was an innovative Britsh mathematician, physicist, and psychologist who first tried to apply mathematical concepts to weather forecast. Although his method for weather forecasting was not entirely successful during his lifetime, it was rediscovered with the advent of computers and formed the basis for computer-based weather forecast. The recorded change over a given distance of temperature and wind (gradient) is named the Richardson number after him.

Lewis Fry Richardson was born into a wealthy Quaker family in Newcastle-Upon-Tyne on October 11, 1881. His mother, Catherine Fry, was the daughter of corn merchants, and his father, David Richardson, came from a family of tanners, a profession that he took up himself. Lewis was the youngest of a large family of seven children. He attended Newcastle Preparatory School where he already showed his predilection for math, particularly the study of Euclid. Then in 1894 he went to Bootham School in York, an elite Quaker institution established in 1823. It was here that Richardson first combined his interest for math with science and meteorology in particular. One of his teachers, Edmund Clark, was in fact an expert in meteorology and greatly influenced Richardson. The institution also reinforced Lewis's pacifism, a value that had been taught to him by his parents and a fundamental tenet of Quakerism which led him to difficult career choices in his maturity. After leaving Bootham in 1898, Richardson spent two years in Newcastle at the Durham College of Science where he studied mathematics, physics, chemistry, botany, and zoology. Richardson completed his education at King's College, Cambridge, from which he graduated with a First Class degree in the Natural Science Tripos in 1903.

After graduation, Richardson was employed at many different posts. He worked in the National Physical Laboratory (1903–04, 1907–09) and the Meteorological Office (1913–16), and he was hired as a university lecturer at University College Aberystwyth (1905–06) and Manchester College of Technology (1912–13). In addition he was a chemist with National Peat Industries (1906–07) and directed the physical and chemical laboratory of the Sunbeam Lamp Company (1909–12). He married Dorothy Garnett in 1909 and although they had no children of their own, they adopted two sons and a daughter.

Richardson was working for the Meteorological Office as superintendent of the Eskdalemuir Observatory at the outbreak of World War I in 1914. Because of his Quaker beliefs, he declared himself a conscientious objector and could not, therefore, be drafted into the military. This choice implied that he would never be able to qualify for university posts. While Richardson was not involved in military operations, from 1916 to 1919 he served in the Friends Ambulance Unit, attached to the 16th French Infantry Division, where his work earned him praise. After the war, Richardson returned to his position in the Meteorological Office, but had to resign from it in 1920 when the Meteorological Office became part of the Air Ministry. His pacifist beliefs could not allow him to continue to work for an institution which was part of the military. Richardson then went back to teaching. From 1920 to 1929 he headed the Physics Department at Westminster Training College, and from 1929 to 1940, he was principal of Paisley College of Technology and School of Art in Scotland. He retired in 1940 at the age of 59 to concentrate on research.

Richardson had a lifelong interest in the application of mathematics to meteorology. He was the first to apply the mathematical method of finite differences to the prediction of the weather in his study *Weather Prediction by Numerical Process* (1922). His method of finite differences was designed to solve differential equations, arising in his work on the flow of water in peat for the National Peat Industries. As these methods allowed him to obtain highly accurate solutions, he decided to apply them to solve the problems of the dynamics of the atmosphere encountered while working for the Meteorological Office. The initial conditions were defined through observations from weather stations, and would then be used to solve the equations. Finally, a prediction of the weather could be made. Richardson's remarkable insight was ahead of its time since the time taken for the necessary hand calculations in a precomputer age took too long. Even with a large group of people working to solve the equations, the solution could not be found in time to be useful to predict the weather. Richardson himself admitted that it would take 60,000 people to have the prediction of tomorrow's weather before the weather actually arrived. In spite of this flaw, Richardson's work pioneered present day weather forecasting.

Throughout his life, Richardson published extensively on the application of mathematics to the weather and contributed to the theory of diffusion, specifically regarding eddy-diffusion in the atmosphere. For his scientific achievements, he was elected to the Royal Society in 1926. His deeply-rooted interest in pacifism led him to apply mathematics to the study of wars and military conflicts. His results were published in three major books: *Generalized Foreign Politics* (1939), *Arms and Insecurity* (1949), and *Statistics of Deadly Quarrels* (1950). Richardson used mathematics to challenge the assumption that war was a rational national policy in the interests of a nation. He gave systems of differential equations governing the interactions between countries. Starting with the armament of two nations, Richardson constructed an idealized system of equations calculating the rate of a nation's military buildup as directly proportional to the amount of arms its rival has and also to the disputes toward the enemy. This rate is, instead, negatively proportional to the amount of arms it already has itself. Richardson died on September 30, 1953, in Kilmun, Argyll, Scotland.

Risk

RISK IS A concept that captures the probability and, in some instances, the potential severity of the occurrence of a negative outcome (that is, being exposed to a hazard). There is much discussion surrounding the various risks associated with global warming and climate change, such as those related to the environment, ecosystem, human health, and the world economy. In this regard, various experts have used risk analysis to assess, manage, and communicate these associated risks.

Global warming occurs as a result of the accumulation of greenhouse gases in the atmosphere. These greenhouse gases occur both naturally (such as water vapor, carbon dioxide, methane, and ozone) and as a result of human activity (for example, from the burning of fossil fuels, deforestation, and the use of chlorofluorocarbons and fertilizers). The latter has been the focus of a 2007 report from the Intergovernmental Panel on Climate Change (IPCC). This has led to a great deal of discussion surrounding the various policy implications that lie ahead.

There are several environmental risks associated with global warming and climate change—some of which have been noted by researchers worldwide as already occurring, and others that have been forecast. Climate change affects countries differently depending partly on their geographical location.

The record high temperatures documented over the past two decades have resulted in early ice thaw on rivers and lakes. Furthermore, the rates of sea-level rise are expected to continue to increase as a result of both the thermal expansion of the oceans and the partial melting of mountain glaciers and the Antarctic and Greenland ice caps. It has been reported that increasing temperatures have also been the cause of many extreme weather events such as heat waves, droughts, and wildfires.

Moreover, changes to ocean temperatures and wind patterns have resulted in more frequent and intense rain and ice storms, floods, and some natural disasters such as hurricanes and typhoons. An increase in the frequency and severity of disasters can lead to secondary effects such as massive mudslides—as was the case with Hurricane Mitch in 1998. They can also have far-reaching effects that can result in a loss of livelihood, displacement, as well as local and global migration, particularly for those living in communities in the most vulnerable areas (such as low-lying coastal areas and estuaries, alpine regions, and tropical and subtropical population centers). Additionally, these risks can be exacerbated for marginalized groups as well as those living in more vulnerable communities (for example, regions that are poverty laden or more crowded).

HUMAN HEALTH AND DISEASE RISKS

Extreme weather events can have disastrous effects on physical and mental health as well as environmental health. The occurrence of droughts can lead to problems associated with water availability and quality (for example, people sharing water with livestock). Similarly, heat-related effects such as exhaustion, cramps, heart attacks, stroke, and even death are possible outcomes as a result of heat waves. Furthermore, excessive rainfalls and flooding are associated with the risk of injuries and death (as from drowning), as well as the spread of various water-borne diseases (via fecal-contaminated waterways and drinking supplies), and exposure to toxic pollutants (from nearby industrial sites and municipal sewage—as was the case with the Elbe flood which took place in 2002 in central Europe). The variation of risks associated with the transmission of infectious diseases as a result of extreme weather events have also been documented; however, their relation to global warming and climate change have not yet been conclusively reported in the literature.

The risks associated with the transmission of infectious diseases are dependent upon the kind(s) of weather event(s) that have occurred. As such, the reproduction and survival of disease-carrying vectors such as mosquitoes could be impaired by heavy rainfalls (such as flushing larvae from pooled water) or heightened by changes in climate and rainfall patterns. For instance, changes in climate have allowed vector-borne diseases such as malaria and dengue fever to survive in otherwise inhospitable areas (in higher elevations). Other vector-borne diseases (such as cholera, Ross River virus, and West Nile) and food-borne diseases (like the proliferation of bacteria in contaminated foods) are also at risk of occurring as a result of higher temperatures.

As noted by the Canadian Lung Association, climate change and the effects of it can lead to air quality problems such as those resulting from the increased burning of fossil fuels as a direct result of rising temperatures (for example, increased use of air conditioners, refrigerators, and freezers); increases in forest fires; and increased mold growth as a result of elevated levels of precipitation. Associated health effects such as asthma and allergies as well as other respiratory-related morbidity and mortality are also of concern. The Canadian Lung Association provides a more comprehensive explanation of the connection between climate change, air quality, and respiratory health.

Global warming and climate change can impact both the balance and health of the ecosystem, which in turn puts human health at risk. A report by the UN Environment Programme provides an overview of the relationship between climate change and ultraviolet radiation, ozone depletion, terrestrial and aquatic ecosystems, and biogeochemical cycles. Changes and losses related to biodiversity (disruption in ecosystems and species extinction) are also of concern. In a 2007 article, Frederic Jiguet and colleagues note a number of studies that have shown that habitat degradation is taking place; particular reference is made to research on plants, butterflies, beetles, mammals, bumblebees, birds, coral reefs, and coral-dwelling fishes—however, there are a number of other habitats which may also be at risk. Moreover, based on findings from the first comprehensive assessment of extinction risk, the Natural Resources Defense Council notes, "more than one million species could be committed to extinction by 2050 if global warming pollution is not curtailed."

Diversity in species is important, because it aids in ecosystem services/functions (maintaining soil fertility and pollinating plants and crops); a change in ecosystem services/functions can have far-reaching implications (it can affect agro-ecosystems, marine systems, and fresh water, as well as the transmission of vector-borne diseases). Furthermore, there are also risks associated with nutrition, which is dependent on the state of agricultural output (such as changes in food productivity and associated pests which are involved in the transmission of diseases) as well as other food sources (like fisheries and mammals); this can have consequences on ecosystem and human health in the immediate area(s) and globally.

ECONOMIC RISKS

As far as businesses are concerned, environmental risks are usually understood in terms of costs, managed by regulatory compliance, potential liability, and pollution release mitigation. Supply chain risks might occur, whereby suppliers may eventually pass the costs pertaining to carbon-related and more energy efficient alternatives (technology advancement) to customers. Also, businesses that generate significant carbon emissions could face similar litigation risks (lawsuits) as those experienced by tobacco, asbestos, and pharmaceutical industries that in turn may also put the company's reputation at risk.

Organizations that seek a competitive advantage in light of global warming and climate change may use a Strengths, Weaknesses, Opportunities, and Threats (S.W.O.T.) analysis to examine their organization's strengths and weaknesses in relation to the opportunities and threats posed by the environment in order to transform the various business-related threats into opportunities. For instance, organizations that are able to identify and implement new market opportunities for climate-friendly products and services may fare better than other organizations that are unable to achieve this. Additionally, organizations may want to take measures such as quantifying their carbon footprint (the amount of CO_2 created by business operations) in order to show consumers that they are aware of their role in climate change—and then take measures to correct the identified shortcomings. This could lead to the development of new and profitable products that are also environmentally friendly, as well as an increase in consumer loyalty.

There are other far-reaching economic implications outside the immediate business arena. For instance, the costs associated with insurance (both for the customer and for insurance companies) may affect those living in more vulnerable areas. Moreover, it has been argued that the impacts of climate change are not evenly distributed; for instance, developing countries are not only at a geographical disadvantage (with high rainfall variability), but their economic livelihood is heavily dependent on their agricultural output (which is at risk with climate change). Furthermore, the implementation of more stringent regulations as well as the adoption of better and safer technological alternatives and advancements may not seem like a feasible option economically for developing countries.

There are various types of risks that need to be considered with respect to global warming and climate change. Risk analysis is a process that considers the scientific, social, cultural, economic, and political issues that shape the identification, evaluation, decision making, and policy implementation concerning risk. As such, risk analysis encompasses the assessment, management, and communication of risks, each in turn having their own framework. In the context of environmental health, Annalee Yassi and colleagues have provided a comprehensive list of hazards which arise from both natural and anthropogenic (caused or induced by human activity) sources and explain the processes involved in the assessment and management of these risks—some of the hazards identified are applicable to global warming and climate change.

The risk assessment framework most frequently used in relation to environmental and human health follows the steps first identified by Lawrence, E. McCrae in 1983; these steps include problem formulation, hazard identification, dose-response relationships, exposure assessment, and risk characterization. Once characterized, risks are sometimes ranked by organizations through the use of a risk matrix. Risk matrices are made up of rows and columns that denote the severity or impact of the hazard and the likelihood or probability of its occurrence, where the former is usually more subjective, and the latter is relatively objective.

Accurately predicting (through the use of modeling and other forecasting techniques) and assessing (via the five aforementioned steps) the environmental, ecosystem, and human health risks related to global warming and climate change is challenging because of the level of complexity and uncertainty involved. These factors can result for various reasons; among these are: incomplete, insufficient or inaccurate data; gaps and errors in observation; measurement error(s); lack of knowledge (inadequate or conflicting modeling, or unknowns pertaining to feedback effects); variation in assumptions; unforeseen circumstances; variability in natural conditions, exposures, and human activity; and contributions of natural and human-induced changes.

Both risk assessment and cost-benefit analysis (a tool used to determine whether or not costs outweigh benefits—the applicability of this tool has been a widely debated issue in the face of climate policy) usually drive risk management. As such, risk management is the process through which a regulatory agency decides which action(s) to take and which regulation(s) and policies to implement based on risk assessment estimate(s) and cost-benefit analyses. With respect to global warming and climate change, there are three risk management strategies that are frequently discussed in the literature—these are mitigation, adaptation, and geoengineering.

Mitigation strategies are those that are concerned with taking actions that are aimed at reducing the extent of global warming and climate change. For instance, mitigation strategies might include adopting measures that reduce anthropogenic sources of climate change (for example, limiting greenhouse gas emissions relating to fossil-fuel combustion, or deforestation). On the other hand, adaptation strategies are aimed at decreasing vulnerability to global warming and climate change. Adaptation solutions include insulating buildings (for heat-related illness); installing window screens (for vector-borne diseases); and constructing strong sea walls (for health and extreme weather events). A third strategy is geoengineering; this is essentially when large-scale manipulation of the environment takes place in an attempt to correct climate change. An example of geoengineering would include the (proposed) manipulation of the Earth's global energy balance by blocking a percentage of sunlight (via the use of superfine reflective mesh, or orbiting mirrors) in order to offset the doubling of carbon dioxide. However, approaches such as these carry great risks and are therefore largely debated.

Good risk communication includes the two-way exchange of information, concerns, and preferences between decision makers and the public in a manner where the mutual understanding of risks is achieved. The risks associated with global warming and climate change are numerous and have far-reaching implications; it is therefore imperative that all aspects of risk are carefully considered.

Romania

LOCATED IN EASTERN Europe, Romania has a land area of 92,043 sq. mi. (238,392 sq. km.), with a population of 21,438,000 (2006 est.), and a population density of 236 people per sq. mi. (93 people per sq. km.). Some 41 percent of the land of Romania is arable, with a further 21 percent used for meadows and pasture, and 28 percent is forested. For the generation of electricity in the country, 53 percent comes from fossil fuels, with 37 percent from hydropower, and 10 percent from nuclear power, with a small amount of electricity exported, and an even smaller part imported. The heavy use of hydropower has resulted in Romania having one of the lowest per capita rates of carbon dioxide emissions: 6.7 metric tons per person in 1990, falling to 3.8 metric tons per person in 1999, and rising slowly to 4.16 metric tons in 2004.

The generation of electricity contributed to 49 percent of the country's carbon dioxide emissions, with

Bucura Lake in the Retezat mountains in Romania. Global warming has increased the risk of flooding.

24 percent from manufacturing and construction, 11 percent from transportation, 8 percent from residential uses, and the remaining 8 percent from nonelectricity energy industries. The source of the emissions comes from gaseous fuels (33 percent), liquid fuels (32 percent), and solid fuels (31 percent), with 4 percent from cement manufacturing.

Global warming has caused increased risks of flooding in parts of the country. It is also thought to be the major reason for the heat wave in the summer of 2007, which resulted in shortages of water in some parts of the country, and the deaths of some people, especially in Bucharest and other urban centers. The highest temperature ever recorded in Romania was, however, in the 1950s, when 45 degrees C was registered at the city of Calafat in the far south of the country. The hot summer of 2007 followed an extremely warm winter, especially in January and February 2007, during which the Romanian Soccer Federation even announced that if the trend of warm winters continued, they would change their calendar, which brought the problem to national attention.

The Romanian government of Ion Iliescu took part in the UN Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. They signed the Kyoto Protocol to the UN Framework Convention on Climate Change on January 5, 1999, and ratified it on March 19, 2001, with it entering into force on February 16, 2005; the government committing itself to a reduction of emissions by 1.2 percent as a stage toward ratification, and by another 8 percent by 2012. The Romanian government has long signaled its interest in emissions trading.

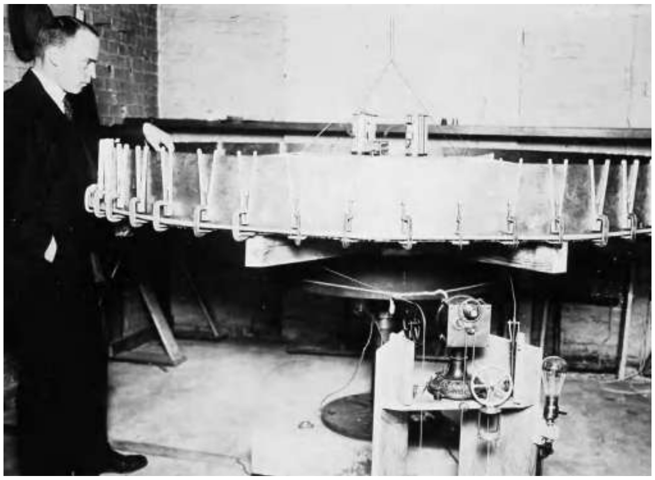
Rossby, Carl-Gustav (1898–1957)

CARL-GUSTAV ROSSBY WAS a Swedish-American meteorologist whose innovations in the study of large-scale air movement and introduction of the equations describing atmospheric motion were largely responsible for the rapid development of meteorology as a science. Rossby explained the large-scale motions of the atmosphere in terms of fluid mechanics and was one of the first scientists to notice the problem of global warming.

Rossby was born on December 28, 1898, in Stockholm, Sweden. When he was 20, he moved to Bergen, Norway, to study under pioneering atmospheric scientist Vilhelm Bjerknes at the Geophysical Institute. At that time, Bjerknes and his so-called Bergen School were making great progress in laying the foundations of meteorology as a science with their breakthroughs in the polar front theory and air mass analysis. The center was the world's leading center of meteorological research. The young Rossby contributed his brilliant ideas to the development of the group's projects. Because of the impact of Bjerknes's guidance, Rossby, who had previously been interested in studying mathematics and astronomy, committed himself to meteorology.

Rossby moved to the United States in 1926, where he worked in Washington, D.C. He was employed as a fellow of the American-Scandinavian Foundation



Carl-Gustav Rossby with a rotating tank used to study atmospheric motion. Rossby explained atmospheric motion.

for Research at the U.S. Weather Bureau to explain the innovations of the polar front theory. While at the Weather Bureau Rossby established the first weather service for civil aviation. The Weather Bureau was not a stimulating context for Rossby, who, in 1928, became professor and head of the first department of meteorology in the United States at the Massachusetts Institute of Technology, Cambridge. At MIT, he made important contributions to the understanding of heat exchange in air masses and atmospheric turbulence. He also investigated oceanography to study the relationships between ocean currents and their effects on the atmosphere.

Rossby was given American citizenship in 1938. The following year, he became assistant chief of the Weather Bureau. In that capacity, Rossby was responsible for research and education and began his studies of the general circulation of the atmosphere. In 1941, he became chairman of the department of meteorology at the University of Chicago. Rossby carried out pioneering work on the upper atmosphere, proving how it affects the long-term weather conditions of the lower air masses. Measurements recorded with instrumented balloons had demonstrated that in high latitudes in the upper atmosphere there is a circumpolar westerly wind, which overlies the system of cyclones and anticyclones lower down. In 1940 Rossby developed the theory of wave movement in the polar jet stream. He demonstrated that long sinusoidal waves of large amplitude, now known as Rossby waves, are generated by perturbations caused in the westerlies by variations in velocity with latitude. Rossby also showed the importance of the strength of the circumpolar westerlies in determining global weather. When these are weak, cold polar air will sweep south, but when they are strong, they cause the normal sequence of cyclones and anticyclones. Rossby worked on mathematical models for weather prediction and introduced the Rossby equations, which, with the introduction of digital computers in the 1950s, were of fundamental importance to forecast the weather. During World War II, Rossby was in charge of training military meteorologists, and, at the end of the war, hired many of them to work in his department at the University of Chicago. Rossby served as president of the American Meteorological Society for 1944 and 1945, and laid the foundations for the Society's first scientific journal, the *Journal of Meteorology*.

Rossby and his Chicago Group were able to compile weather charts over periods of five to 30 days to extract the general features, and tried to analyze these using basic hydrodynamic principles. The group made radical simplifying suppositions, ignoring essential but transitory weather effects like the movements of water vapor and the dissipation of wind energy. Still, they began to conceptualize how large-scale features of the general circulation might arise from simple dynamical principles.

In 1950 Rossby returned to Sweden, but continued to visit the United States. In his home country, he worked with the Institute of Meteorology, which he founded in connection with the University of Stockholm. From 1954 to 1957 he was instrumental in arousing interest in atmospheric chemistry and the interaction of airborne chemicals with the land and the sea. On December 17, 1956, Rossby appeared on the cover of *Time* magazine and was praised for his key role in raising meteorology to the status of science. The piece also referred to a theory that Rossby was developing as a result of his interest in atmospheric chemistry. According to Rossby, the world's climate might be altered by solar heat trapped in the atmosphere due to a buildup of carbon dioxide. This was one of the first insights into the problem of global warming and paved the way for many researches in the field. Rossby was unable to fully develop this insight as he died on August 19, 1957, just nine months after the *Time* article.

The Carl-Gustav Rossby Research Medal is the highest award for atmospheric science presented by the American Meteorological Society for outstanding contributions to the understanding of the structure or behavior of the atmosphere. Rossby himself was the second recipient of this prestigious award when it was still called Award for Extraordinary Scientific Achievement.

Royal Dutch/Shell Group

THE ROYAL DUTCH/SHELL group is a major contributor to the release of greenhouse gases, and has been among the leading oil companies to publicly embrace the need for sustainable development, including the need to address climate change. It is by most measures the world's second largest oil company, with over 100,000 employees, operations in over 130 countries, 2006 production of nearly 3.5 million barrels of oil equivalent per day, and proven reserves of nearly 8.5 billion barrels of oil equivalent. Shell's 2006 income was $26.3 billion on revenue of $318 billion.

HISTORY

Shell Transport began in 1833 with a British shopkeeper importing oriental shells, leading to an export/import business importing oil. Royal Dutch Petroleum Company began producing petroleum in the Dutch East Indies. A partnership was formed in 1907, expanded rapidly, and was the main fuel supplier to the British in World War I, and the world's leading oil company by 1930. During this period, it also began developing its global network of service stations. Demand for petroleum exploded after World War II. During the 1960s, Shell strengthened its presence in the Middle East, and discovered reserves in the North Sea. The 1973 oil crisis led Shell to diversify into other energy sources such as coal and nuclear power, with little economic success. Shell also acquired 50 percent of an Australian solar energy company, and began producing renewable softwoods that could be used for paper, construction, and fuel. Shell is the world's leading biofuels distributor.

After oil prices collapsed in 1986, Shell invested in research and development that led to huge improvements in drilling techniques, and began some of its most challenging offshore exploration. During the 1990s, high oil prices allowed Shell to further develop biomass technologies. Since 2000, Shell's greatest expansion has been in China. In 2005, the old partnership was dissolved, and one company was created, Royal Dutch Shell.

SUSTAINABLE DEVELOPMENT

The company experienced two major public image setbacks in 1995 related to sustainable development. After the British government approved Shell's plans to decommission the Brent Spar oil storage platform by sinking it in the North Sea, Greenpeace claimed this would create large amounts of pollution. Shell argued this would create the least environmental damage. Greenpeace activists protested, boarding the rig as it was being towed to the disposal area. Widespread media coverage followed, and resulted in huge negative publicity for Shell, spawning boycotts and even a firebombing of a Shell station. Shell eventually reversed its decision and towed the rig to port in Norway for dismantling. Dismantling revealed that claims of a negligible amount of oil in the rig were accurate, and Greenpeace later issued an apology.

That fall, Shell experienced another public relations fiasco. A wholly-owned subsidiary, Shell Nigeria, is the major international oil-producing company in Nigeria, with joint ventures with the Nigerian state-owned oil company and other multinational oil companies. Significant revenues from oil production go to the central government, with little benefit accruing to people in oil producing regions. Author Ken Saro-Wiwa, a member of the Ogoni tribe from the Niger Delta, led protests against the government for not using oil revenues to benefit the Ogoni, many Ogoni leaders for complicity with the central government, and Shell for substantial pollution from exploration and pipeline spills and gas flaring and for seeking security assistance from Nigerian military forces. Violence broke out, in which several Ogoni chiefs were killed, and Saro-Wiwa and eight of his associates were arrested, tried, and found guilty of murder.

International human rights activists regarded the charges as groundless, and the trial as unfair. Activists called on the Nigerian government to commute the sentences, and on Shell to use its influence to this end. Shell's CEO and the Shell Nigeria managing director appealed for clemency on humanitarian grounds, but Saro-Wiwa and his associates were executed 10 days after the verdict. Shell was heavily criticized for not doing more to attempt to influence the government to free Saro-Wiwa.

These events prompted Shell to expand its attention to sustainable development. The company has a Social Responsibility Committee that directs its sustainable development policies and performance, and it annually produces an extensive sustainability report stating that sustainable development is part of the duties of every manager at Shell. Every one of Shell's businesses is responsible for complying with corporate sustainable development policies and achieving unit-specific targets in this area.

FUEL ALTERNATIVES

Shell expresses a commitment to help meet the energy challenge by providing more secure and responsible energy. Shell is developing more environmentally friendly fossil fuel technologies like gas to liquids (GTL), which turns natural gas into cleaner-burning fuels. While they don't receive the same financial support, Shell also supports several renewable energies. Shell was the first energy company to build demonstration hydrogen filling stations in Asia, Europe, and the United States, and is one of the world's leading distributors of biofuels. However, Shell has not yet provided the financial investment needed for hydrogen expansion, and the hydrogen is derived from fossil fuels.

In 2006, Shell sold over 3.5 billion liters of biofuels, mainly in the United States and Brazil, enough to avoid over 3.5 million tons of CO_2 production. Shell believes that "first generation" biofuels are unreliable, requiring too much acreage to be planted to feedstocks, thus putting strain on the environment and food supply. Shell has therefore invested in "second generation" biofuels, such as the production of ethanol from straw rather than corn. Shell claims this second-generation biofuel could cut well-to-wheel CO_2 production by 90 percent, compared with conventional gasoline. In early 2007, Iogen, acquired by Shell in 2002, was one of six companies selected to receive funding under the U.S. Department of Energy's cellulosic ethanol program.

Shell invested in CHOREN Industries to create the first demonstration-scale biomass-to-liquids (BTL) plant, scheduled to come online in late 2007. This process relies on the use of a woody feedstock, gasifies it, and then uses the Shell Middle Distillates Synthesis (SMDS) process to convert the gas into a high-quality fuel identical to GTL that can be blended with diesel fuel. If used at 100 percent concentration, it could also cut well-to-wheels CO2 production by 90 percent compared with conventional diesel. Shell also has small investments in solar and wind power. Currently, their financial impact on Shell is very small, and they are not seen as offering substantial room for growth.

GREENHOUSE GAS REDUCTION

In 1997, Shell started managing its CO_2 output with the goal of reducing total greenhouse gas emissions. In 2006, Shell facilities emitted 98 million tons of greenhouse gases, about seven million lower than in 2005 and more than 20 percent below 1990 levels. Yet, Shell has target emissions limits of only 5 percent below the 1990 level for 2010. Shell claims its standards are very aggressive, but agrees they may need to be reconsidered if they have already been met. Most of Shell's reductions came from ending the venting of natural gas. Most of its anticipated reductions will continue to come from ending continuous flaring and increasing energy efficiency.

In 2006, Shell missed its annual Energy Intensity target, as it had underestimated how much extra energy would be required to produce more environmentally friendly low-sulfur fuels, and because of unplanned equipment shutdowns at several facilities that required extra energy to restart. In 2007, Shell launched a new energy efficiency effort that will make up for part of the increase. Its plan is to continue efforts to end continuous flaring by 2008, except in Nigeria where the target is 2009. Further greenhouse gas reductions are planned from energy efficiency improvements at refineries and chemicals plants.

Shell also states it is trying to reduce its customers' CO_2 emissions. Shell's customers emit six to seven times (750 million tons of CO_2 in a typical year) more CO_2 consuming Shell products than Shell does producing them. Shell promotes the use of natural gas, which emits less CO_2 than coal, and is a more profitable part of Shell's business than coal. Shell has also patented a coal gasification technology that can reduce CO_2 emissions by up to 15 percent, compared to conventional coal-fired power plants.

Shell also actively supports governments in designing and implementing effective CO_2 trading schemes. They are part of the UN Partnership for Clean Fuels and Vehicles and the World Bank Clean Air Initiative in Asia to provide cleaner fuel and improve air quality in the developing world. Shell is also a member of the U.S. Climate Action Partnership created in 2007 by over 30 companies and environmental groups.

Shell's annual sustainability report is audited by an external review committee, which has praised Shell for its leadership and transparency in reporting, but has questioned whether the speed with which Shell is acting to tackle climate change is consistent with the urgent nature of the challenge. The committee specifically noted the expected rise in future emissions, the lack of published targets after 2010, how Shell will achieve future greenhouse gas reductions after it stops flaring, and the absence of adequate research and development fund allocation information to assess Shell's commitment to develop renewable energy sources and to greenhouse gas mitigation.

Royal Meteorological Society

THE ROYAL METEOROLOGICAL Society is a British charity whose mission is to "continue to be a world-leading professional and learned society in the field of meteorology. It will encourage and facilitate collaboration with organizations that are active in Earth Systems Sciences. It will serve its professional and amateur members and the wider community by undertaking activities that support the advancement of meteorological science, its applications and its understanding." A Council and its committees are responsible for running the society, within the constraints of the Royal Charter.

The Council comprises a total of 21 officers and ordinary members of council elected at the annual general meeting. The president, elected for a two-year term, is supported by a vice-president for Scotland and three other vice-presidents, the treasurer, general secretary, four journal editors, four main committee chairmen and Ordinary Members of Council. The Council convenes five times a year to consider applications for membership and supervise the running of the Society through its Honorary Officers, Committees and permanent staff. The work of the Council is largely organized by the recommendations made by its Committees. The society staff are based at the society's headquarters in Reading where committee meetings are normally held. The society's patron is HRH The Prince of Wales. Its membership in 2006 consisted of more than 3,000 members worldwide.

The Royal Meteorological Society is the national British society for all those individuals whose profession or interests are in any way connected with meteorology or related subjects. It controls the national qualifications of the profession and, under its royal charter, follows its mission to advance meteorological science. The society intends the terms meteorological science in their broadest meaning which includes its day-to-day application in weather forecasting and in disciplines such as agriculture, aviation, hydrology, marine transport and oceanography, as well as in the areas of climatology, climate change, and the interaction between the atmosphere and the oceans. The society publishes the results of new research and provides support both for researchers and professional meteorologists and also for those whose work is connected to the weather or climate and for those who have a general interest in environment and the weather. The membership of the society thus includes a variety of figures: professional scientists, practitioners, and weather enthusiasts. Associate fellows may be any age and do not require any specific qualification in meteorology. Fellows normally require a formal qualification in a subject related to meteorology plus five years experience and must be nominated by two other fellows. The society has a number of regular publications: the monthly magazine *Weather*, the *Quarterly Journal of the Royal Meteorological Society, Meteorological Applications*, and the *International Journal of Climatology and Atmospheric Science Letters.*

The society was established in April 1850 with the name of the British Meteorological Society, and was later incorporated by Royal Charter in 1866, when its name was changed to the Meteorological Society. The privilege of adding 'Royal' to the title was granted by Her Majesty Queen Victoria in 1883. In 1921, the society merged with the Scottish Meteorological Society.

In 1995, the Royal Meteorological Society developed a set of atmospheric dispersion modeling guidelines to encourage good practice in the use of mathematical atmospheric dispersion models, stressing the importance of selecting the most suitable modeling procedures and of fully documenting and reporting the results of modeling assessments. The 1995 guidelines provided broad general principles of good practice for modeling studies applying across a wide range of modeling situations. The UK Atmospheric Dispersion Modeling Liaison Committee (ADMLC) commissioned an upgrading of the 1995 guidelines to take into account the new developments in modeling techniques. The updated guidelines were completed and published in 2004.

The Royal Meteorological Society has specific resources on global warming for teachers and for educational purposes. The society has acknowledged that global warming is taking place and that it is the result of human activity. Yet, one of its former presidents, Chris Collier, and one of its leading researchers, Paul Hardaker, complained in 2007 about catastrophism and the "Hollywoodization" of weather and climate that only work to create confusion in the public mind. They argue for a more sober explanation of the uncertainties about possible future changes in the Earth's climate so as not to undermine scientists' credibility. According to both Collier and Hardaker, several organizations, including the American Association for the Advancement of Science (AAAS), have overplayed the evidence that the phenomenon of global warming is causing short-term devastating impacts.

Russia

SITUATED IN BOTH Europe and Asia, the Russian Federation has a land area of 6,592,800 sq. mi. (17,075,400 sq. km.), with a population of 142,499,000 (2006 est.), and a population density of 21.8 people per sq. mi. (8.3 people per sq. km.). Moscow, the capital and the largest city, has a population of 10,654,000, with a density of 25,022 per sq. mi. (9,644 per sq. km.). The second largest city, Saint Petersburg, has a population of 3,990,267.

In spite of the vast size of Russia, some 8 percent of the land is arable, with a further 4 percent assigned as meadows and pasture, and 46 percent of the country is forested, including vast expanses of the Siberian tundra. The per capita rate of greenhouse gas emissions from the Russian Federation was 13.4 metric tons in 1992, falling steadily to 9.9 metric tons per person by 2002, partially as the economy in the country was struggling, and then rising to 10.5 metric tons per person by 2004. Because of its climate, and the need for extensive heating, 60 percent of the country's carbon dioxide emissions come from the production of electricity, of which 66.1 percent is generated from fossil fuels, 18.9 percent from hydropower, and 14.7 percent from nuclear power. This heavy use of fossil fuels is largely because of the abundance of coal, and also the availability of locally extracted petroleum in parts of the country. However, by 1998, the use of natural gas from Siberia had become much more important, with gaseous fuels making up 48 percent of all carbon dioxide emissions, solid fuels making up 26 percent, and liquid fuels 24 percent. In terms of the sector producing the emissions, with the bulk created in electricity production, 14 percent came from manufacturing and construction, 13 percent from transportation, and 10 percent from residential use.

The coal-mining areas of western Russia still remain important, politically, but the discovery of the Siberian gas fields around Omsk and other cities has led to the Russian Federation's exportation of gas to neighboring countries, and also some parts of Western Europe. Russia has suffered some of the effects of global warming and climate change, with the melting of the Arctic sea ice creating major problems for the northern parts of the country. Satellite measurements of the Arctic Ocean have revealed that the area of perennial ice cover has fallen by about 7 percent per decade since 1978. There has also been the melting of some of the Siberian permafrost, which some Russians have welcomed, as it has the potential to open up more arable land. However, it has also caused damage to hundreds of buildings in cities of Yakutsk and Norilsk, with the average temperature of the permanently frozen ground at Yakutsk having warmed by 2.7 degrees F (1.5 degrees C) between 1968 and 1998. Lake Baikal has also experienced a shorter freezing period in the last century, with winter freezing taking place 11 days later than had been the case, and the spring ice breaking up some five days earlier. There has been a similar problem in the Caucasus Mountains, where half of all the glacial ice there has disappeared in the last 100 years.

Although the amount of arable land has increased, and some people have managed to survive more easily in an otherwise hostile climate in Siberia, there has been a threat to some of the native fauna and flora. In Khabarovsk, in the far eastern part of the Russian Federation, drought and high winds led to forest fires in 1998, which destroyed 3.7 million acres (1.5 million hectares) of coniferous forest, the taiga, and threatened nature reserves where the last remaining Amur tigers live.

The Russian government of Boris Yeltsin took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992. The Russian government of Aleksandr Rutskoy accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on March 11, 1999, but the new government of Vladimir Putin was initially against the ratification of it, voicing opposition in 2003. However, Putin decided to support it, and the Russian Federation ratified it on November 18, 2004, with it entering into force on February 16, 2005. This immediately changed the entire situation as regards the Kyoto Protocol, making Russia a central player in international climate policies. The Russian ratification means that countries contributing to more than 55 percent of the world's carbon dioxide emissions in 1990 had ratified the treaty, and as a result, the Kyoto Protocol became international law on February 16, 2005, 90 days after the Russian ratification. To try to reduce its greenhouse gas emissions, the Russian government has embarked on a process of expanding its hydroelectric power generation, with the Boguchan Dam scheduled to be completed in 2012.

Rwanda

THE REPUBLIC OF Rwanda, located in central Africa, has a land area of 10,169 sq. mi. (26,798 sq. km.), with a population of 9,725,000 (2006 est.), and a population density of 829 people per sq. mi. (320 people per sq. km.), the second highest in Africa, and the highest on the African mainland. Some 35 percent of the country is arable land, with 18 percent used for meadows and pasture, and 10 percent of the country remains forested.

A fisherman in Lake Kivu struggles with his boat. The lake has declined in size due to increased temperatures.

In terms of its per capita carbon dioxide emissions, Rwanda had less than 0.1 metric tons per person in 1990, with 0.07 percent in 2003, making it the 10th lowest country in terms of per capita emissions. With less than 1 percent of this coming from cement manufacturing, the remaining 99 percent is the result of the use of liquid fuels. This is because 97 percent of the country's electricity production comes from hydropower, with only 3 percent from fossil fuels.

The effects of global warming and climate change in the country have been rising average temperatures, with a decline in the size of Lake Kivu, and also less irrigation water in the marshlands around the River Kagera and from the other lakes, Lake Rwanye, Lake Ihema, and Lake Mugesera. This also represents a threat to the rainforests where the mountain gorillas live, and which are also a home for 43 species of reptiles (including many frogs) and 31 species of amphibians.

The Rwanda government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, which it ratified in 1998, and in 2001 ratified the Vienna Convention. It accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on July 22, 2004, with it entering into force on February 16, 2005.

Saint Kitts and Nevis

LOCATED IN THE West Indies, Saint Kitts and Nevis are two islands in the Leeward Islands chain. They have a land area of 68 sq. mi. (168.4 sq. km.) for Saint Kitts and 35.9 sq. mi. (93.2 sq. km.) for Nevis. They have an overall population of 50,000 (2006 est.) and a population density of 426 people per sq. mi. (164 people per sq. km.). Some 75 percent of the population lives on the island of Saint Kitts, with 49 percent of the overall population living in urban areas, even though the capital—Basseterre—has a population of only 14,000. Some 22 percent of the land is arable, with another 3 percent used for meadow and pasture.

Traditionally, the economy of Saint Kitts, and especially Nevis, was centered on the sugar industry, with sugar cane growing well on the volcanic slopes of both islands. Although demand for sugar for food has declined, its use in ethanol, in an effort made to reduce the world's dependence on gasoline, has become more important starting in the 1990s. Although Saint Kitts and Nevis do face trouble from Caribbean hurricanes, they face less of a problem than many other islands in the West Indies with regard to rising water levels. However, rising water temperatures are expected to have a major effect on the population of sea turtles and also on many other types of marine life that live around the black coral off the shores of Saint Kitts. This is expected to have an effect on the growing tourism industry, which now makes up some 12 percent of the country's economy. The effect of increased development on both Saint Kitts and Nevis has resulted in an increase in per capita carbon dioxide emissions, up from 1.6 metric tons per person in 1990 to 3 metric tons per person in 2003.

The government of Kennedy A. Simmonds took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992, but the government of Denzil Douglas, which came to power in 1995, has so far not expressed any position on the Kyoto Protocol to the UN Framework Convention on Climate Change.

Saint Lucia

THE ISLAND OF Saint Lucia, located in the Windward Islands and surrounded by the Caribbean Sea and the Atlantic Ocean, has a land area of 239 sq. mi. (616 sq. km.), with a population of 165,000 (2006 est.) and a population density of 774 people per sq. mi. (298 people per sq. km.), making it the 39th most densely populated country in the world. About a third of the population lives in the capital, Castries, on the sheltered western coast, with 8 percent of the land being arable and a further 5 percent used for meadows and pasture. Some 41 percent of the exports of the country come from bananas.

Saint Lucia has a number of offshore coral reefs, the most well known being those near Soufrière, in the southeast of the island. Just south of these are other coral reefs that also attract many tourists. There are worries about their preservation, with signs of coral bleaching resulting from the increase in water temperatures. There is extensive public transport on the island, maintained by private bus companies. As with many other developing economies, Saint Lucia has seen a rise in carbon dioxide emissions per capita, going from 1.2 metric tons per person in 1990 to 2.2 metric tons in 1996 before falling to 1.4 metric tons in 1998, but rising again to between 1.9 and 2.1 metric tons per person since then. All the carbon dioxide emissions in the country come from liquid fuel, and all electricity production in the country comes from fossil fuels.

The government of John Compton took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention; two years later, Saint Lucia was represented at the Global Conference on the Sustainable Development of Small Island Developing States held in Barbados. The Saint Lucia government of Kenny Anthony signed the Kyoto Protocol to the UN Framework Convention on Climate Change on March 16, 1998, with the country ratifying it on August 20, 2003, and it entering into force on February 16, 2005.

Saint Lucia has seen a rise in carbon dioxide emissions per capita, from 1.2 metric tons per person to 2.1, since 1990.

Saint Vincent and the Grenadines

SAINT VINCENT AND the Grenadines are part of the Windward Islands chain, surrounded by the Caribbean Sea and the Atlantic Ocean, and have a land area of 150 sq. mi. (388 sq. km.), of which the island of Saint Vincent itself accounts for 107 sq. mi. (240 sq. km.). The country has a population of 120,000 (2006 est.) and a population density of 798 people per sq. mi. (307 people per sq. km.), with Kingstown, the nation's capital, having a population of about 16,000.

Some 10 percent of the land is arable, much of which is used for the growing of coconuts and bananas, and a further 5 percent is used for meadows and pasture. Traditionally, few tourists visit Saint Vincent.

Some of the islands of the Grenadines are low lying, and the country faces major problems with the rising water level; its coral reefs are also threatened by the rising temperature of the water. The flooding feared in some parts of the islands threatens to increase the prevalence of insect-borne diseases such as malaria and dengue fever and also threatens low-lying parts of the country. Global warming has also been blamed for the deaths of many fish in 1999 off the coast of Saint Vincent and other nearby islands. The carbon dioxide emissions per capita in Saint Vincent remain very low, being 0.7 metric tons per person in 1990, although this number has risen significantly since then, reaching 1.6 metric tons in 2003. The carbon dioxide emissions come entirely from liquid fuels, with fossil fuels making up 73.2 percent of the electricity production in the country and the remainder—26.8 percent—coming from hydropower.

The government of James Fitz-Allen Mitchell took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992, and two years later, Saint Vincent was represented at the Global Conference on the Sustainable Development of Small Island Developing States held in Barbados. In 1996, the government ratified the Vienna Convention, and on March 16, 1998, the Saint Vincent government signed the Kyoto Protocol to the UN Framework Convention on Climate Change, with the country ratifying it on August 20, 2003, and it entering into force on February 16, 2005.

Salinity

TWO ATTRIBUTES OF the oceans, temperature and salinity, determine the density of seawater, and the differences in density between the water masses in the world's oceans causes the water to flow in thermohaline circulation, thereby producing the greatest oceanic current on the planet.

Salinity is the distinct taste of seawater and is the result of the presence of dissolved salts (more than 85 dissolved constituents), among which chloride (Cl) and sodium (Na), the elements of common table salt, are the most abundant. The term *salinity* refers to the content of these dissolved salts and has been defined as grams of dissolved salts per kilogram of seawater. Salinity has been expressed as parts per thousand (‰ or ppt) and, more recently, by practical salinity units (psu).

On average, a kilogram of seawater has 35 grams of dissolved salts, so its salinity content is 35‰, or 35 psu. The accuracy of most laboratory salinometers (see below) is about 0.001 psu. Thus, only those components with a concentration over 0.001‰ will contribute to such salinity estimates. Only 15 of the dissolved salts have concentrations above that limit.

A key observational result (known as the principle of Dittmar, after William Dittmar, a Scottish professor of chemistry; the principle of Maury, after Matthew Fontaine Maury, an American astronomer, oceanographer, and geologist; or the hypothesis of Forchhammer, after Johan Georg Forchhammer, a Danish mineralogist and geologist) is that the relative concentration between some of these most abundant salts is virtually constant over much of the World Ocean. This finding indicates that the physical characterization of seawater is given by its temperature, pressure, and a single number reflecting the concentration of the most abundant components. Salinity is that number.

MEASURING SALINITY

In 1902, an international commission defined salinity as the total amount of solid material, in grams, contained in 1 kg. of seawater when all the carbonate has been converted to oxide, the bromide and iodine replaced by chlorine, and all organic matter completely oxidized. With this definition in hand, the commission estimated the salinity of several seawater samples and the fixed relationship between salinity (S) and chlorinity:

$$S(‰) = 003 + 1.805 \text{ Cl } (‰)$$

This was known as Knudsen's equation, after Martin Hans Christian Knudsen, a Danish physicist (1871–1949), and was redefined in 1969 as

$$S(‰) = 1.80655 \text{ Cl } (‰).$$

Defining salinity in terms of chlorinity alleviates the practical difficulties of measuring salinity through evaporating water samples to dryness. For calibration purposes, artificial water with salinity almost equal to 35‰, known as Copenhagen water, is manufactured to serve as a reference. Copenhagen water has a chlorinity of 19.381‰. This approach requires the chemical titration of water samples usually obtained by Nansen bottles, named after Fridtjof Bedel-Jarlsberg Nansen, a Norwegian explorer and scientist (1861–1930), which are self-closing containers that collect water from different depths.

Pure water is a poor electrical conductor. However, the presence of dissolved salts greatly increases its conductivity, which, in fact, is a function of pressure, temperature, and the degree of ionization of the dissolved salts. In the second half of the 20th century, technical improvements in the measurement of the electrical conductivity of seawater led to the development of the so-called salinometers. Conductive salinometers measure the ratio between the conductivity of the sample against that of a reference sample of known salinity. Researchers using conductivity salinometers in the beginning were giving a salinity value of 35‰ to any sample having the same conductivity as the Copenhagen water, even though the mass of salt per kilogram of water was not guaranteed to be the same in both cases. This was because conductivity depends on the degree of ionization of the dissolved salts and not on the absolute mass of salt. In 1978, the salinity scale was redefined in terms of the conductivity ratio, K_{15}, between any given sample and the reference solution:

$$S(\text{psu}) = 0.0080 - 0.1692\,K_{15}^{1/2} + 25.3851\,K_{15} + 14.0941\,K_{15}^{3/2} - 7.0261\,K_{15}^{2} + 2.7081\,K_{15}^{5/2}$$
$$K_{15} = C(S,15,0)/C(KCl,15,0),$$

where $C(S,15,0)$ is the conductivity of the water sample at a temperature of 15°C and atmospheric pressure, and $C(KCl,15,0)$ is the conductivity of a standard solution that contains 32.4356 g. potassium chloride (KCl) at the same temperature and pressure. The practical salinity unit is thus defined as a ratio of conductivities and has no physical units.

An alternative to conductivity salinometers are refractive salinometers, based on the fact that the speed of light through a medium depends on its density. In a refractive salinometer, a drop of sample water is placed on a prism. Because the water and the prism have different densities, light passing through the system is refracted at an angle that depends on the density (i.e., the temperature and salinity). On average, conductive salinometers have a precision of about 0.001 psu, whereas laboratory refractive salinometers have a precision of 0.06 psu, and handheld refractometers have a precision of 0.2 psu. Today's standard instrument for measuring both temperature and salinity is the Conductivity-Temperature-Depth profiler, which allows a quasi-continuous vertical sampling and a precision of 0.005 psu. Based on the same principle, conductivity/temperature instruments are mounted on autonomous profilers (e.g., Argo floats) and the thermosalinographs that use near-surface water intakes of ships to continuously measure temperature and salinity.

A promising approach for remote sensing of the salinity is the microwave radiometry measuring the emissivity or brightness temperature of the sea surface, because the dielectric constant of seawater depends on temperature and salinity. The largest sensitivity of the surface emissivity to salinity has been observed in the L-band (1.40–1.43 GHz). The Soil Moisture and Ocean Salinity of the European Space Agency and the Aquarius-SAC/D mission of NASA-Argentine Space Agency are the first two space missions designed to provide global, synoptic estimates of the sea surface salinity with an accuracy of about 0.1 psu every 30 days with a 100- to 200-km. spatial resolution.

PROCESSES AFFECTING SALINITY

Since the *Challenger* expedition in 1877, when the chemical composition of seawater was first reported, no changes in the composition of seawater have been observed. Thus, it can be supposed that for the timescales pertinent to climate change, viz., decadal to centennial, salinity behaves as a conservative tracer.

Thus, its time evolution is given by the three-dimensional transport of salinity by advection (as water parcels carry properties) or diffusion (tendency to smooth salinity gradients even in still water). At the surface of the oceans (up to a depth where the turbulent action of the wind is balanced by the laminarity of the stable ocean stratification), salinity concentrations are also modified by the dilution/concentration resulting from mass fluxes through the air-sea interface such as evaporation and precipitation, river runoffs, and the thawing/freezing of ice caps. In open oceans, the lowest values of salinity (below 30 psu) are found at high latitudes and at the mouth of the largest rivers. The highest salinities are found in the subtropics (over 35 psu), where evaporation dominates. In the tropics, which tend to be regions of strong precipitation, salinity is around 34 psu.

SALINITY AND CLIMATE

The range of temperatures on Earth allows water to be present as a solid (ice) in ice caps and glaciers; liquid (water) in oceans, groundwater, lakes, and rivers; and gas (water vapor) in the atmosphere. The idealized path of a water molecule from one phase to the other is known as the hydrological cycle. The residence times, that is, the average time that the molecules spend in each phase, range from a few days (water vapor in the atmosphere), to several months (seasonal snow cover, rivers), to the thousands of years (oceans and groundwater). Changes in the hydrological cycle affecting precipitation, evaporation, ice cap thawing, and river runoff have the potential to change the salinity of the oceans. The reverse is also true, and salinity changes may have an imprint in the hydrological cycle after thousands of years.

The mechanisms by which salinity affects the hydrological cycle are numerous. Because of its role in density variations, salinity gradients contribute to ocean currents transporting heat, salt, microorganisms, and nutrients across the oceans. In regions of strong precipitation, a layer of low salinity may isolate the uppermost surface of the ocean from the cold ocean below, forming the so-called barrier layer, which blocks the wind-stirring effects that cool the surface by mixing heat downward. This manifests as warmer sea surface temperatures, modifying the surface temperature gradients that drive surface winds. In the equatorial Pacific Ocean, such a phenomenon is of importance in the El Niño–La Niña cycles. Similar salinity effects also occur in the tropical Indian and Atlantic oceans and have potential feedbacks to the hydrological cycles in the region. Tropical surface anomalies may be advected to the deep convection regions, modulating the thermohaline circulation. One of the largest ocean climate events recorded in the Atlantic Ocean is the Great Salinity anomaly, which lasted from 1968 to 1982. A salinity anomaly propagated over thousands of kilometers reached the Labrador Sea and perturbed the thermohaline circulation intensity. The origin and evolution of these anomalies is still not fully understood because of the historical lack of salinity observations, and studies of the mechanisms by which these salinity anomalies evolve are usually based on ocean and climate models.

Samoa

SAMOA, KNOWN UNTIL 1997 as Western Samoa, has a land area of 1,093 sq. mi. (2,831 sq. km.), with a population of 187,000 (2006 est.) and a population density of 169 people per sq. mi. (65 people per sq. km.). With the economy dominated by subsistence agriculture, 19 percent of the country is arable, and 47 percent is forested.

From 1990 until 2003, the per capita carbon dioxide emissions from the country have been fairly stable, at between 0.7 and 0.8 metric tons per person. These emissions come entirely from liquid fuels, which are

Samoa is at risk of serious land loss because of global warming and climate change.

produced from transportation, electricity generation, and the running of small household and factory generators. Fossil fuels—petroleum—generate 59.2 percent of the electricity, with the remainder coming from hydropower.

Samoa is at risk of serious land loss because of global warming and climate change. Indeed, Upolu and Savaí, the two major islands in the country, have both experienced the loss of about 1.5 ft. (0.46 m.) of shore each year for the last 90 years. The only two other inhabited islands in Samoa—Apolina and Manono—have also suffered land loss, and some of the uninhabited islands are expected to become completely submerged if the water levels continue to rise.

The Samoan government ratified the Vienna Convention in 1992 and took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992, ratifying it in 1994. It signed the Kyoto Protocol to the UN Framework Convention on Climate Change on March 16, 1998, which was ratified on November 27, 2000, and entered into force on February 16, 2005.

San Marino

THE LAND-LOCKED REPUBLIC, entirely surrounded by Italy, has a land area of 23.5 sq. mi. (61 sq. km.), with a population of 31,000 (2006 est.) and a population density of 1,198 people per sq. mi. (461 people per sq. km.), the 20th highest density in the world. It is a very prosperous country, with gross domestic product per capita being US$34,600. As a result, it makes heavy use of electricity—air conditioning in the hot summers and heating for the winter, as well as regular domestic and business use. All electricity for San Marino is supplied by Italy, which produces some 80 percent of its electricity from fossil fuels.

Because of its geographical position, there are few data available for San Marino for greenhouse gas emissions, with Sanmarinesi emissions usually included under Italy, which has had carbon dioxide emissions per capita ranging from 6.9 metric tons per person in 1990, rising to 7.7 metric tons per person by 2003. With tourism being the major source of income, most tourists come to the country in buses or by train from the nearby Italian town of Borgo Maggiore. The Sanmarinesi government took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992, but has, so far, not expressed any policy position on the Kyoto Protocol to the UN Framework Convention on Climate Change.

São Tomé and Principe

THE CENTRAL AFRICAN country of São Tomé and Principe, formerly a Portuguese colony, is located on two islands, São Tome and Principe, in the Atlantic Ocean. Together they have a land area of 372 sq. mi. (964 sq. km.), with a population of 158,000 (2006 est.), and a population density of 454 people per sq. mi. (171 people per sq. km.). About 42 percent of the population live in urban areas. Only 2 percent of the land is arable, with a further 1 percent used for meadows and pasture, with 75 percent of the country being forested.

Until the recent discovery of oil, the country has been poor, with the carbon dioxide emissions in the country being 0.6 metric tons per capita from 1990 until 2003 when the emission level was recorded as 0.62 metric tons per person. For the electricity production in the country, 58.8 percent comes from hydropower, with 41.2 percent from fossil fuels. The entire carbon dioxide emission comes from liquid fuels, being from car emissions, and also from small gas-driven generators. Gasoline prices in the country have been relatively low, but there is a very poor public transport system.

Both the islands of São Tomé and Principe might suffer flooding if global warming and climate change continue to raise the level of the Atlantic Ocean. The rising temperature of the water might also affect the country's fishing industry, which centers on catching shrimp and tuna. The São Tomé government took part in the United Nations Framework Convention on Climate Change signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention in 2001. The government has so far expressed no opinion on the Kyoto Protocol to the UN Framework Convention on Climate Change.

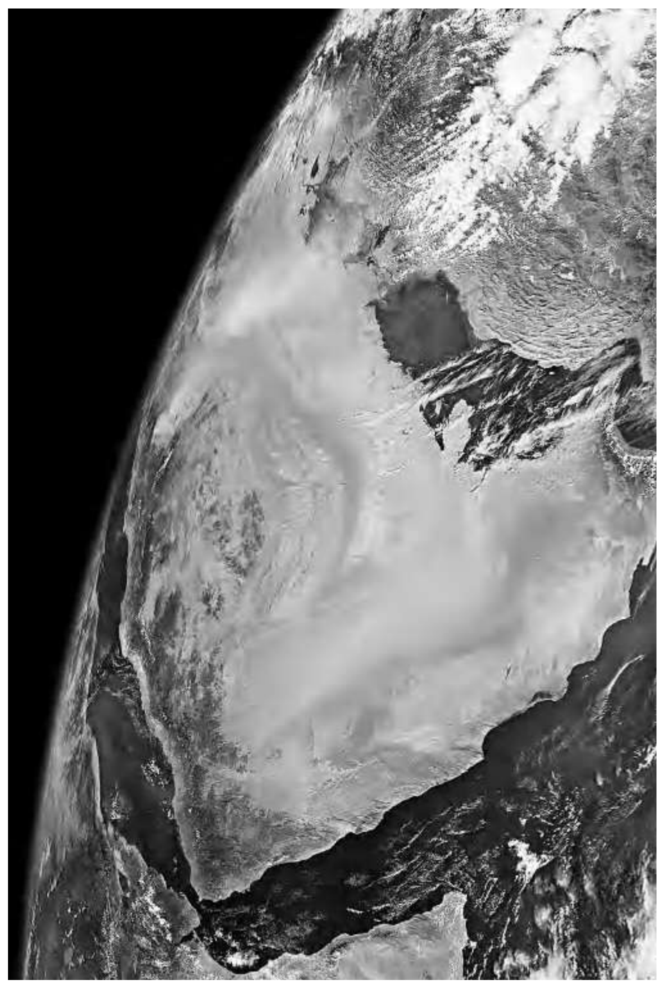
Saudi Arabia

COVERING MOST OF the Arabian Peninsula, the Kingdom of Saudi Arabia has a land area of 829,996 sq. mi. (2,149,690 sq. km.), with a population of 24,735,000 (2006 est.) and a population density of 29 people per sq. mi. (11 people per sq. km.). Riyadh, the capital and the largest city, has a population of 4,193,000 and has a population density of 3,891 per sq. mi. (1,500 per sq. km.). Some 2 percent of Saudi Arabia is arable land, with a further 56 percent used for meadows and pasture. With a high standard of living coming from the petroleum industry, and fossil fuels being used for all the country's electricity production, Saudi Arabia has a high rate of per capita carbon dioxide emissions, rising from 12.1 metric tons per person in 1990 to 18.4 metric tons in 1993.



Massive sandstorms over Saudi Arabia, seen from space. A rise in global temperatures is likely to increase desertification.

In 1998, emissions had fallen to 10.9 metric tons per person but rose to 13.4 metric tons in 2004.

Some 64 percent of the carbon dioxide emissions in the country come from liquid fuels, and 32 percent come from gaseous fuels. Electricity generation accounts for 30 percent of carbon dioxide emissions, with other energy industries contributing another 30 percent. Some 22 percent of carbon dioxide emissions come from manufacturing and construction, with 16 percent from transportation—Saudi Arabia has a high level of private ownership of automobiles and a limited public transport service.

Global warming and climate change, leading to a rise in the temperature, is likely to destroy more arable land, leading to increasing desertification. As the country has no perennial rivers or permanent water bodies, it has established power-hungry desalination plants. It has also drawn up plans for desert reclamation and irrigation schemes to try to achieve self-sufficiency in basic foods.

The Saudi Arabian government took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992. It accepted the Kyoto Protocol to the UNñ Framework Convention on Climate Change on January 31, 2005, with it entering into force on May 1, 2005.

Schneider, Stephen H. (1945–)

AMERICAN CLIMATOLOGIST AND professor in the Department of Biological Sciences, Senior Fellow at the Center for Environment Science and Policy of the Institute for International Studies, and professor by courtesy in the Department of Civil and Environmental Engineering at Stanford University since September 1992, Schneider has been an outspoken advocate of the global warming theory since the 1980s and has helped draw public attention to the issue of climate change. He has argued for sharp reductions of greenhouse gas emissions to combat the phenomenon. Schneider has also served as an adviser to different U.S. administrations and federal agencies since the presidency of Richard Nixon. His research includes modeling of the atmosphere, climate change, and the relationship of biological systems to global climate change.

Schneider was born on February 11, 1945, in New York. He received his Ph.D. in mechanical engineering and plasma physics from Columbia University in 1971. He investigated the role of greenhouse gases and suspended particulate material on climate as a postdoctoral fellow at NASA's Goddard Institute for Space Studies. He was appointed a postdoctoral fellow at the National Center for Atmospheric Research in 1972 and was a member of their scientific staff from 1973 to 1996, where he cofounded the Climate Project. Although Schneider emerged as a public figure in the global warming debate in the 1980s, his interest in the subject dates back to the early 1970s, when he coauthored an article in *Science* ("Atmospheric Carbon Dioxide and Aerosols: Effects

Stephen H. Schneider at the Center for Environment Science and Policy of the Institute for International Studies.

of Large Increases on Global Climate"), which examined the competing effects of cooling from aerosols and warming from CO_2. The paper, however, predicted that carbon dioxide would only have a minor role and warned about a large possible decrease of the Earth's temperature. In the late 1970s, Schneider modified his position stating that, at that time, it was not possible to be certain whether the climate was cooling or warming. In *The Genesis Strategy: Climate and Global Survival* (1976), he wrote that "consensus among scientists today would hold that a global increase in atmospheric aerosols would probably result in a cooling of the climate; however, a smaller but growing fraction of the current evidence suggests that it may have a warming effect."

It was with his 1989 book, *Global Warming: Are We Entering the Greenhouse Century?*, that Schneider became a main figure in scientific debates about human effects on the environment. In clear language exempt from academic jargon, Schneider argued his case for global warming. The burning of fossil fuels, he claimed, causes a buildup of greenhouse gases in the atmosphere. Those gases trap the solar energy reradiated by the earth that would otherwise escape into space. This phenomenon could have devastating effects such as droughts, more frequent and more powerful tropical storms, and a rise in sea level. Schneider believes that temperature change appears less noticeable than it would otherwise be thanks to the capacity of the oceans to absorb heat. He is persuaded of the necessity to improve climate models that will take fully into account the interactions between atmosphere and oceans.

Schneider has always tried to involve the public in his research and has frequently appeared in media events relating to environment. He has tried to popularize complex scientific ideas to make them more available to the larger public. This has earned him praise as well as criticism, as several of his colleagues have charged him with trying too hard to get media attention for himself and his ideas. Still others describe Schneider as an alarmist, as in their view, his statements are not always supported by evidence. Yet Schneider is aware that as a scientist he is ethically bound to tell the truth. At the same time, he is concerned that, to be effective, his ideas have to take hold of the public and its imagination. Schneider finds this a double ethical bind in which scientists frequently find themselves. This condition "cannot be solved by any formula. Each of us has to decide what the right balance is between being effective and being honest. I hope that means being both."

Schneider has served in many key positions as an academic and a policymaker. He has also received many honors for his research. He is the founder and editor of the journal *Climatic Change* and has authored or coauthored over 450 scientific papers, proceedings, legislative testimonies, edited books, and book chapters, as well as some 140 book reviews, editorials, published newspaper and magazine interviews and popularizations. He was a coordinating lead author in Working Group II IPCC TAR and is currently a coanchor of the Key Vulnerabilities Cross-Cutting Theme for the Fourth Assessment Report (AR4). For his ability to integrate and interpret the results of global climate research for both the academic community and the general public, Schneider was awarded the MacArthur Fellowship in 1992. For his furtherance of public understanding of environmental science and its implications for public policy, he also received, in 1991, the American Association for the Advancement of Science/Westinghouse Award for Public Understanding of Science and Technology. In 1998, he became a foreign member of the Academia Europaea, Earth and Cosmic Sciences Section. He was elected chair of the American Association for the Advancement of Science's Section on Atmospheric and Hydrospheric Sciences (1999–2001). Schneider was elected to membership in the U.S. National Academy of Sciences in April 2002.

Scripps Institute of Oceanography

SCRIPPS INSTITUTE OF Oceanography is the world's preeminent center for ocean and earth research, teaching, and public education. Also known as SIO, Scripps Institute of Oceanography is located in La Jolla, California. The mission of the institute is to seek, teach, and communicate scientific understanding of the oceans, atmosphere, Earth, and other planets for the benefit of society and the environment. A graduate school of the University of California, San Diego, Scripps's leadership in many scientific fields reflects its continuing commitment to excellence in research, modern facilities and ships, distinguished faculty, and outstanding students—and its horizons continue to expand. The institute offers a number of undergraduate and graduate courses in a variety of marine and earth science disciplines.

Research at Scripps encompasses physical, chemical, biological, geological, and geophysical studies. Ongoing investigations include the topography and composition of the seafloor, waves and currents, and the interchanges between the oceans and atmosphere. Scripps's research ships are used in investigations throughout the world's oceans. Today, the Scripps staff of 1,300 includes approximately 100 faculty, 300 other scientists, and some 225 graduate students, with an annual budget of more than $140 million. Other observations and collections are made by ocean devices, airplanes, remotely operated aircraft, land stations, and satellites. Scripps's educational program has grown hand in hand with its research programs. In its most recent survey of graduate schools, the National Research Council ranked Scripps the number one oceanographic program in faculty quality, distinction, and scholarly publications.

Instruction is on the graduate level, and students are admitted as candidates for a Ph.D. degree in oceanography, earth sciences, or marine biology. Academic work is conducted through the graduate department and eight curricular groups: biological oceanography, physical oceanography, marine biology, geological sciences, marine chemistry and geochemistry, geophysics, climate sciences, and applied ocean sciences.

The Scripps Institute of Oceanography department offers over 45 undergraduate courses covering a wide breadth of earth and marine sciences on several different levels. There are several introductory classes for nonmajors, as well as upper-division courses intended for a wide range of students in natural science majors. For students interested in careers in earth sciences, the Scripps Institute of Oceanography offers a B.S. degree and a contiguous B.S./M.S. degree in earth sciences. In addition, students may follow a chemistry/earth sciences major, a physics major with a specialization in earth sciences, or an environmental systems/earth sciences major. The program also offers an academic minor in earth sciences.

Scripps is one of the oldest and largest centers for global science research and graduate training in the world. More than 300 research programs are now conducted at the institute, aimed at gaining comprehensive understanding of the oceans, atmosphere, and structure of the Earth.

Oceanography, by its very nature, is interdisciplinary. It spans many sciences including physics, chemistry, geology, biology, meteorology, climatology, and paleontology. Scripps scientists pioneered exploration of the world's marine environments. They are leaders in studies of climate change, plate tectonics, ocean circulation, marine biology and ecology, marine pharmaceuticals, seafloor mapping, seismology, coastal processes, the El Niño phenomenon, biodiversity and conservation, and atmospheric sciences.

Graduate students play an integral role in the Scripps missions of teaching and research. Scripps offers excellent graduate instruction, and students perform a significant part of Scripps research activities. The stature of the institution is manifested in the quality both of the students it attracts to the program and of the scientists it graduates.

Climate sciences concerns the study of Earth's climate system, with emphasis on the physical, dynamic, and chemical interactions of the atmosphere, ocean, land, ice, and the terrestrial and marine biospheres. One of the central challenges is developing the ability to predict future climate changes, whether they are the consequences of human activities or the result of natural climatic cycles. A related challenge is understanding how and why the climate of the Earth has changed in the past.

To understand Earth's climate system requires understanding the mechanistic links between physical and chemical changes in the atmosphere (e.g., changes in winds, clouds, rainfall, sunlight, greenhouse gas abundance, or stratospheric ozone) and changes in the oceans (e.g., shifts in the current systems, temperature structure, or ocean biota), in the ice sheets (e.g., advances and retreats), and in land biota (e.g., changes in length of growing seasons or habitat range).

The climate system includes powerful feedback mechanisms. The amount of moisture in the atmosphere, for example, increases with global temperature, but the moisture also contributes to additional warming through the greenhouse effect. Scientists studying the climate system need experience in many disciplines, including meteorology, oceanography, geography, ecology, geology, and paleontology.

Observing the climate system depends increasingly on new measurement technologies, such as satellite and in situ measurements of the atmosphere, oceans, and land surface. These developments are enabling Scripps scientists to develop a more precise and detailed understanding of various conditions that affect climate, such as winds, ocean currents, clouds, and amount of vegetation.

Charles David Keeling, a professor of oceanography at Scripps, received the Tyler Prize for Environmental Achievement, which is awarded for accomplishments in environmental science, energy, and medicine that confer great benefit on mankind. Keeling, a world leader in research on the carbon cycle and the increase of carbon dioxide (CO_2) in the atmosphere, known to influence the greenhouse effect, has been affiliated with Scripps since 1956. Keeling was the first to confirm the accumulation of atmospheric carbon dioxide by very precise measurements that produced a data set now known widely as the Keeling curve. Before Keeling's investigations, it was unknown whether the oceans and vegetated areas on land would absorb any significant excess carbon dioxide from the atmosphere produced by the burning of fossil fuels and other industrial activities. Keeling became the first to determine definitively the fraction of carbon dioxide from combustion that is accumulating in the atmosphere.

Keeling's major areas of interest include the geochemistry of carbon and oxygen and other aspects of atmospheric chemistry, with an emphasis on the carbon cycle in nature. He has been a world leader in the study of the complex relationships between the carbon cycle and changes in climate. The Keeling record of the increase in atmospheric carbon dioxide measured at Mauna Loa, Hawaii, represents what many believe to be the most important time series data set for the study of global change.

Sea Ice

SEA ICE IS frozen ocean water. It forms primarily in and near the polar regions, though it can grow closer to the equator as far as 40 degrees N latitude and 55 degrees S latitude. Sea ice has a strong seasonal variability. In the Northern Hemisphere, the annual maximum extent occurs in late winter (March), covering about 5,791,532 sq. mi. (15 million sq. km.) on average. It then melts during spring and summer to an annual minimum extent of about 2,702,715 sq. mi. (7 million sq. km.) in September. In the Antarctic, the annual maximum is about 7,335,941 sq. mi. (19 million sq. km.) during September, and the annual minimum is about 1,158,306 sq. mi. (3 million sq. km.) in February or March. Overall, roughly 10 percent of the world's ocean area is covered with sea ice at some point during the year.

The point at which the ocean begins to freeze is a function of the salt content of the water, which for typical ocean salinities is around 29 degrees F (minus 1.6 degrees C). The saline nature of the ocean makes the formation of sea ice distinct from freshwater ice growth in lakes and rivers. Freshwater becomes less dense as it approaches the freezing point, keeping the coldest water at the surface and allowing ice to form as soon as the surface cools to the freezing point. However, the presence of salt changes the character of near-freezing water such that as saline water nears the freezing point, it continues to increase in density. Thus, cooling surface waters will become denser and sink. This means that there is overturning, and subsurface waters must also cool before ice can begin to form.

Sea ice typically grows to an average level thickness of 3 to 6 ft. (1 to 2 m.) in the Antarctic and 10 to 13 ft. (3 to 4 m.) in the Arctic. The ice is thinner in the Antarctic because most ice melts during the austral summer, whereas in the Arctic a significant fraction (~40 percent) remains through the summer and can grow over several years. A larger ocean heat flux at the bottom of the ice in the Antarctic also keeps the ice thinner.

However, thicker ice is not uncommon because of the effect of ice motion. Most sea ice is almost constantly in motion mainly because of the force of winds and ocean currents (other factors include the Coriolis effect, the slope of the ocean surface, and the internal structure of the ice). The speed of sea ice motion varies considerably; it can move 31 mi. (50 km.) or more in a day, though 1.2 mi. (2 km.) per day is typical. The motion of the ice can result in convergence between different parts of the ice cover, causing the ice to pile up into features called ridges. Ridges may easily rise 16 to 33 ft. (5 to 10 m.) above the surrounding level ice (and many tens of m. below the surface).

Sea ice plays an important role in climate. It has a much higher albedo than the unfrozen ocean, meaning that 60 to 70 percent of the sun's energy is reflected by the sea ice surface, whereas the unfrozen ocean reflects less than 10 percent of the sun's energy, resulting in much less energy absorption where ice is present. Sea ice is also a physical barrier between the ocean and atmosphere. This prevents the transfer of heat and moisture between the two and during winter. Thus, sea ice keeps the polar regions cooler and drier than they would be without ice. Sea ice also reduces fetch and dampens waves, limiting coastal erosion.

Sea ice has important effects on wildlife and human activities. Polar bears, seals, and other creatures rely on the ice to traverse and hunt, and during summer, the sea ice edge is a fertile area for phytoplankton and other microorganisms. Native communities in the Arctic are intimately tied into the presence of sea ice, and it plays an important role in their traditional culture and ways of life, such as hunting and transportation. Navigation of surface ships is severely limited or curtailed altogether, and for ships that do sail in or near ice-infested waters, it represents a significant hazard. Finally, sea ice plays a role in military operations, providing a useful cover for submarine activities.

Because of its location near the poles, the thin nature of the ice cover, and its interaction with the ocean and the atmosphere, sea ice is a sensitive indicator of the climate state. Sea ice in the Arctic has been decreasing dramatically over the past several decades. Overall, the Arctic has lost approximately 20 percent of the average summer ice extent since the late 1970s. Reductions during winter are less but are still significant. On the basis of current trends and projects by climate models, the Arctic may be ice free during summer by 2050 or earlier. This reduction in sea ice has been linked to warming temperatures resulting from the anthropogenic emission of greenhouse gases, though other factors also play a role. Unlike in the Arctic, there has been no significant trend seen in Southern Hemisphere ice, likely because of its remoteness relative to other continental land areas, the seasonal nature of the ice, and a greater ocean influence.

Changes in Arctic sea ice cover will have profound effects on climate, human activities, and wildlife, some of which are already being felt. Polar bears and other animals may be endangered, as well as the traditions of native communities. Less ice may also have benefits by opening up shipping routes and facilitating extraction of natural resources. Nonetheless, most effects are expected to be negative, and their implications for future climate will extend to regions far beyond the Arctic.

Sea Level, Rising

SEA LEVEL RISE is caused by thermal expansion of the oceans, melting of glaciers and ice caps, melting of the Greenland and Antarctic ice sheets, and changes in terrestrial storage. Changes in sea level will be felt through increases in the intensity and frequency of storm surges and coastal flooding; increased salinity of rivers, bays, and coastal aquifers resulting from saline intrusion; increased coastal erosion; loss of important mangroves and other wetlands (the exact response will depend on the balance between sedimentation and sea level change) and its effect on marine ecosystems (i.e., coral reefs).

Global sea level rose by about 394 ft. (120 m.) during the several millennia that followed the end of the last Ice Age (approximately 21,000 years ago) before stabilizing between 3,000 and 2,000 years ago. Sea level indicators suggest that global sea level did not change significantly from then until the late 19th century, when the instrumental record of modern sea level change shows evidence for onset of sea level rise. Estimates for the 20th century show that global average sea level rose at a rate of about 1.7 mm. per year.

Satellite observations available since the early 1990s provide more accurate sea level data with nearly global coverage. This decade-long satellite altimetry data set shows that since 1993, sea level has been rising at a rate of around 3 mm. per year—significantly higher than the average during the previous half century. Coastal tide gauge measurements confirm this observation and indicate that similar rates have occurred in some earlier decades.

Sea level rise is currently determined by the employment of two techniques: the use of tide gauges and satellite altimetry. Tide gauges provide sea level variations with respect to the land on which they lie. To extract the signal of sea level change resulting from ocean

The Lower Patuxent River in Maryland, showing the flooding of low-lying areas by extreme high tides. If climate change causes sea level to continue to rise, this type of flooding will become increasingly common.

water volume and other oceanographic change, land motions need to be removed from the tide gauge measurement. Sea-level change based on satellite altimetry is measured with respect to the Earth's center of mass and thus is not distorted by land motions, except for a small component resulting from large-scale deformation of ocean basins. The total 20th-century rise is estimated to be around 0.5 ft. (0.17 m.).

Sea-level rise is accelerating worldwide. Globally, 100 million people live within about 3 mi. (1 m.) of sea level. Eight to 10 million people live within 3 mi. (1 m.) of high tide in each of the unprotected river deltas of Bangladesh, Egypt, and Vietnam. Intergovernmental Panel on Climate Change (IPCC) reports estimate that the global average sea-level rose at an average rate of 1.8 (1.3–2.3) mm. per year between 1961 and 2003, and within that period, the rate of rise was faster between 1993 and 2003—about 3.1 (2.4–3.8) mm. per year. Overall, the IPCC concludes that there is high confidence that the rate of observed sea-level rise has risen from the 19th to the 20th century. The total 20th-century rise is estimated to be 0.17 (0.12–0.22) m. In 2001, IPCC projections were for a sea-level rise of between 9 and 88 cm. between 1990 and 2100 and a global average surface temperature rise of between 2.5–10.4 degrees F (1.4–5.8 degrees C). In 2007, IPCC projections based on different scenarios predict seal level rise from 0.18 to up to 0.59 mm. by 2099.

Toward the end of the 21st century, projected sea-level rise will affect low-lying coastal areas with large populations. The cost of adaptation could amount to at least 5 to 10 percent of gross domestic product. Mangroves and coral reefs are projected to be further degraded, with additional consequences for fisheries and tourism. Snowmelt runoff as a result of sea-level rise will have major consequences. For example, one change will be a change from spring peak flows to late winter peaks in snowmelt–dominated regions. Many species, both aquatic and riparian (i.e., riverine), have evolved to take opportunity of the spring flows as a result of snowmelt. For example, some fish time their reproduction strategies specifically to avoid the stress of springtime flows. Changes in springtime flow regimes, or high winter flows associated with rain or snow events, can scour streambeds and destroy eggs. Trees that provide riparian habitat along rivers may find it harder to reproduce, as they are dependent on high spring flows. Many species, such as salmon, that are already under pressure from other environmental effects will be significantly affected by climate change. For example, higher temperatures and a reduced stream flow in the Columbia River Basin may be increasing the mortality of juvenile coho salmon, or in some cases, increased temperatures may be creating thermal barriers for the migration of adult salmon.

There are a number of associated events that are the result of climate change and that will also have affects on sea-level rise. For example, the Kangerdlugssuaq Glacier in Greenland is moving much faster, now melting at a rate of 8.7 mi. (14 km.) a year in comparison to just 3 m. (5 km.) a year in 1988. This loss will also have serious implications for sea-level rise, with some scientists predicting that within the next 100 years, ice cover in this region will completely disappear over summer, and hence species living within it, such as polar bears, will be threatened. The complete melting of the Greenland Ice Sheet and the West Antarctic Ice Sheet would lead to a contribution to sea-level rise of up to 23 ft. and about 16 ft. (7m. and 5 m.), respectively.

The potential socioeconomic impacts of sea-level rise are as follows: direct loss of economic, ecological, cultural, and subsistence values through loss of land, infrastructure, and coastal habitats. For example, it is estimated that the total of people at risk of sea-level rise in Bangladesh could be 26 million, in Egypt 12 million, in China 73 million, in India 20 million, and elsewhere 31 million. This makes an aggregate total of 162 million people affected by sea-level rise. There will be an increased flood risk for people, land, and infrastructure. There will be other affects related to changes in water management, salinity, and biological activities. A rise in sea level would inundate wetlands and lowlands, accelerate coastal erosion, exacerbate coastal flooding, threaten coastal structures, raise water tables, and increase the salinity of rivers, bays, and aquifers. Similarly, the areas vulnerable to erosion and flooding are also predominantly located in the southeast, whereas potential salinity problems are spread more evenly throughout the coast. Such a loss would reduce available habitat for birds and juvenile fish and would reduce the production of organic materials on which estuarine fish rely.

Some of the most important vulnerable areas are recreational barrier islands and spits such as found within the Atlantic and Gulf coasts. Coastal barriers are generally long narrow islands and spits (peninsulas) with the ocean on one side and a bay on the other.

Typically, the ocean-front block of an island ranges from 6.5 ft. to 13 ft. (2 to 4 m.) above high tide, whereas the bay side is less than a meter above high water. Thus, even a 1-m. rise in sea level would threaten much of this valuable land with inundation. Erosion, moreover, threatens the high parts of these islands and is generally viewed as a more immediate problem than the inundation of their bay sides. Although inundation alone is determined by the slope of the land just above the water, coastal engineer Per Bruun showed that the total shoreline retreat from a rise in sea level depends on the average slope of the entire beach profile. For example, most U.S. recreational beaches are less than 30 m. (100 ft.) wide at high tide, thus even a 30-cm. (1-foot) rise in sea level would require a response.

Finally, a rise in sea level would enable saltwater to penetrate farther inland and upstream in rivers, bays, wetlands, and aquifers, which would be harmful to some aquatic plants and animals and would threaten human uses of water. In Delaware in the United States, for example, salinity is seen as a factor resulting in reduced oyster harvests.

Coastal areas worldwide will become more vulnerable to flooding as a result of sea-level rise because higher sea levels provide higher bases for storm surges to build on. In this context, a 1-meter rise in sea level would mean that a 15-year storm will flood many areas that today are only flooded by a 100-year storm. Beach erosion will make land more vulnerable to storm waves, and higher water levels will increase the effects of flooding caused by rainstorms by reducing coastal drainage. Sea level will also raise water tables in various systems.

There are many examples of nations vulnerable to sea level rise. Japan, for instance, is particularly vulnerable to the effects of sea-level rise; a 1-meter rise in sea level would increase the area situated below mean high water from 332 sq. mi. to 903 sq. mi. (861 sq. km. to 2340 sq. km.). Future estimates show this would affect up to 4.1 million people and cost 109 trillion Yen ($1,300 billion). Over 57 and 90 percent of the existing sandy beaches would be eroded by sea-level rises of 0.3 and 1.0 m., respectively. In response, Japan has initiated a new coastal policy that combines disaster prevention, human resource use, and nature conservation. This policy includes an increase in monitoring of changes in mean sea level and the frequency of extreme events, the consideration of climate-change scenarios when developing plans for ports and landfills, and the preparation of a set of technological countermeasures to prevent effects on port facilities and maintain coastal protection.

Egypt's Nile Delta is one of the world's areas most vulnerable to sea-level rise. It is estimated that about 30 percent of the area will be lost because of inundation, almost 2 million people will lose their homes, and approximately 195,000 jobs will be lost, with a predicted economic impact of over US$3.5 billion over the next century.

In the chapter on coasts, the United Nations Environment Programme Handbook on Adaptation and Mitigation Methodologies specifically outlines a suite of strategic responses to sea-level rise. It cautions, however, that before applying these strategies, policymakers must decide whether or not their adaptation is to be autonomous or planned, reactive or proactive.

There are three management responses to sea-level rise: retreat, accommodation, and protection. Retreat involves no effort to protect the land from the sea. The coastal zone is abandoned, and ecosystems shift landward. This choice can be motivated by excessive economic or environmental effects of protection. In the extreme case, an entire area may be abandoned.

Accommodation implies that people continue to use the land at risk but do not attempt to prevent the land from being flooded. This option includes erecting emergency flood shelters, elevating buildings on piles, converting agriculture to fish farming, or growing flood- or salt-tolerant crops.

Protection involves hard structures such as sea walls and dikes, as well as soft solutions such as dunes and vegetation, to protect the land from the sea so that existing land uses can continue.

Seasonal Cycle

THERE ARE SEVERAL versions of seasons. The classical concept of season is of the four seasons that divide the year—spring, summer, fall, and winter. Some regions of the globe have weather-based seasons, such as rainy or dry seasons. Certain natural occurrences are more frequent during particular times of year; therefore, we have hurricane season as well as tornado season.

Seasonal cycles for weather patterns occur because of the atmosphere. Although the atmosphere is hundreds of miles thick, weather occurs in the base 7 mi. (11 km.), called the troposphere. Wind patterns in the troposphere are affected by the earth's rotation. This pattern is stereotypical and is the cause for seasonal cycles such as monsoon season in the northern Indian Ocean.

Other seasonal cycles include patterned flooding of rivers, such as the Nile River in Egypt. Ancient Egyptians utilized flood patterns for agriculture; today many cultures try to alter flood patterns. For example, the Colorado River floods created the Grand Canyon; today those floods no longer occur, due to dams and rerouting of the river.

A well-known example of a seasonal cycle is El Niño. It usually occurs in late December, around Christmas; hence it was named with the word for "child" in Spanish. El Niño is a warm ocean current, typically based off of Australia, that once every three to five years travels northeast towards Ecuador and Peru. Its opposite cycle, La Niña, contains cooler winds. Additionally, El Niño weakens trade winds, while La Niña brings stronger trade winds.

Tornados typically follow a seasonal cycle as well. They usually occur in the spring, yet they can happen at any time. Tornados occur when warm air at the surface of the earth rises quickly, and for a long distance. Air that is actively warmed at the surface, as occurs during the spring, is more buoyant and more likely to form a tornado.

Although hurricanes can form year-round, June 1 through November 30 is officially the Hurricane Season on the Atlantic coast of the United States. Hurricanes generally arise in the Caribbean and travel westward to the coast. Typically during these months, the most frequent type of storm is a tropical storm. Hurricanes are more frequent in the months of August, September, and October; however, severe hurricanes are usually limited to September, the midpoint of hurricane season.

Seawater, Composition of

SEAWATER IS A solution of salts of nearly constant composition, dissolved in variable amounts of water. It is denser than fresh water. It is risky to drink seawater because of its high salt content. More water is required to eliminate the salt through excretion than the amount of water that is gained from drinking the seawater. Seawater can be turned into potable water by desalination processes or by diluting it with freshwater. The origin of sea salt is traced to Sir Edmond Halley, who in 1715 proposed that salt and other minerals were carried into the sea by rivers, having been leached out of the ground by rainfall runoff. On reaching the ocean, these salts would be retained and concentrated as the process of evaporation removed the water. There are more than 70 elements dissolved in seawater as ions, but only six make up more than 99 percent of all the dissolved salts; namely, chloride (55.04 weight percent [wt%]), sodium (30.61 wt%), sulphate (7.68 wt%), magnesium (3.69 wt%), calcium (1.16 wt%), and potassium (1.10 wt%). Trace elements in seawater include manganese, lead, gold, and iodine. Biologically important elements such as oxygen, nitrogen, and iron occur in variable concentrations depending on utilization by organisms. Most of the elements occur in parts per million or parts per billion concentrations and are important to some positive and negative biochemical reactions. Properties such as salinity, density, and pH could be used to highlight the composition of seawater.

Salinity is the amount of total dissolved salts present in 1 L. of water and is used to express the salt content of seawater. Normal seawater has a salinity of 35 g./L. of water; that is, 3.5 percent. The salinity of seawater is made up by the dissolved salts. Seawater is more enriched in dissolved ions of all types than freshwater. Salts dissolved in seawater come from three main sources: volcanic eruptions, chemical reactions between seawater and hot newly formed volcanic rocks of spreading zones, and chemical weathering of rocks. Because of some chemical reactions between seawater and hot newly formed volcanic rocks, the composition of seawater has been nearly constant over time. Salinity affects marine organisms because the process of osmosis transports water toward a higher concentration through cell walls. Marine plants and many lower organisms have no mechanism to control osmosis, which makes them very sensitive to the salinity of the water in which they live. The density of surface seawater ranges from 1,020 kg. per cu. m. to 1,029 kg. per cu. m., depending on the temperature and salinity: the saltier the water, the higher its density. Seawater pH is limited to the range from 7.5 to 8.4 and increases with phytoplankton production. The speed of sound in seawater is about about 4,921 ft. (or 1,500 m.) per second and varies with water temperature and pressure.

Carbon (IV) oxide in the sea exists in equilibrium with that of exposed rock containing limestone ($CaCO_3$). Seawater also contains small amounts of dissolved gases such as nitrogen, oxygen, carbon (IV) oxide, hydrogen, and trace gases. Water at a given temperature and salinity is saturated with gas when the amount of gas entering the water equals the amount leaving during the same time. Surface seawater is normally saturated with atmospheric gases such as oxygen and nitrogen. The concentrations of oxygen and carbon (IV) oxide vary with depth. The surface layers are rich in oxygen, which reduces quickly with depth to reach a minimum between 656 and 2,625 ft. (200 and 800 m.) in depth. The amount of gas that can dissolve in seawater is determined by the water's temperature and salinity. Increasing the temperature or salinity reduces the amount of gas that can be dissolved. As water temperature increases, the increased mobility of gas molecules makes them escape from the water, thereby reducing the amount of gas dissolved. The gases dissolved in seawater are in constant equilibrium with the atmosphere, but their relative concentrations depend on each gas' solubility. As salinity increases, the amount of gas dissolved decreases because more water molecules are immobilized by the salt ion. Inert gases like nitrogen and argon do not take part in the processes of life and are thus not affected by plant and animal life, but gases like oxygen and carbon (IV) oxide are influenced by sea life. Plants reduce the concentration of carbon (IV) oxide in the presence of sunlight, whereas animals do the opposite in either light or darkness.

The world under water is different from that above in the availability of important gases such as oxygen and carbon (IV) oxide. Whereas in air about one in five molecules is oxygen, in seawater this is only about four in every thousand million water molecules. Whereas air contains about one carbon (IV) oxide molecule in 3,000 air molecules, in seawater this ratio becomes four in every 100 million water molecules. Thus, carbon (IV) oxide is much more available in seawater than is oxygen. All gases are less soluble as temperature increases, and particularly nitrogen, oxygen, and carbon (IV) oxide, which become about 40 percent to 50 percent less soluble with an increase of 45 degrees F (25 degrees C). When water is warmed, it becomes more saturated, resulting in bubbles leaving the liquid.

Senegal

THIS WEST AFRICAN country, formerly a French colony, has a land area of 75,955 sq. mi. (196,723 sq. km.), with a population of 12,379,000 (2006 est.) and a population density of 153 people per sq. mi. (59 people per sq. km.). Some 31 percent of the country is forested, with 12 percent being arable and a further 16 percent being used for meadows or pasture, mainly for cattle and sheep.

Senegal's entire electricity production comes from fossil fuels. The country has maintained a relatively stable level of carbon dioxide emissions from 0.4 metric tons per capita in 1990, rising to 0.44 metric tons by 2003. About 85 percent of this carbon dioxide comes from liquid fuels, with the remainder coming from cement manufacturing. In terms of sectors, that covering electricity and heat production accounts for 38 percent of carbon dioxide emissions, with 33 percent from transportation, 18 percent from manufacturing and construction, and 10 percent for private residences. The high level of emissions from transportation comes from the lack of adequate public transport systems and the heavy use of old minibuses, which have inefficient fuel usage rates. Although there is a railway in Senegal, connecting Dakar with Bamako, the capital of Mali, few people use it for travel within the country.

The effects of climate change and global warming will result in potential flooding on the Atlantic coast of the country. This has already led to coastal erosion in some parts of the country, with illegal mining adding to this problem, especially around Malika and Rufisque to the north of the Cap Vert peninsula. A rise in temperature will lead to more arable land becoming marginal, and probably to increased desertification. The Senegal government of Abdou Diouf took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention in the following year. On July 20, 2001, Senegal signed the Kyoto Protocol to the

Net fishing in Nianing, near Dakar, Senegal. Senegal has experienced coastal erosion in some areas.

UN Framework Convention on Climate Change, with it entering into force on February 16, 2005.

Serbia and Montenegro

SERBIA AND MONTENEGRO are two of six independent countries that formed after the disintegration of the former Yugoslavia in the early 1990s. These two countries neighbor each other in eastern Europe and cover geographic regions with diverse climates. Serbia is landlocked and geographically positioned in the region of mild continental climate, whereas Montenegro also has a coastal region with a Mediterranean climate. Both countries have significant local climate variations resulting from local atmospheric circulations, as well as mountainous and hilly terrain away from Montenegro's Adriatic coast. In general, the subalpine climate with short cold winters and relatively hot summers is typical for elevations of from 2,000 ft. (600 m.) to 4,000 ft. (1,200 m.), and the Alpine climate with long and snowy winters and short warm summers is characteristic for elevations above 4,000 ft. (1,200 m.).

The capital of Serbia is Belgrade. Belgrade has a moderate continental climate that has hot summers, cold winters, and moderate precipitation. The yearly average temperature in Belgrade is around 53.1 degrees F (11.7 degrees C). The capital of Montenegro is Podgorica. Podgorica has a Mediterranean climate that has dry and hot summers, as well as rainy and mild winters, resulting in yearly average temperature of 61.5 degrees F (16.4 degrees C). In the summer, the temperatures in both capital cities go over 104 degrees F (40 degrees C). Interestingly, a town in the costal region of Montenegro has the highest yearly average rainfall in Europe of 183 in. (465 cm.). Nevertheless, the inland regions of these counties have been in "on" and "off" drought conditions resulting from extremely hot summers and unusually low rainfalls and snowfalls since 2000. These drought problems are characteristic for the entire region of the eastern part of Europe, with the drought in 2007 being particularly severe.

Seychelles

THIS COUNTRY CONSISTS of 115 islands spread over 250,966 sq. mi. (650,000 sq. km.) of ocean and has a land area of 176 sq. mi. (451 sq. km.), with a population of 87,000 (2006 est.) and a population density of 458 people per sq. mi. (178 people per sq. km.). With 18 percent of the land forested, 2 percent is arable, and 13 percent is used for meadows and pasture.

The entire electricity production of the country comes from fossil fuels, and the country, largely because of this and a burgeoning luxury tourist industry, has a relatively high level of per capita carbon dioxide emissions. Although it was 1.6 metric tons per person in 1990, it has risen steadily, reaching 2.6 metric tons in 1996, and then, with a massive rise in tourist numbers, rose to 5.5 metric tons per person in 1997, rising again to 6.9 metric tons in 2003. All the carbon dioxide emissions of the country come from liquid fuels, with most of this resulting from little availability of public transport and heavy use of gasoline-operated generators.

The rising water levels and temperatures in the Indian Ocean are likely to have dramatic effects on Seychelles. The former might lead to the loss of some of the smaller islands in the Seychelles, and the latter has led to some coral bleaching, affecting some of the coral reefs around the Seychelles, along with its marine life. As a result, many of them are heavily protected, with the government keen on promoting ecotourism and with money from tourists being invested in environmental protection. This has been particularly true of Cousine Island in the Seychelles, where there have been serious attempts to protect the turtles breeding there and prevent soil erosion.

In 1990, the Seychelles drew up a 10-year environmental management plan, being the first African country to do this. The Seychelles government of France-Albert René took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992, and in the following year ratified the Vienna Convention. The government signed Kyoto Protocol to the UN Framework Convention on Climate Change on March 20, 1998, which was then ratified on July 22, 2002, with it entering into force on February 16, 2005.

Sierra Leone

SIERRA LEONE IS on the West African coast, covering 27,699 sq. mi. (71,740 sq. km.), which is equivalent to an area the size of South Carolina. Sierra Leone has a population of 6,017,643 people (est. in July 2005), with nearly one million people living in the capital, Freetown. Sierra Leone was the lowest ranking, among 177 countries surveyed, in the United Nations Human Development Indicators (2006), in part because of an 11-year civil war (1991–2002) that resulted in 50,000 deaths and the displacement of 2 million people. The civil war also accelerated the depletion of natural resources including diamonds, tropical timber, and wild game. Sierra Leone has a per capita gross domestic product of $600 (2004 est.), with 68 percent of the population living in poverty, most of whom are subsistence farmers. Products of economic significance to the country include cocoa, coffee, rice, palm oil, and fish. Alluvial diamond mining is the major source of hard currency earnings, whereas other extracted minerals include titanium ore, bauxite, iron ore, gold, and chromite. The geography is characterized by coastal mangrove swamps and wooded uplands inland, and the climate is tropical. Four environmental issues facing the country are overharvesting of tropical timber, clearing of forests for cattle grazing, deforestation and related soil erosion, and overfishing.

The contributions that Sierra Leone makes to human-induced climate change are minimal compared with the rest of sub-Saharan Africa. Per capita CO_2 emissions in 1998 were only 100 metric tons, compared with an average of 800 tons for the subcontinent and a global average of 4,100 metric tons. The burning of liquid fuels (petroleum products) represented 90 percent of the country's CO_2 emissions. Other non-CO_2 air pollution in Sierra Leone is low compared with the rest of the continent and the world. Nitrogen oxide and carbon monoxide emissions (in 1995) were 64,000 and 1,380,000 metric tons, respectively, making up just 0.007 and 0.008 percent of the totals for sub-Saharan Africa.

Climate change could have significant consequences on the people and the environment in Sierra Leone. With 248.5 mi. (400 km.) of coastline, significant areas, including the capital, could become more prone to flooding. A rising sea level would also destroy the extensive network of mangrove forests that covers much of the coastline. Climatic change leading to a shortened rainy season, especially inland, could facilitate the conversion of tropical forests to grazing land for livestock. With these land-use changes could come new diseases, as well as the elimination of others. For example, Lassa fever, which is endemic to the rainforest along the eastern border, could disappear with changes in climate and landscapes. However, the intensification of rainfall could accelerate soil erosion and instigate flash flooding (which is already a problem in Freetown), threatening people and their livelihoods.

Simulation and Predictability of Seasonal and Interannual Variations

MEASUREMENTS OF CHANGES in atmospheric molecular oxygen using a new itechnique shows that the oxygen content of air varies seasonally in both the Northern and Southern Hemispheres, and is decreasing from year to year. The seasonal variations provide a new basis for estimating global rates of biological organic carbon production in the ocean, and the interannual decrease constrains estimates of the rate of anthropogenic CO_2 uptake by the oceans.

One example of research into variations are the interannual and interdecadal zooplankton population changes that have been observed in parallel with temperature (SST) changes at Helgoland, in the North Sea, over a period of 32 years.

Temperature determines the phenological timing of populations for each species in a unique way as to be seen in multiannual regressions. Sign, inclination of the regressions of phenophases with temperature and determination coefficient vary from species to species. Besides the limited predictability of annual temperature dynamics the species specificity limits the predictability of future phenophase timing. However, the strong correlation of phenophase timing with preceding SST permits the prediction of the annual seasonality based on statistical models separately for each population.

The regressions determined in the correlation analyses are the first approach to the phenological prognoses which the the Senckenberg Research Institute calculates daily for 192 phenophases of zooplankton including ichthyoplankton on a daily basis and which it publishes since April 2004 on the home page of the institute at www.senckenberg.de/dzmb/plankton. The calculations are based on more than 30 years of weekly and more frequent sampling at Helgoland Roads (54°11'18" N 7°54' E), the only proper offshore island of the North Sea. Temperatures were provided by the Biologische Anstalt Helgoland and the German Weather Service. Beyond the historic data used, current temperature measurements for the operative daily calculations are obtained from the websites. They are corrected according to the historic deviations stemming from current temperature measurements for the position at Helgoland Roads, published on the internet and weather report measurements and are then used for the calculation of the minimum current error for phenophase prediction. The prognoses is exclusively restricted to temporal prognoses. Abundance predictions are not included.

Singapore

THE REPUBLIC OF Singapore covers the main island of Singapore and 57 outlying islands, most of which are uninhabited. It covers a land area of 270 sq. mi. (704 sq. km.) and has a total population of 4,680,600 (July 2003 est.). This means that Singapore has one of the highest population densities in the world—more than 17,335 people per sq. mi. (6425 people per sq. km.). Combined with a high standard of living, Singapore has a high per capita emission level of carbon dioxide, with 15 metric tons of carbon dioxide per capita in 1990, rising to 19.1 metric tons in 1994 and then falling to 16.8 metric tons in 1997, after which date it has fallen significantly, reaching 11.3 metric

The Tanjong container port in Singapore. Singapore is the busiest port in the world in terms of tonnage shipped, and has a population of over 4.5 million people. It is noted for business, finance, manufacturing, exports, refining, and imports.

tons in 2003. Some 98 percent of the carbon dioxide emissions come from liquid fuel, with the remainder being from the manufacture of cement.

Many of the problems associated with global warming are prominent in Singapore, which has a large urban area and increasingly smaller wooded areas. The heavy usage of electricity has come from widespread use of air conditioners, as Singapore is located in the tropics. Not only found in homes and offices, the air conditioning of shops and shopping centers has resulted in significant levels of carbon dioxide emissions, as has heavy economic reliance on industrial development and oil refineries. Another very important contributing factor has been the tourist industry, which involves well over 7 million tourists visiting the country each year—the vast majority of them arriving by airplane, with the consequent effects on the ozone layer; Singapore's Changi airport is one of the busiest airports in the world.

As shown by its reduction in carbon emissions in recent years, Singapore has long been aware of the problems faced by the government. As early as 1963, Singapore's prime minister, Lee Kuan Yew, launched a "Garden City" program that encouraged the planting of trees and also the incorporation of grass verges, trees, and parks into city developments. Emphasis was made on local flora, and the project was extremely successful. The ministry of the environment was formed in 1972, with Lim Kim San as the minister, himself being succeeded by Edmund William "Eddie" Barker, who remained minister until 1979. Recent ministers have included Mah Bow Tan; Yeo Cheow Tong, who was joint minister of health and environment from 1997 to 1999; Lee Yok Suan; Lim Swee Say, acting minister and then minister; and Dr. Ibrahim Yaacob, who presided over the new ministry of the environment and water resources from 2004, reflecting the importance of water in the long-term development of Singapore.

On the international scene, Singapore has been a member of the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in 1992, and also ratified the Kyoto Protocol to the UN Framework Convention on Climate Change on April 12, 2006, coming into force on July 11, 2006.

The smog found in Singapore in 1999 and some succeeding years following the burn-off of forests in Sumatra has led to Singapore doing much to help combat global warming. There are limitations on the use of private automobiles, with the cost of running a car being high, and extra charges to alleviate city congestion. Combined with this there has been one of the best integrated transport systems in the world, with heavy public use of buses and trains (mass rapid transport), including an efficient bus and train service to neighboring Malaysia. In the center of Singapore island, and over to the northwest, there have been reforestation programs, especially on Bukit Batok and around the water reservoirs.

Singer, S. Fred (1924–)

CONTROVERSIAL ATMOSPHERIC PHYSICIST, distinguished research professor at George Mason University, emeritus professor of environmental science at the University of Virginia, and founder of the Science and Environmental Policy Project—a policy institution on climate change and environmental issues, S. Fred Singer has been a leading skeptic of the scientific consensus on global warming. He points out that the scenarios pictured by most scientists are alarmist, that computer models reflect real gaps in climate knowledge, and says that future warming will be inconsequential or modest at most. He has also challenged the connection between ultraviolet-B radiation and melanoma and between secondhand smoking and lung cancer. Singer's critics have pointed out that the financial ties of his nonprofit organizations to tobacco and oil companies make Singer a case of clear conflict of interest.

Dr. Singer was born in Vienna on September 27, 1924. He did his undergraduate work in electrical engineering at Ohio State University and holds a Ph.D. in physics from Princeton University. He has served in numerous government and academic positions such as acting as director of the Center for Atmospheric and Space Physics at the University of Maryland (1953–62); as special adviser to President Eisenhower on space developments (1960); as first director of the National Weather Satellite Service (1962–64); as founding dean of the School of Environmental and Planetary Sciences at the University of Miami (1964–67); as deputy assistant secretary for water quality and research, U.S. Department of the Interior (1967–70); as deputy assistant administrator for policy, U.S. Environmental Protection Agency (1970–71); as professor of environmental sciences, University of Virginia (1971–94), and as chief scientist, U.S. Department of Transportation (1987–89).

To Singer, climate change is not something humans should fear. He argues that the climate has changed constantly throughout this and previous centuries and that people have always successfully adapted to it. In addition, he believes that humans can affect climate at a local level. Yet, whether they can cause global weather changes has still to be proved. Singer has repeatedly claimed that the atmosphere has not warmed up in recent decades. In fact, he has claimed that since 1979, it has slightly cooled down. Surface records that show increases in temperature are not, according to Singer, reliable sources of information, as thermometers tend to be placed in or very near to urban areas, which are traditionally warmer than other locations. Singer claims that models and observations about global warming do not agree. Although climatic models show that there should be an increase of about 1 degree F per decade in the middle troposphere, observations contradict these models. Singer is critical of arguments based on laboratory experiments, as the atmosphere is much more complicated and does not function under controlled circumstances. He recognizes that the increase in atmospheric CO_2 might lead to a slight warming, yet he says that this phenomenon is counterbalanced by increased evaporation of the oceans. The production of aerosols also causes cooling, which may counterbalance the effects of carbon dioxide. Yet, although Singer admits that aerosols last for a maximum of few weeks but CO_2 stays for decades, he is critical of models emphasizing the role of aerosols in connection to carbon dioxide.

Singer argues that because aerosols are mostly emitted in the Northern Hemisphere, where industrial activities are rampant, we would expect the Northern Hemisphere to be warming less quickly than the Southern Hemisphere. Actually, according to such models, the Northern Hemisphere should be cooling. To him, however, the data show the opposite, as both the surface data and the satellite data agree that, in the last 20 years, the Northern Hemisphere has warmed more quickly than the Southern Hemisphere. This fact contradicts the whole idea that aerosols make an important difference and proves that aerosols cannot be invoked as an explanation for the discrepancies between models and observations.

Singer does not have much faith in computer models, which he describes as having been "tweaked" to produce the present climate and the present short-term variation. He also points out that the two dozen models presently used are not entirely consistent with each other. These models also fail to depict all types of clouds, which to Singer is a fundamental flaw. He compares the current concern over global warming and the urgent calls for action to buying insurance with a high premium against a risk that is small. The Kyoto Protocol, to Singer, is part of the high insurance premium. The reduction of energy use by about 35 percent within 10 years implies, according to Singer's estimate, giving up one-third of all energy use, using one-third less electricity, and demolishing one-third of all cars. In spite of accusations aimed at other scientists that they use an apocalyptic tone when describing global warming, Singer too uses apocalyptic overtones to describe the Kyoto scenario: "It would be a huge dislocation of our economy, and it would hit people very hard, particularly people who can least afford it."

To Singer, global warming is a big business, with governments pumping about $2 billion into climate research. Thus people have to justify this expenditure, which supports jobs and research. Yet George Monbiot has emphasized that Singer has strong ties with oil and tobacco company—a fact that constitutes a conflict of interest given his stance on CO_2 emissions and secondhand smoking: "In March 1993, APCO sent a memo to Ellen Merlo, the vice president of Philip Morris, who had just commissioned it to fight the Environmental Protection Agency: 'As you know, we have been working with Dr. Fred Singer and Dr. Dwight Lee, who have authored articles on junk science and indoor air quality (IAQ) respectively.'" Singer's Science and Environmental Policy Project also received multiple grants from ExxonMobil.

Slovakia

LOCATED IN CENTRAL Europe, formerly the eastern part of Czechoslovakia, Slovakia has a land area of 18,932 sq. mi. (49,035 sq. km.), with a population of 5,390,000 (2006 est.) and a population density of 287 people per sq. mi. (111 people per sq. km.). A strongly agricultural country, some 31 percent of Slovakia's land is used for arable purposes, with an additional 17 percent used for meadows and pasture.

In terms of its per capita carbon dioxide emissions, Slovakia ranks 56th in the world, with 8.1 metric tons of emissions per person in 1992, falling to 7 metric tons in 2003. Slovakia sources 35.3 percent of its electricity production from fossil fuels, with 47.6 percent nuclear power and 17.1 percent from hydro power. Because of the heavy use of coal, solid fuels account for 45 percent of the carbon dioxide emissions in the country, with 34 percent from gaseous fuels, 17 percent from liquid fuels (reflecting the fact that transportation accounts for 12 percent of emissions), and the remaining 4 percent from cement manufacturing. The high amount of fossil fuels used in electricity also shows itself in the emissions by sector, with 32 percent of emissions from electricity and heat production and 43 percent from manufacturing and construction. The fossil fuels also account for the nation's relatively high sulfur dioxide and carbon monoxide emissions.

The Slovakian government took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention in 1993. The government signed the Kyoto Protocol to the UN Framework Convention on Climate Change on February 26, 1999, ratified it on May 341, 2002, and entered into force on February 16, 2005.

Independent Scholar

Slovenia

LOCATED IN THE Balkans, and formerly one of the constituent parts of Yugoslavia, Slovenia has a land area of 7,827 sq. mi. (20,251 sq. km.), with a population of 2,030,000 (2006 est.) and a population density of 251 people per sq. mi. (99 people per sq. km.). About 12 percent of the country is arable, with a further 24 percent covered in meadows and pasture and 54 percent in forests.

In spite of its large amount of forestry, because of its high standard of living, Slovenia ranks 50th in the world in terms of its per capita carbon monoxide emissions, with 6.3 metric tons per person in 1992, falling to 5.5 metric tons in 1994 and then rising dramatically to 7.1 metric tons in 1995 before reaching a peak of 8.1 metric tons in 1997, falling slightly to 7.8 metric tons in 2003. Heavily reliant on nuclear power from the nuclear power plant at Krsko in Dolenjska, which accounts for 35.4 percent of the country's electricity production, 34.9 percent of the electricity comes from fossil fuels and 29.4 percent from hydropower. There is heavy use of fossil fuels, especially by the thermal electric power stations using coal to provide electricity for Ljubljana, the capital, and also Sostanj and Trbovlje. This results in electricity and heat production accounting for 42 percent of the country's carbon dioxide emissions.

Apart from electricity generation, there is also heavy use of private automobiles, with 365 vehicles per 1,000 people, similar to the proportions in Germany and the United Kingdom. This leads to regular traffic congestion, especially on roads around Ljubljana and Celje, Koper, and Maribor. Combined with relatively cheap petroleum, compared with prices in Western Europe, this has resulted in transportation contributing 28 percent of all carbon dioxide emissions by sector and 48 percent of emissions by source. This is in spite of the country's small size and an excellent public transport network, with an electrified train network run by Slovenske Zeleznice; the five steam trains are maintained solely for occasional journeys for tourists. In addition, there is an extensive bus network.

The effects of global warming and climate change on the country have been seen first with higher temperatures resulting in the melting of the snow in the mountains, limiting the periods available for skiing and beginning to affect arable crop production. To combat this, the government has succeeded in reducing sulphur dioxide emissions by half between 1985 and 1995 and also in reducing nitrogen oxide emissions by 20 percent. The Slovenian government took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May

1992, ratifying the Vienna Convention in the same year. In 1999, the government drew up a National Environmental Protection Program, and although it signed the Kyoto Protocol to the UN Framework Convention on Climate Change on October 21, 1998, it was not ratified until August 2, 2002, and entered into force on February 16, 2005.

Smagorinsky, Joseph (1924–2005)

AMERICAN METEOROLOGIST AND the first director of the National Oceanic and Atmospheric Administration's Geophysical Fluid Dynamics Laboratory (GFDL), Joseph Smagorinsky developed influential methods for predicting weather and climate conditions and lectured at Princeton for many years. With his decision to move the GFDL to Princeton, Smagorinsky made the university a leading center for the study of global warming.

Joseph Smagorinsky was born to Nathan Smagorinsky and Dina Azaroff. His parents were from Gomel, Belarus, but fled during the pogroms. Smagorinsky's father was the first to immigrate to the United States in 1913, settling in Manhattan's Lower East Side, where he opened a paint store. Three years later, he was joined by his wife and their children. Joseph was born on January 29, 1924, when the family was already living in the United States. Similar to his other three brothers, he worked in his father's paint store. He attended Stuyvesant High School for Math and Science in Manhattan. After high school, he expressed his wish not to stay in the family business and to go to college instead. As his intellectual skills had already become apparent, the whole family decided to support him in his decision. Smagorinsky earned his B.S. (1947), M.S. (1948), and Ph.D. (1953) at New York University. During his sophomore year there, he joined the Air Force and became a member of an elite group of recruits who had been selected for their talents in mathematics and physics. Because of his scientific interests, Smagorinsky was included in the Air Force meteorology program. As a part of the scheme, he was sent to Brown University to specialize in mathematics and physics for six months. Smagorinsky was then sent to the Massachusetts Institute of Technology to learn dynamical meteorology, under Ed Lorenz, the author of chaos theory. During World War II, Smagorinsky worked as a weather observer for the Air Force. In May 1948, Smagorinsky married Margaret Frances Elizabeth Knoepfel—one of the first female weather statisticians.

After the war, Smagorinsky concluded his studies. Although he had planned a career as a naval architect, the rejection of the Webb Institute led him to choose meteorology as a field. After a question-and-answer session with prominent Princeton meteorologist Jule Charney, Smagorinsky was invited to carry out the research for his doctoral dissertation at the Princeton Institute for Advanced Studies. In 1950, Smagorinsky was part of Charney's team of scientists who successfully solved Charney's equations on the Electronic Numerical Integrator and Computer, also known as ENIAC. This was a milestone event in modern meteorology, as it pioneered the use of computers for weather forecasting. At the Institute for Advanced Studies, Smagorinsky and Charney developed the technique of the so-called numerical weather prediction. This technique relied on data collected by weather balloon, which were then elaborated by computers according to the laws of physics. This enabled researchers to forecast the interaction of turbulence, water, heat, and other factors in the production of weather patterns.

After completing his doctorate, in 1953 Smagorinsky accepted a position at the U.S. Weather Bureau and was among the founders of the Joint Numerical Weather Prediction Unit. Two years later, at the suggestion of eminent meteorologist John von Neumann, the U.S. Weather Bureau created a General Circulation Research Section and appointed Smagorinsky to direct it. Smagorinsky conceived his task as the completion of the von Neumann/Charney computer modeling program. He wanted to obtain a three-dimensional, global, primitive-equation general circulation model of the atmosphere. The section was initially located in Suitland, Maryland, but was moved to Washington, D.C., where it was renamed the General Circulation Research Laboratory in 1959. In 1963, it became the GFDL before moving to Princeton University, where it is still located, in 1968. Smagorinsky continued to serve as director of the lab until his retirement in January 1983.

Under Smagorinsky's directorship, the GFDL expanded, and Smagorinsky was able to attract respected international scientists such as Syukuro Manabe and Kirk Bryan to work there. The laboratory's work profoundly influenced the practice of numerical weather prediction around the world. Thanks to the GFDL's climate models, scientists have been able to assess more precisely humans' capabilities to affect climate change. In his years at Princeton, Smagorinsky was also appointed as visiting professor in geological and geophysical sciences at the university. As a member of the teaching staff, he helped to develop the Program in Atmospheric and Oceanic Sciences, a doctoral program in the Department of Geosciences that collaborates closely with the GFDL. After his retirement as director of the GFDL in 1983, Smagorinsky became a visiting senior fellow in atmospheric and oceanic sciences at Princeton until 1998.

It is thanks to the connection established by Smagorinsky between Princeton and the GFDL that the university became a major center for the study of global warming. From the 1970s onward, scientists working under Smagorinsky created the first models illustrating how climate could change in the face of increasing levels of carbon dioxide in the atmosphere. These models provided the first modern estimates of climate sensitivity and stressed the importance of water vapor feedback and stratospheric cooling. Research at the laboratory also allowed the development of the first models coupling atmosphere–ocean climate for studies of global warming, establishing the important differences between "equilibrium" and "transient" responses to the growing levels of carbon dioxide.

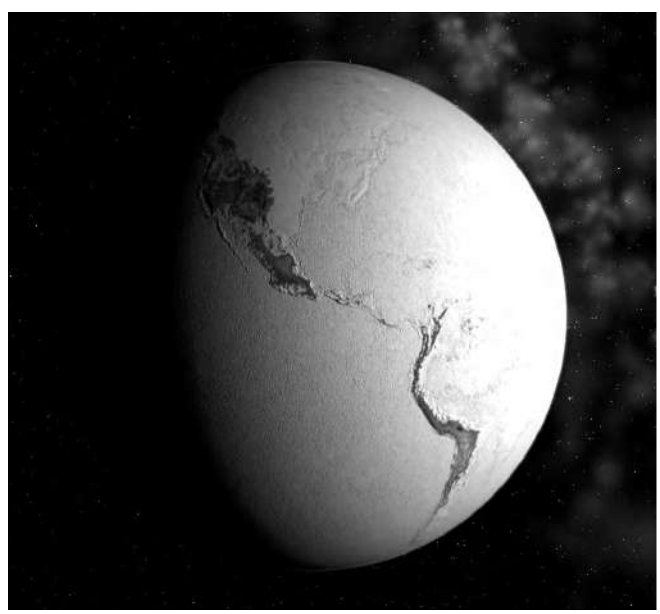
Snowball Earth

IN THE EARLY 1960s, Brian Harland, a geologist at Cambridge University, observed that rocks on several continents, dating from the Neoproterozoic era (approximately 800–680 million years ago), contain glacial debris. Some of the glacial debris included carbonate rocks, which are known to form in the tropics (e.g., in the present-day Bahama Banks). This conclusion later gained additional support from paleomagnetic data. One potential explanation is that the



The Snowball Earth hypothesis proposes that the Earth was entirely covered by ice in part of the Cryogenian period.

entire Earth was covered by ice and snow during the Neoproterozoic. This has come to be known as the "Snowball Earth" hypothesis.

One early problem was understanding how a global ice age could have commenced. During the 1960s, the Russian climate scientist Mikhail Budyko used a computer simulation to establish that a runaway ice–albedo feedback effect could lead to global glaciation. The term albedo refers to the amount of the sun's energy that is reflected by the Earth's surface. As glaciers grow in extent, they reflect more of the sun's energy, which causes the atmosphere to cool. This in turn causes the glaciers to grow. Budyko showed that if the glaciers extended beyond a certain critical point, this ice–albedo feedback could lead to a global ice age.

A second obstacle was understanding how a global ice age could ever end once it began. In the early 1990s, Joseph Kirschvink of the California Institute of Technology observed that during a global ice age, the carbon cycle would shut down. Volcanoes sticking up through the ice cover would continue to add carbon dioxide to the atmosphere. Having nowhere else to go, the carbon dioxide would then accumulate over millions of years until a runaway greenhouse effect caused the ice to melt.

One important rival to the Snowball Earth hypothesis is the high obliquity hypothesis. If the tilt of the earth's axis had been much different during the Neoproterozoic, the poles could have received more solar energy than the tropics. If so, it would be possible to explain the evidence for glaciers in the tropics without supposing that the entire planet had frozen over.

In his widely cited 1992 paper, Kirschvink also proposed an explanation for banded iron deposits observed in Neoproterozoic glacial debris. Iron is not soluble in seawater in the presence of oxygen. During a true Snowball Earth episode, the oceans would have become deoxygenated over time. Iron from thermal vents would build up in the seawater. Then, when the ice finally melted, and oxygen was once again exchanged between the oceans and atmosphere, oxidized iron would have been left along with the debris from the retreating glaciers.

During the 1990s, two Harvard scientists, Paul Hoffman and Daniel Shrag, gathered additional, highly suggestive evidence that seemed to favor the Snowball Earth theory. They found that in many places, the Neoproterozoic glacial debris occurs right below thick layers of carbonate rock (which are known as "cap carbonates"), and they showed how Kirschvink's proposal could account for this. During a Snowball Earth episode, very large amounts of carbon dioxide would have built up in the atmosphere. As the ice receded and the carbon cycle resumed, large amounts of carbon would have been washed out of the atmosphere during storms and ended up in the form of carbonate rock on the ocean floor. More controversially, Hoffman and Shrag also studied the ratio of carbon-12 to carbon-13 isotopes in the cap carbonates. They argued that an unusual dip in the carbon isotope ratio signified a temporary shutdown of photosynthetic activity in the earth's oceans.

CHALLENGES TO THE SNOWBALL EARTH THEORY

One potentially serious challenge to the Snowball Earth theory comes from paleontology. Today, most geologists agree that there were at least two major ice ages during the Neoproterozoic: the Sturtian, around 750 million years ago, and the Varanger, around 590 million years ago. The second of these episodes occurred shortly before the Cambrian Explosion of metazoan life. However, a true Snowball Earth episode would have killed off nearly all eukaryotic life, and it is not clear that there was enough evolutionary time for life to recover from a global ice age. Some scientists have used computer models to show that softer versions of the Snowball Earth episode might have been possible—for example, a mostly ice-covered planet with massive continental ice sheets in the tropics but largely ice-free tropical oceans.

Although scientists generally agree that there was low-latitude glaciation during the Neoproterozoic, they continue to use a combination of fieldwork and numerical modeling techniques to work out the details. The Snowball Earth scenario remains an intriguing live hypothesis.

Social Ecology

SOCIAL ECOLOGY IS an ecological vision for the future developed by the anarchist thinker Murray Bookchin. This theory is part of a left-wing tradition that rejects notions of hierarchy, domination, power, and place to advocate political reformism, or restructuring that will resolve basic issues of societal, gender, and environmental imbalance. Social ecology is based on the understanding that all our present ecological problems are a result of deep-seated social problems. As Bookchin states, "economic, ethnic, cultural, and gender conflicts, among many others, lie at the core of the most serious ecological dislocations we face today." Specifically, social ecologists argue that the chief source of ecological destruction is the capitalist system and its products, such as overconsumption, consumerism, and concomitant economic growth.

Trade for profit, industrial expansion, and the association of progress with corporate self-interest are among others. Bookchin argues, therefore, that to separate ecological from social problems underplays not only the sources of the environmental crisis but also the interplay among all of these factors. Human beings must not downplay the importance of how they deal with each other as social beings. This, social ecologists argue, is the key to addressing the environmental crisis. The social ecological vision is to see a society that is based along social ecological lines. In this context, there are a number of principles that characterize social ecology.

First, a society based on social ecology would be one in which ecological regeneration would be inseparable from social regeneration. For example, social regenerative strategies might include the formation of ecocommunities and the adoption of ecotechnologies that establish a creative intersection between humanity and human nature. Spirituality, or what Bookchin calls regeneration of the spirit, is another principle, signifying the growth and development of a whole society. Such a society would be diverse and holistic in nature. Spirituality is defined as a natural phenomenon—one that focuses on the ability of humans to act as moral agents and actively promote the end to needless suffering, undertake ecological restoration, and foster aesthetic appreciation of all living things. Building on this spirituality will ensure the presence of liberty (in the sense of encouraging and nurturing individual and collective creativity, imagination, and personality) as a "continuum of natural evolution," resulting in a healthy society.

SOCIAL ECOLOGY AND THE ENVIRONMENT

Social ecology goes further, however, addressing the deep structural failures within society, and seeks to redress the ecological effects humans are having on the environment. Social ecology here seeks to change the definition of the very idea of a society based on hierarchy, class, and domination to one based on equity and the ethics of complementarity. In this case, social ecologists argue that humans must play a supportive role in maintaining the integrity of the planet. As such, they promote the establishment of community institutions that can embrace community-based ethical systems that in turn encourage the qualities of wholeness so integral to the social ecology vision. Societal structures that are supported by social ecology include confederal municipalism, in which municipalities conjointly gain rights to self-governance through the networks of confederal councils; empowerment of people; ecocommunities that are linked into the confederations of economy, fostering a healthy interdependence; and shared property.

Bookchin notes that "Social ecology calls upon us to see that nature and society are interlinked by evolution into one nature that consists of two differentiations: first or biotic nature, and second or human nature." By first nature, social ecologists refer to the way in which human beings are ultimately connected to their biological and evolutionary history. Second nature refers to the way in which humans produce or have a distinct social nature, as opposed to animals. As reflexive reflective beings, humans have the responsibility of being the voice of first nature. To understand and work within society, social ecologists argue we must understand and embrace both natures. Consistent with anarchist theory, social ecologists see social hierarchy to be the enemy of natural order.

In his early work, *The Ecology of Freedom* (1971), Bookchin in fact highlights a model of evolutionary human social development that suggests that social hierarchy first emerged in the Neolithic period with simple forms of governance within and between different social groups. As such, social ecologists perceive that humans are always rooted within their own biological evolutionary history. The separation of the current society of the human from the biological is a failure to think organically and to recognize wholeness. In this context, social ecologists argue that the human and the nonhuman must be seen as being part of an evolutionary continuum and, as such, we are in a state of continual becoming. Unlike deep ecology, which is underpinned by the belief that all organisms have intrinsic rights, proponents of social ecology argue that the environment has rights when and if they are conferred by humans.

Social ecologists also believe, however, that human beings have, by virtue of their innate creativity and powers of reason, intrinsic value. As such, Bookchin maintains that the most ethical standpoint is for humans to understand different forms of hierarchy in nature, that is, different ecosystems, patterns, and orders, without implying that humans thus have the right to dominate those hierarchies. Social ecology attacks capitalism at a fundamental level, believing that modern capitalism is "structurally amoral and hence impervious to any moral appeals." It believes that the driver for capitalism is to grow or die, and as such, that the system is inherently ecologically destructive. They advocate instead a society based on complementarity and mutual aid. In this way, social ecologists advance the need to redress the ecological effect humans have had on society by calling for social reconstruction based along ecological lines. The ethics of complementarity are based on a system in which human beings play a supporting role in upholding the integrity of the biosphere and the planet. Social ecologists argue we have a moral responsibility to do this, as well as to enshrine the ethics of complementarity within social institutions in ways that will enable active participation of all in the process of reconstruction. In such a society, property would be shared, which would ultimately give rise to individuals for whom there is no separation between the individual and collective interest, the private and the personal, the political interest and the social.

Social ecologists stress the social causes and consequences of the degradation of the environment above all else. In this context, social ecologists seek answers to societal problems that are organic. They argue that as human forms of hierarchy have evolved, so has the human capacity to impose forms of domination on nature. Hence, it is the responsibility of the human race to redress the inequalities and problems attendant on the imposition of our own social order on nature. If social change in line with the organic elements ascribed to does not occur, social ecologists believe that the biosphere as we know it is heading toward complete destruction.

Overall, the position of social ecologists has attracted critique from those who argue that their position is going too far in its interrogation of the link between society and the environment. Nonetheless, Bookchin's analysis of the relationship between society and the environment, and how this relationship constitutes and causes forms of domination—and hence ecological destruction—has played an important role in highlighting the nexus between social and natural dimensions of environmental decision making.

Soil Organic Carbon

THE EARTH'S TERRESTRIAL ecosystems store over 2000 gross tons (Gt; 1 Gt = 1,015 g) of soil organic carbon (SOC), which is about four times more carbon than is stored in the atmosphere. Annually, soils release over 60 Gt Carbon to the atmosphere, which is about 10 times that amount released by fossil fuel combustion. Warming can increase the rate at which fresh organic matter (e.g., recently senesced leaves, fruits) decomposes, with the highest rates found where it is wet and warm. Less is known about how more thoroughly decomposed material (e.g., SOC) responds to changes in temperature, but it has been assumed that global warming will increase SOC decomposition rates, with the sensitivity of SOC decomposition to warming determining the extent to which SOC storage will be altered by climate change. Because the sensitivity of SOC decomposition to temperature remains poorly quantified, it cannot be accurately predicted whether global soils will change from a net sink to a net source of CO_2 as the planet warms.

SOC serves many important ecosystem roles. Because the supply of organic carbon exerts a dominant control on the activity of soil heterotrophic organisms—from bacteria to insects—SOC is critical to regulating the structure and functioning of soil communities. Further, during SOC decomposition, large quantities of nutrients are released from organic to mineral forms, and so SOC provides a critical source of nutrients to growing vegetation. The amount of SOC can also affect the water-holding capacity of a soil, as well as water movement through soils. Despite these important roles, the tremendous complexity of SOC in natural and agricultural systems presents important challenges to quantifying SOC formation and decomposition, including the sensitivity of these processes to climate change. This complexity results from the fact that very large quantities of organic matter are cycled through soils annually, but only a very small fraction remains in soils, typically in a highly transformed state that can persist in soils for millennia as a result of chemical recalcitrance or protection by clay minerals.

Given the important effect that climate may have on SOC decomposition, it is critical that tools be developed to accurately predict how SOC formation, decomposition, and storage respond to climate change. Of particular importance is quantifying interactions among driving variables, as these interactions will influence responses in difficult-to-predict ways. For example, warming in cold and wet climates may result in the loss of SOC, as warming can dry out often anaerobic soils in which oxygen supply limits decomposition rates. In contrast, warming in temperate or tropical climates may have little effect on or even slow SOC decomposition rates, especially if moisture is limiting for the soil microbes responsible for decomposing SOC. Reducing uncertainty is important for accurately predicting how the terrestrial carbon cycle, and hence the climate, will respond to global warming.

Soils

SOIL CONTAINS PULVERIZED rock, organic matter, and microorganisms, which convert the organic matter to humus. Soils range from loosely-packed sandy soil, to finely packed, sticky clay soil. Between these two extremes is loam, whose high content of organic matter makes it easy to cultivate. Soils are thin in the Mediterranean basin, and thick in northern Europe, Russia, and the American Midwest and Mississippi delta. As the basis of agriculture and as a factor in the formation of climate, soils have shaped the destiny of humans.

Soils warm when absorbing sunlight, and cool when reflecting sunlight. Soil temperature coincides with an area's climate. In tundra, for example, the air warms in spring and summer much faster than the soil does. Only the outermost layer of the soil warms enough to thaw, and then for only a few months, before winter returns. Not all soils absorb and reflect sunlight at the same rate. Wet soil darkens, and absorbs the most sunlight and gains the most heat. Dark soil absorbs as much as 86 percent of sunlight, gray soil absorbs 80 percent, and light soil absorbs only 20 percent of sunlight, reflecting the rest into the atmosphere. When water saturates soil, however, its color lightens. Being light, saturated soil reflects sunlight, yet the large amount of water that soil can hold increases the capacity of soil to absorb heat. Saturated soil absorbs and radiates heat slowly and in large quantities. Water evaporating from soil liberates heat, warming the surrounding air. Dry soil reflects more sunlight and heat than wet soil. Yet dry soil, because it contains little moisture, warms quickly on a cloudless day and becomes hot. At night, dry soil quickly cools, radiating heat back into the atmosphere.

The term *albedo* is the ratio of the amount of sunlight an object reflects to the amount it absorbs. A solid black object absorbs all sunlight and reflects none, and so has an albedo of zero. A white object absorbs no sunlight, reflects all of it, and has an albedo of one. The mean albedo of earth is 0.36. Dark soil has an albedo between 0.1 and 0.2. Clay soil has an albedo between 0.15 and 0.35. Sandy soil has an albedo between 0.25 and 0.45, and light soil has an albedo between 0.4 and 0.5.

At most sunlight penetrates only a few feet of soil. Infrared light, for example, penetrates to a depth of 3 ft (.9 m.). Because the amount of sunlight that soil receives varies during the day, soil temperatures vary. Soil temperatures also vary throughout the year. In Bridgewater, Massachusetts, for example, soil at a depth of one inch varied from a low of 35.2 degrees F (1.7 degrees C) in February to a high of 63.5 degrees F (17 degrees C) in August. Soil temperature therefore varies less than the temperature of air. Sunlight penetrates more deeply in rocky and wet sandy soil than in wet clay. Sunlight penetrates least in dry sandy soil.

Vegetation affects the capacity of soils to absorb sunlight. Plant cover decreases the albedo of light soil and increases the albedo of dark soil. Dense foliage blocks sunlight from reaching the soil, and so lessen the soil's absorption of sunlight and heat. Before the evolution of plants, soils must have been, along with the oceans, the major reservoirs of heat by absorbing sunlight. Like water, soil absorbs the most heat when the sun is overhead. Soil reflects increasing amounts of light as dusk approaches. Along with the oceans, the soil shapes the climate and influences the course of life.

Solar Energy Industries Association (SEIA)

THE SOLAR ENERGY Industry Association (SEIA) is an American trade association for the solar industry, working to expand markets, strengthen and develop research, and improve education for the employment of solar energy. SEIA is affiliated with the PVNow coalition of photovoltaic companies, which aims to expand the North American–distributed, grid-connected photovoltaic market opportunities and eliminate market barriers. They are pursuing this goal through lobbying key state legislatures, utility rate–making authorities, and other state energy policymaking agencies. SEIA represents over 700 companies and 20,000 employees in the U.S. energy sector.

SEIA headquarters are located in Washington, D.C. The organization is divided into 14 state SEIA organizations. Members of the state organizations monitor and advocate in the state governments and also supply grassroots support for solar consumers

SEIA's mission is to reduce regulatory barriers to photovoltaic installations, increase photovoltaic markets across the nation.

and small businesses. SEIA chapters have up-to-date information on retailers and distributors in their area and frequently host workshops and discussion groups. SEIA's mission is to reduce regulatory barriers to photovoltaic installations, increase photovoltaic markets across the nation through meaningful and appropriate incentive programs at the state and federal levels, guarantee continuing federal research into high standards of photovoltaic devices, and supporting technologies such as inverters and balance-of-system equipment. SEIA campaigns for legislation in favor of renewable energy and technologies that could provide emission-free energy sources. It also advocates for a reduction of CO_2 emissions.

Rhone Resch is the president of SEIA. Together with his organization, he applauded the U.S. Congress and President George W. Bush for producing the strongest national policy for solar power since the 1980s. The solar tax benefits in the 2005 Energy Bill were acclaimed by SEIA as an important victory and as the measure necessary to allow the solar industry to meet the challenge of playing a significant role in supplying energy for the United States. To Resch, the United States has the best solar resources in the industrialized world, and by choosing solar energy, Americans can make a real contribution to their country's energy independence: "Installing solar energy on your roof is one of the most meaningful steps an individual can take to reduce our reliance on foreign sources of energy and help declare energy independence. Now solar comes with a more affordable price tag, and more consumers will take a step towards energy independence by choosing solar power. That means cleaner air, more jobs, and greater energy security for all." SEIA also supports the Solar Energy Research and Advancement Act of 2007—legislation that Resch described as "helping solar energy to make major strides in contributing to a clean, domestic, renewable supply of electricity."

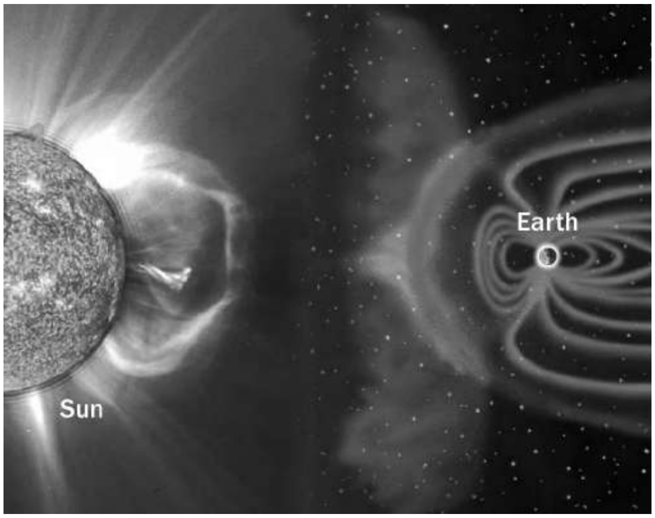
Solar Wind

TWO COMPETING THEORIES for global warming and their effect on Earth's changing climate persist today. The first theory suggests that the driver for global warming is the increasing amount of greenhouse gases dumped into the atmosphere as a result of humanity's burning of fossil fuels. The second theory posits that the solar wind and its associated magnetic field alters the Earth's cloud cover and adjusts the atmosphere's water vapor content, which leads to the steady temperature rise known as global warming.

The latter theory involves a stream of plasma, or high-energy charged particles, propelled from the sun's upper atmosphere. This stream of electrons and protons escapes the gravitational pull of the sun and creates the solar wind. It varies in speed from 190 to 500 mi. (306 to 805 km.) per second and passes by Earth as the sun rotates in space. The solar wind affects Earth's magnetic field and, in turn, is believed to have a major effect on climate change.

Opponents to the greenhouse gas theory of global warming argue that increasing radiation activity from the sun over the past 300 years has been the primary culprit—not an increase of atmospheric carbon dioxide. Researchers believe that because the doubling of the sun's magnetic flux recorded in the 20th century had led to increased sunspot activity as it follows its periodic 11-year cycle, the ferocity of the solar wind and the overall brightness of the sun also increased.

Proponents of global warming who subscribe to increasing carbon dioxide emissions as the cause of the problem avoid citing work done by NASA's Goddard Institute for Space Studies (GISS) or other scientific evidence offering credence to the solar wind theory. Just like the greenhouse gas theory, the GISS climate model is used to show that changes in the solar wind throughout the ages have varied surface warming. Climate researchers determined that the sun has played a role in modulating the atmosphere's moisture content and its circulatory patterns, causing droughts in ancient times. Backing up these computer-generated data are a number of natural records that correlate with the model's projections. Lake sediment analysis, fire records, and tree-ring measurements from the Yucatan Peninsula, Mexico, and Peru, to name a few locations, illustrate that periods of drought occurred during times of heightened solar output.



The Earth's magnetosphere, or magnetic field, protects us from most effects of the solar wind and from solar storms.

Increasing solar wind produces more ozone in Earth's upper atmosphere by breaking up oxygen molecules and heating the atmosphere. As a consequence, the circulation of the atmosphere is affected right down to the surface, which, in general, warms and reinforces existing rainfall patterns. Wet regions receive more rain, and dry regions become more susceptible to drought as the warmer air temperature pulls more moisture out of the soil. Droughts become more intense.

Although such facts are rarely disputed, the scope of the influence of solar wind is hotly debated. Some researchers state that the current period of global warming cannot be caused by the changes in solar output alone. Other researchers suggest that a double effect is in play, in which a more vigorous solar wind increases the global temperature, which in turn causes the oceans to warm, as made evident by melting sea ice. Because warm water absorbs less carbon dioxide, more of that greenhouse gas remains in the atmosphere. The debate boils down to whether all, some, or none of the burning of fossil fuels leads to global warming. As of this writing, most scientists and the popular media believe that human activity adds so much greenhouse gas to the atmosphere that this round of global warming could be catastrophic to life on Earth.

Solar-focused satellites have been monitoring the sun since the 1970s. More recently, the Solar and Heliospheric Observatory and the Wind and Advanced Composition Explorer have kept their instruments trained on the sun to measure the sun's temperature, capture the ion content of the solar wind, determine how the solar wind is accelerated, and more. Recently, the twin STEREO spacecraft were launched to expand on and augment existing satellite measurements by tracking the sun together and reporting on its solar behavior. The Solar Terrestrial Relations Observatory became operational in 2007 and will provide researchers the first three-dimensional space forecasts associated with solar activity.

Whatever the conclusion as to the ultimate cause of global warming, it is clear that the "third rock from the sun" will play a big role. The question for humanity is to determine which theory best describes global warming—greenhouse gas emissions or solar wind influences—and to develop policies to mitigate the effects on human civilizations.

Solomon Islands

LOCATED IN THE Pacific, east of Papua New Guinea, the Solomon Islands have a land area of 11,157 sq. mi. (28,896 sq. km.), covering 249,000 sq. nautical mi., with a population of 496,000 (2006 est.) and a population density of 43 people per sq. mi. (17 people per sq. km.). Only 1 percent of the land is arable, with a further 1 percent being used for meadows and pasture and 91 percent of the country forested, although a massive timber industry is resulting in heavy deforestation.

The entire electricity production in the country is from fossil fuels, with liquid fuels making up the entire carbon dioxide emissions from the country. Because the country is largely undeveloped, the per capita carbon dioxide emissions rate is low, being 0.5

metric tons per person in 1990 and falling to 0.39 metric tons in 2003. The increasing deforestation of the islands, however, will start to lead to a heavy increase in the country's carbon dioxide emissions in subsequent years.

The possible effects of global warming and climate change on the Solomon Islands are significant. There is the strong probability of increased flooding, which in turn could lead to a rise in the prevalence of insect-borne diseases such as malaria and dengue fever. The flooding might also result in the inundation of some of the several hundred islands that make up the country.

The Solomon Islands government took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention in the following year. The government signed the Kyoto Protocol to the UN Framework Convention on Climate Change on September 29, 1998, and ratified it on March 13, 2003, with it entering into force on February 16, 2005.

Somalia

LOCATED IN NORTHEAST Africa—the "Horn" of Africa—Somalia has a land area of 246,201 sq. mi. (637,657 sq. km.), with a population of 8,699,000 (2006 est.) and a population density of 34 people per sq. mi. (13 people per sq. km.). About 80 percent of the population is dependent on agriculture, though only 2 percent of the land is arable, with a further 69 percent used for meadows or pasture, mainly low-intensity grazing of cattle, goats, and pigs. Some 14 percent of the land is forested.

Because the country is underdeveloped, it has a very low level of electricity usage, with the carbon dioxide emissions per capita being the lowest of any country in the world, even though accurate statistics have not been available for the last 10 years. Official statistics from 2001 give the entire electricity production for the country at 245 million kWh, with consumption levels at 228 kWh, with 100 percent of all electricity coming from fossil fuels.

The effects of global warming and climate change on Somalia are expected to be extensive. The rising temperature is expected to make more of the arable land unusable for the growing of crops and to render the pasture land even less productive than it is at the moment. There is also the possibility of flooding in some low-lying parts of the country.

The Somali government sent an observer to the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992, and ratified the Vienna Convention on 2001. Because of the instability in the country, there have been few measures introduced to combat some of the effects of climate change, and the current government has so far not expressed any opinion on the Kyoto Protocol to the UN Framework Convention on Climate Change.

Somali Current

THE SOMALI CURRENT can be found on the surface of the northern Indian Ocean, serving as a western boundary of this ocean. It is a movement of waters around the Indian Ocean, dispersing heat. Atmospheric circulation and ocean circulation together are the major mechanisms for global heat distribution. As atmospheric circulation defines large-scale air movements around the globe, ocean circulation refers to the patterned movement of particular waters.

In summer, a southwest monsoon blows upward from the east coast of the Horn of Africa. Carried along with the monsoon are the waters of the western Indian Ocean, moving in a northeast direction underneath, and powered by winds. These waters may reach speeds of 9 mi. per hour (14 km. per hour). As the current reaches Somalia, the waters turn eastward. Some stay on near the Arabian Peninsula to form the East Arabian Current. Those that continue eastward eventually become the northeast monsoon during the autumn and winter, flowing southwest back to their origins. During the months of December and March, the Somali Current typically hovers between 5 degrees and 1 degree of latitude North of the equator, with this reach extending to span between 10 and 4 degrees latitude North during the central months of January and February.

The Somali Current is of interest because it creates an upwelling of cold water that is the only other region of such low surface temperatures within 10 degrees of the equator outside of Peru, and perhaps even colder. The cold surface temperatures around Peru are caused by the Peruvian or Humboldt Current which is related to El Niño.

The waters of the Somali Current swirl into what is known as the Great Whirl, an eddy with a diameter that can reach 500 km. (approximately 311 mi.), spinning in an anticyclonic direction. Anticyclonic direction is opposite to the earth's rotation; in the Northern Hemisphere the eddy therefore spins clockwise. The upwelling occurs during the months of May through September, and can lower the surface temperature in the western Indian Ocean by up to 9 degrees F (5 degrees C). Ocean surface temperatures are an important data source for monitoring global warming; therefore it is important to record the temperatures found during the northern (summer) swing of the Somali Current.

The Somali Current and other phenomena in the Indian Ocean were investigated at length in the year 1995 in a study that began in late 1994 and concluded in early 1996. It was an ambitious project that attempted to record all data related to the Indian Ocean during that year, and was undertaken by the World Ocean Circulation Experiment (WOCE) Indian Ocean Expedition.

South Africa

THE REPUBLIC OF South Africa has a land area of 471,443 sq. mi. (1,221,037 sq. km.), with a population of 48,577,000 (2006 est.) and a population density of 101 people per sq. mi. (39 people per sq. km.). Some 10 percent of the country is devoted to arable purposes, with a further 67 percent used as meadows and pasture, much of it for low-intensity grazing of cattle and goats. Only 7 percent of the country is forested.

As the nation is a major producer of coal, some 92.6 percent of South Africa's electricity production comes from fossil fuels, with 6.7 percent from nuclear power and 0.7 percent from hydropower. In spite of its location, South Africa has made little use of solar power. In 1990, South Africa produced 7.8 metric tons per capita of carbon dioxide, and this level of emissions remained relatively stable until 2003, rising to 9.2 metric tons per capita in the following year. Coal and other solid fuels contribute to 80 percent of the country's carbon dioxide emissions, with 18 percent being from liquid fuels and 1 percent from gaseous fuels. By sector, 63 percent of South Africa's carbon dioxide emissions come from the generating of electricity, with 21 percent from manufacturing and 13 percent from transport.

Recently observed climates in South Africa, possibly attributable to global warming, include the following: The temperature of the Benguela Current has recently been increasing, resulting in a decrease in the fishing catch off the coast of the country. This, in turn, has led to a significant reduction in the diversity of species of fish in the region. In January 2000, following one of the driest Decembers on record, with many days having temperatures above 104 degrees F (40 degrees C), there were many bush fires along the coast of the Western Cape, leading to the destruction of woodland and other vegetation.

The South African government of Frederik W. de Klerk took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992. They accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on July 31, 2002, with it entering into force on February 16, 2005. In August 2005, Marthinus van Schalkwyk, the environmental affairs minister for South Africa, attended a week-long ministerial meeting in Greenland to discuss what became dubbed the Greenland Dialogue to examine further ways of making the Kyoto Protocol more effective.

A windmill near Johannesburg: Wind resources could be used to reduce carbon dioxide emissions from generating electricity.

South Carolina

SOUTH CAROLINA IS 32,020 sq. mi. (82,931 sq. km.), with inland water making up 1008 sq. mi. (2,610 sq. km.), coastal water making up 72 sq. mi. (186.5 sq. km.), and territorial water making up 831 sq. mi. (2,152 sq. km.) South Carolina's average elevation is 350 ft. (106 m.) above sea level, with a range in elevation from sea level on the Atlantic Ocean to 3,560 ft. (1,085 m.) at Sassafras Mountain. The major natural regions include what is referred to as the low country—the Coastal Plain with offshore islands (inland is rolling, and along the coast is flat)—and what is referred to as the up-country—piedmont (higher elevation, with forests and pastureland) and Blue Ridge (mountainous and forested). South Carolina has river systems; the large lakes are artificially created.

The state's hot summers and warm winters come from the combination of the state's relatively low latitude, low elevation, proximity of the warm Gulf Stream in the Atlantic, and the Appalachian Mountains. During the winter, the mountains limit cold air entering the interior of the continent. Low country summers are hot and humid, though a sea breeze brings some relief. The up-country is usually cooler than the low country, even in the middle of the summer. The highest temperature recorded in the state was 111 degrees F (44 degrees C) on June 28, 1954, and the lowest temperature recorded was minus 19 degrees F (minus 28 degrees C) on January 21, 1986. Winters in South Carolina are mild, with brief periods of cold (lakes and rivers rarely freeze over), throughout the state. Precipitation is abundant all year; snow falls in the mountains but is rare in other parts of the state. Most of the state receives about 48 in. of rain a year, though the mountains areas receive more.

Forests cover much of the state, and wood is commercially harvested for lumber, wood pulp, paper, and furniture. Agriculture products include tobacco, cotton, corn, soybeans, and wheat. South Carolina's electricity is generated by nuclear power plants and coal-fueled power plants, and a small portion is hydroelectric.

South Carolina is already experiencing the effects of higher temperatures and rising sea levels (nine in. in the last century), and hurricanes and other major storms have increased in intensity and duration by about 50 percent since the 1970s; they are linked to increases in average sea surface temperatures and eroding coastlines. The coastal plains have already experienced problems with water supplies, and the increased use of groundwater for irrigation has lowered groundwater levels.

Although climate models suggest an increase in temperature of 5.4 degrees F (3 degrees C) by the end of the 21st century, potential risks anticipated include sea levels rising an additional 19 in. or 48 cm. (causing beach erosion and saltwater incursion); decreased water supplies; population (both human and animal) displacement; changes in food production, with agriculture improving in cooler climates and decreasing in warmer climates; forest loss, with persistent drought and loss of trees unsuited to higher temperatures; change in rain pattern to downpours, with the potential for flash flooding (causing sediments, agricultural chemicals, and other substances to leach into water sources); and increased health risks of certain infectious diseases stemming from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents and of heat-related illnesses.

In populated areas at higher elevations, as in northwestern South Carolina, water quality and amount may both become issues. Should the levels of streams, groundwater, and lakes decrease, shortages of water for industrial and municipal markets would occur. Shallow wells would be affected, with rural communities losing water supplies. Higher rainfall would increase flooding and erosion, as well as contaminating the remaining water supplies with runoff.

South Carolina's economy relies on tourism, and beach erosion resulting from climate change would damage the coastline.

On the basis of energy consumption data from the Energy Information Administration's State Energy Consumption, Price, and Expenditure Estimates (SEDS), released June 1, 2007, South Carolina's total CO_2 emissions from fossil fuel combustion in million metric tons for 2004 was determined to be 88.56, made up of contributions from commercial (1.53), industrial (14.59), residential (2.36), transportation (32.10), and electric power (37.98) sources.

South Carolina established the Governor's Climate, Energy, and Commerce Advisory Committee (CECAC) in February 2007 to research and evaluate, for presentation to the governor, recommended policy options to mitigate the effects of global warming. Appointed by the governor, the CECAC comprises a diverse group of stakeholders who bring broad perspective and expertise to the topic of climate change in South Carolina. Members represent the following sectors: energy, manufacturing, agriculture, forestry, tourism and recreation, heath care, nongovernmental organizations, academia, and state and local government. The advisory committee has held regular meetings considering options including renewable energy and recycling options.

Over the past three years, the University of South Carolina has purchased 70 flex-fuel vehicles that run on E-85, a mixture that is 85 percent ethanol and 15 percent gasoline. Much of South Carolina's renewable energy potential comes from biomass—organic matter such as plant fibers and animal waste that can be converted into electricity and fuel.

A number of programs have been undertaken for the conservation and improvement of South Carolina's soils, forests, and wildlife resources. Conservation efforts, including the protection of critical land areas, are carried on by a number of federal and state agencies as well as private organizations.

Watershed management considers economic interests as well as the protection of natural resources. Management plans are used to guide watershed management for water quality, recreation, wildlife management, and agricultural and forestry practices, balanced against community economic development.

The principal soil conservation effort is directed toward covering the badly eroded lands with pasture grasses or trees to prevent further soil removal. Reforestation, supervised cutting and replanting, and fire protection are practiced to provide adequate timber supplies in the present and future.

South Dakota

SOUTH DAKOTA'S GEOGRAPHICAL location near the center of the North American continent provides it with a high degree of sensitivity to climatic change, as any variations from mean weather conditions will be readily apparent. The state is situated in a region that experiences all of the conditions of the continental climate classification, which usually means pronounced seasonality with long, cold winters; hot summers; midlatitude cyclonic storms; and variable precipitation. A border, running north-south, between the semihumid and semiarid precipitation regimes of North America, essentially divides the state (generally corresponding to the 100th meridian) and responds to changes, oscillating from east to west, in relation to overall global weather patterns. Thus, if there were significant changes in the global atmospheric system, such as warming resulting from anthropogenic or natural factors, climatic conditions would manifest themselves across the state.

This brief essay presents a summary of historical climate research and recent climate modeling in an effort to illuminate possible consequences of climate change on South Dakota's people and landscape. The state's climate parameters are summarized as follows: mean normal precipitation varies from 25 in. (635 mm.) in the southeastern part of the state to less than 14 in. (350 mm.) in the northwestern sector; temperatures range from summer highs in the lower 100 degrees F (40 degrees C) to minus 40 degrees F/C in winter, with an average annual temperature of less than 39 degrees F (4 degrees C). Record high and low temperatures are 120 degrees F (49 degrees C) and −58 degrees F (−50 degrees C.) Strong surface winds patterns, principally blowing from the north and northwest during the colder part of the year, also persist across the northern Great Plains, of which the state is a part. The region also experiences severe weather episodes such as tornadoes, hail storms, and blizzards in their respective seasons. The state's Black Hills subregion represents an anomaly to the general southeast-northwest precipitation and north-south temperature gradients, which vary temporally, with average wetter and warmer conditions prevailing at the higher elevations that support coniferous forest vegetation cover.

South Dakota's state climatologist presented research in 2001 revealing that the state had experienced a "definite climate shift" during the 1990s, recording an average increase of two or three in. (51–76 mm.) of precipitation annually over the previous three decades. The agricultural effect of increased moisture allowed advancement of the production of corn and soybeans westward toward the Missouri River—a feature that essentially divides the state into eastern and western sectors. Semihumid climatic characteristics associated with western Minnesota shifted as much as 200 mi. (320 km.) to the west, according to the report.

Contrary-wise, in the current decade, the semiarid extreme southwestern part of the state has been in the grips of a seven-year-long drought with severe consequences in terms of agricultural losses and forest and range wildfires, plus tendencies toward desertification conditions. The drought-affected area is the northeast extension of a multistate region in the western United States that has been experiencing prolonged, abnormally dry weather patterns.

In 2005, research was published indicating that future global warming may adversely affect wetlands within the eastern half of the state (Johnson et al., 2005) and, by implication, the general area as well. Eastern South Dakota's geologic landscape was produced mainly by Wisconsin age glacial deposits. The retreating ice left a terrain of ground moraines, outwash plains, and end moraines and a swath of tens of thousands of prairie potholes and larger kettles (shallow lake basins), which can be very productive waterfowl breeding areas when moisture conditions are favorable. The area is a part of the Prairie Pothole Region (PPR), which covers parts of five other states and two Canadian provinces. With large-scale Anglo-American settlement and development, beginning in the second half of the 19th century, much of the area has been transformed through drainage projects and intensive cultivation into a productive agricultural region, although a considerable acreage of natural wetlands remains. Western, or West River, South Dakota was unglaciated during the Pleistocene epoch, and the landscape is heavily influenced by the presence of the semiarid climatic regime. Contemporary agriculture is focused predominantly on cattle production, with some row crops, across vast areas of grasslands and rough terrain cut by a network of valleys occupied by mostly intermittent stream courses.

Johnson's research, based on climate modeling methodology, suggested that the most productive habitat for ducks in the PPR would shift under a drier climate from eastern South Dakota to areas to the east and much farther north—locations currently less productive or where most wetlands have been drained. The conclusion that was drawn indicates negative effects on both waterfowl production and commercial agriculture. This work concurs with other climate change studies that predict adverse consequences with a warming global climate in various areas of the world, especially in heavily populated or agriculturally productive regions of the Northern Hemisphere.

In sum, the climate region in which South Dakota is located has experienced a variable regime for millennia because of its geographical continentality. Temporally, the eastern half of the state was wetter than most of the early 20th century. However, if the current global climate change forecasts become reality, the outlook for South Dakota's environment for the next several decades, especially the eastern portion, becomes problematic, with anticipation of less precipitation and its associated effects on land and life. Some degree of mitigation may be possible in the shorter run, according to experts, if initiated in time, but the issue may be ultimately beyond any human control or even influence.

Southern Ocean

THE GLOBAL OCEAN influences the Earth's climate by storing and transporting vast amounts of heat, moisture, and carbon dioxide. Huge quantities of carbon are cycled annually among the biosphere (forests, grasslands, and marine plankton), the atmosphere, and the oceans. The oceans are the largest active reservoir of carbon, containing 50 times more carbon than the atmosphere. Of the 6 to 7 billion tons of carbon currently released into the atmosphere by human activities, approximately 3 billion tons remain in the atmosphere, 1 to 3 billion are absorbed by the oceans, and up to 2 billion appear to be absorbed by the terrestrial biosphere.

Oceanographers commonly refer to the oceanic region that surrounds the continent of Antarctica as the Southern Ocean. The northern boundary of the Southern Ocean is not well defined, but it coincides approximately with a broad zone of transition between the warm, saline surface waters of the subtropical regime and colder, fresher subantarctic waters, called the Subtropical Front, which occur between 40 degrees S and 45 degrees S. Using this definition, the surface area encompassed by the Southern Ocean represents approximately 29.7 million sq. mi. (77 million sq. km.), or 22 percent of the global surface ocean. Its unique geography makes it a key player in global climate.

The Southern Ocean is the only ocean that encircles the globe unimpeded by a land mass. It is home to the largest of the world's ocean currents: the Antarctic Circumpolar Current (ACC). The ACC carries between 135 and 145 million cu. m. of water per second from west to east along a 12,427 mile- (20,000-km.) path around Antarctica, thus transporting 150 times more water around the globe than the total flow of all the world's rivers. By connecting the Atlantic, Pacific, and Indian Oceans, the ACC redistributes heat around the Earth and so exerts a powerful influence on global climate.

Near the Antarctic continent, the Southern Ocean is a source of cold, dense water that is an essential driving force in the large-scale circulation of the world's oceans. The cooling of the ocean and the formation of sea ice during winter increases the density of the water, which sinks from the sea surface into the deep sea. This cold, high-salinity water includes Antarctic Bottom Water and Antarctic Intermediate Water. Antarctic Bottom Water originates on the continental shelf close to Antarctica, spills off the continental shelf, and travels slowly northward, hugging the seafloor beneath other water masses, moving as far as the North Atlantic and North Pacific. Antarctic Intermediate Water is less saline and forms farther north, when cold surface waters sink beneath warmer sub-Antarctic waters at the Antarctic Convergence at about 55 degrees S. Together, these motions form a complex, three-dimensional pattern of ocean currents that extends around the globe, known as the thermohaline circulation, or "great ocean conveyor." The thermohaline circulation has a critical influence on climate by transporting heat efficiently around the globe and by controlling how much dissolved inorganic carbon is stored in the ocean.

At the sea surface, seawater exchanges gases such as oxygen and carbon dioxide with the atmosphere at the same time that it is being cooled. As a result, sinking water efficiently transfers changes in temperature, fresh water, and dissolved gases into the deep ocean 2.5 to 3 mi. (4 to 5 km.) beneath the sea surface; in terms of carbon sequestration, this is called the solubility pump. Biological processes also play a role in the surface layer, where photosynthesis by single-celled marine phytoplankton can sequester carbon dioxide in the surface water and, through the process of sedimentation, transfer this organic carbon to deeper waters—the so-called biological pump.

The Southern Ocean is distinguished as a region of high levels of dissolved nutrients, but with modest rates of annual net primary production, so that the biological pump appears to be operating well below its maximum capacity. An interesting idea of recent years is that it may be possible to sequester much more atmospheric carbon if iron, an essential micronutrient, is added to the ocean to encourage the growth of marine phytoplankton, and thus stimulate the biological pump. The overall effect would be to lower the concentration of dissolved carbon dioxide in surface waters, allowing more atmospheric carbon dioxide to dissolve into the sea.

Understanding the global circulation and conditions under which surface waters penetrate into the deep ocean is critical for scientists estimating the timing and magnitude of climate change. At this time, the Southern Ocean is considered to be a net sink for atmospheric carbon dioxide; however, the magnitude of this sink has a high uncertainty, with mean annual estimates ranging between 0.5 and 2.5 billion tons. The degree of interannular variability in the Southern Ocean carbon sink, and its possible future response to climate change, is still poorly understood. However, climate model projections indicate that the Southern Ocean overturning circulation will slow down as the Earth warms. A decrease in the rate of overturning circulation will result in a decrease in the rate of carbon dioxide absorbed by the Southern Ocean, which represents a positive feedback and tends to increase the rate of climate change.

The presence of sea ice in the Southern Ocean is another factor that contributes to the Southern Ocean's important role in climate. Sea ice formation during the winter months is the largest single seasonal phenomenon on Earth, with approximately 7.7 million sq. mi. (20 million square km.) of ice formed annually, effectively doubling the size of Antarctica. This has a profound effect on both regional and global climate processes. Because of its high albedo, sea ice reflects the sun's heat back into space, intensifying the cold. However, it can also act as a blanket, insulating against heat loss from the ocean to the atmosphere. Its yearly formation injects salt into the upper ocean, making the water denser and causing it to sink downward as part of the deep circulation. As ocean temperatures increase in response to the global warming, the amount of sea ice is expected to decrease; this has already been observed in the Arctic Ocean. The resulting decrease in the planetary albedo would act as a positive feedback, increasing the amount of energy from the sun absorbed by the Earth and tending to further increase the rate of climate change.

Southern Oscillation

FIRST DESCRIBED EXTENSIVELY by British meteorologist Sir Gilbert T. Walker in the 1920s, the Southern Oscillation refers to the periodic exchange of mass across the equatorial Pacific that is recorded in sea level pressure fluctuations between the eastern and western Pacific. Under normal conditions in the tropical Pacific, surface high (low) pressure prevails in the eastern (western) Pacific, with the easterly trade winds dominating surface wind and ocean flow.

This pressure pattern, also known as the Walker circulation, tends to support rising air motions and convectional precipitation near eastern Australia, as well as sinking air motions and dry conditions near coastal northern Peru. Every two to seven years, this generalized atmospheric surface pressure pattern weakens as equatorial Pacific air pressure rises in the west and lowers in the east. This shift in the pressure field considerably weakens the trade winds and promotes the eastward movement of warm surface water across the tropical Pacific. The associated abnormal warming in the eastern Pacific is known as El Niño. Because the reversals in pressure and associated ocean temperature fluctuations are often simultaneous, this coupled climate variability between the tropical Pacific Ocean and atmosphere is often collectively referred to as the El Niño/Southern Oscillation (ENSO).

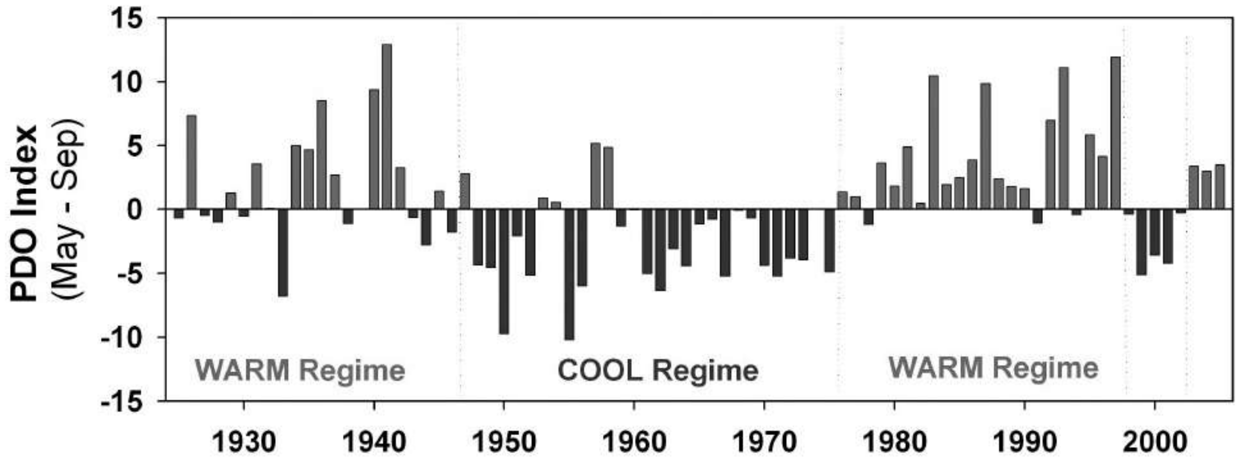
MEASURING SOUTHERN OSCILLATION

The mode and relative strength of the Southern Oscillation during a given time period is determined using one of several indices that signifies changes in the Walker circulation. A relatively simplistic and common method employed to gauge this change is the Southern Oscillation Index (SOI), which measures the monthly or seasonal sea level pressure differences between two stations, one located in the central Pacific at Tahiti and the other in the western Pacific at Darwin, Australia. Negative SOI values result from abnormally low pressure occurring in Tahiti and high pressure occurring at Darwin, which tends to indicate an El Niño episode; positive SOI values indicate the cold phase of ENSO, or La Niña. The sea level pressures at these two stations thus are negatively correlated and are associated with significant, yet contrasting shifts in regional temperature and precipitation patterns. Some of the most severe Australian summer droughts and heat waves (e.g., in 1983) have been associated with a strongly positive SOI.

ENSO events often affect the temperature and precipitation regimes in tropical regions. The magnitude of these effects differs with the intensity of individual ENSO events. Climatic anomalies associated with ENSO's warm phase in other tropical regions include dry summers and autumns for northern South America, Central America, and southeastern Africa (including Madagascar), as well as less rainfall during the Indian monsoon. Drier-than-normal conditions negatively affect crops—a particularly serious concern in developing regions. Such atmospheric conditions are also conducive to the threat of wildfires. Wetter conditions pervade the Chilean coast, as well as parts of east-central Africa.

EFFECTS OF ENSO

Despite being primarily a tropically located phenomenon, ENSO also has extensive effects on extratropical global precipitation and temperature variability. This is achieved, in part, by shifts in storm



The term PDO Index refers to Pacific Decadal Oscillation. The horizontal scale is marked in units of decades from 1925 to 2006, in the months of May through September. The vertical lines show positive (warm) years and negative (cool) years.

tracks. Changes in large-scale atmospheric circulation include deviations from the normal jet stream paths and persistent pressure systems, which in turn steer storms in new directions. During the warm ENSO phase in winter, a deepened Aleutian Low moves southeast of its average position. This is coupled with a strong subtropical jet stream and a weak polar jet stream over eastern Canada, setting up the circulation pattern that redirects storms into the southern United States. The winter cold ENSO phase is characterized by a blocking high forming in the Gulf of Alaska and a split polar jet. The main branch flows from Alaska and northern Canada south toward the western and northern United States; the jet's southern branch moves from the Pacific Ocean toward the Pacific Northwest.

Winter tends to bring the strongest North American precipitation and temperature responses to ENSO, though effects are noted in other seasons. Warm ENSO events typically result in wetter-than-normal conditions for much of the southern United States, with California often experiencing flooding as a result of the position of the stronger-than-normal subtropical jet stream, which directs storms into the region. Conversely, dry conditions tend to occur in the midwestern United States. Warm ENSO events also bring mild, warm winters into western Canada and Alaska, as well to Canada's Maritime Provinces. Cold ENSO events bring considerably drier, warmer winters to the American Southeast and below-average temperatures to western and central Canada and the northern tier of the United States.

Global climate models have been used in recent decades to predict how changes in our current climate will affect the frequency, strength, and position of cycles of interannular variability such as the Southern Oscillation. Although the predictability of the Southern Oscillation has been subject to differences between observed and predicted timescales, researchers have shown that the current climate models do tend to place warm ENSO events within the observed two- to seven-year timescale. Ensemble forecasts, in which average forecasts are generated by running models with slight variations in initial conditions, produce good results, with multimodel ensembles generally outperforming single-model ensembles. These models serve to enhance our understanding of atmosphere-ocean interactions, such as ENSO, for improving long-range weather and climate forecasts.

Spain

THE COUNTRY OF Spain lies on the Iberian Peninsula on the Mediterranean and Atlantic and is separated from Europe by the Pyrenees Mountains. The central plateau is drained by three rivers. Special geographic features include two sets of archipelagos, with the Balearic Islands in the Mediterranean and the Canary Islands in the Atlantic off the coast of Africa. Spain has a variety of ecosystems: snowcapped peaks in the Pyrenees, green meadows in Galicia, orange groves in Valencia, and desert in Almeria. The Partido Socialista Obrero Espanol government set aside more than 400 protected areas covering 15,444 sq. mi. (40,000 sq. km.) and protecting a broad range of ecosystems including mountains, wetlands, islands, wood and forest, and volcanic landscapes.

With extremes in temperature and low rainfall, water is a valuable resource. Droughts in the 1950s, 1960s, and 1990s were the driving force behind water policy. The Tajo-Segura water diversion system can divert 600 cu. m. of water per year from Tajo region in central Spain to the Valencia and Murcia regions. In 2000, a National Water Plan (Plan Hidrologico Nacional) intended to double the amount of water diverted from Rio Ebro basin was heavily protested, and in 2004 the plan was cancelled. Although climate models vary on what the temperature increase will be for Spain, from a conservative 3 degrees –4 degrees C to a pessimistic 6 degrees–7 degrees C by the end of the century, Spain is already experiencing the effects of global warming, with glacier melt in the Pyrenees (continued warmer winters would reduce snow cover and tourism to the area for winter sports); Europe's first hurricane (Hurricane Vince), which made landfall on the southwestern coast of Spain in October 2005; and an 11 percent decrease in average rainfall in 2005–06, which followed an extreme drought the year before.

Precipitation is expected to decrease, though not in all areas. Spain's northeast could see an increase in autumn and winter rainfall, and there may be a decrease in rainfall in the arid southwest. Spring and summer precipitation would be expected to decrease, except in the Canary Islands. Higher storm activity under climate change over the adjacent Atlantic is likely to lead to an increase in the intensity of winds over some parts of the country by the end of the century. Maximum wind speeds could increase by 2–4 percent in northwestern Spain by the end of the century, whereas in Galicia, the number of days with high winds could increase by up to 10 percent. Northern Spain could expect increased yield for most crops, and southern Spain could expect decreased yields.

In May 2002, Spain ratified the Kyoto Protocol, an international and legally binding agreement to reduce greenhouse gas emissions worldwide, entered into force on February 16, 2005, with Spain's entry into force on the same date.

In 2005, Spain became the second-highest wind capacity electric generator by adding 1,764 megawatts of wind power for a total of 10,027 megawatts, surpassing their 2010 goal.

In July 2007, the Spanish government approved numerous legislative measures related to environmental preservation and mitigating climate change. Spain has made fighting climate change a priority in the government's working agenda. By approving the Spanish Strategy for Climate Change and Clean Energy, Horizon 2007–2012–2020, issued by the Minister of environment, the government reinforced a commitment to the Kyoto Protocol. In addition to a plan for reducing government energy consumption and greenhouse gas emissions from government buildings and for the increasing use of blended biofuel in official vehicles, increasing energy efficiency with equipment and appliances as well as heating and cooling is a priority. Vehicle registration taxes will be directly related to emissions and responsibility will be put on the consumer (low-emission vehicles will be exempt from the tax, and higher-emission vehicles will be taxed at the highest rate).

Species Extinction

CHANGING CLIMATES INCREASE the uncertainties of life for all organisms. A long-term warming trend would alter the distribution of life on the planet as colder habitats shrink and warmer ones expand. Some species would become more common, and others would become rarer. We cannot predict with any precision which species will become extinct—or when. Plants and animals that are highly adapted to already extreme (hot, cold, or dry) climates are most likely to be the first and most drastically affected.

We consider a species to be extinct once all known individuals of that type have died. Many interacting factors affect the survival of individual organisms, and therefore the persistence of their species. In general, extinction results when a species' requirements and abilities no longer match the resources and hazards in its environment. For animals, these factors include food, water, and shelter from predators and weather extremes. For plants, they include water and nutrients and the action of herbivores and pollinators. Sometimes a factor is critically important, like rainfall in a desert. It determines whether enough individuals will survive that a species can persist. If that "limiting factor" changes in some way, survival rates may rise or fall. If they fall far enough, extinction results. Climate is a major limiting factor for life on Earth. When it changes, life on Earth also changes. A continuing trend of global warming, cooling, or drying will lead to extinctions that might otherwise not occur as soon. We still know little about the precise climate limits or thresholds of most species. Because it is also difficult to predict precisely what the climatic conditions will be like in any given place at any given time in the future, it is even harder to predict which species will become extinct as a direct result of climate change, and when it will happen. In addition, because species interact and rely on each other in many ways, climate change produces many sometimes indirect or complex effects among them. This adds further layers of uncertainty to predictions about extinctions. For the most part, we can make only very general predictions about climate change and extinctions. This uncertainty leads many climate scientists and ecologists to conclude that humans would be wise to avoid or resist contributing to the uncertain risks of climate change whenever it lies within our power to do so.

CLIMATE, BIOGEOGRAPHY, AND EXTINCTION

Climate change is complex. Tracking the local effects of regional or global change requires a great deal of data. Much of this information is now collected via remote sensing devices like radar and satellite-mounted cameras. So much data is collected that they can only be compiled into a usable form with very high-speed computers. However, those technologies are very recent. Scientists began collecting accurate and extensive climate measurements in the 18th century, recording data by hand. Naturalists like Alexander von Humboldt and H.C. Watson first correlated climates and species distributions in the early 19th century. Thus began the study of biogeography.

Long before there were biogeographers, it was evident that different kinds of plants and animals occupied different kinds of places. Biogeography added mathematical precision to the folk knowledge that temperatures were lower at higher elevations and higher latitudes and that mountain ranges received more precipitation to windward than to leeward and were warmer on the sunnier slopes facing the equator. More climate and biogeographical data became available at the same time that cartography and species inventories were improving. All were necessary for accurately describing what lived where and for predicting what sorts of species would live in various places. Repeated inventories, measurements, and mapping were needed to show whether and how biogeography was changing.

Among the first patterns understood by biogeographers was that average temperatures on the earth's surface changed with latitude. Temperatures tended to be low in polar regions and higher near the equator. At the same time, they saw that temperatures near sea level tended to be warmer than temperatures at higher elevations. They found that even near the equator, the tops of very tall mountains (such as the Andes) were as cold as the poles and discovered that the plants and animals of polar and alpine locations were very similar. As observations accumulated, biogeographers were able to begin mapping the ranges of different species. Climate measurements helped biologists determine the limits of heat, cold, and precipitation that various species could tolerate.

It was long debated whether species actually could become extinct. It was not until large, easily observed birds like the dodo and the great auk could no longer be found and the fossilized remains of large, otherwise unknown animals were being discovered, that the fact of extinction was established. Not until the third quarter of the 19th century did it become clear that extinctions might regularly follow as the unintended consequences of intensive human activities. Climate changes traceable to human activities were hardly recognized for over another century, during which our population doubled twice over. During the roughly same period, our major technologies changed from being mostly animal, wind, and water powered to being combustion powered, using wood and fossil fuels.

CLIMATE DYNAMICS AND LIFE ON EARTH

Conditions on the Earth's surface and in its atmosphere have undergone many changes over time. Some of these changes were quite drastic and had proportionally drastic effects on living things. We can say with some confidence that the Earth's climate has sometimes been much warmer than it is today, and we know that at other times it has been much colder. This much can be inferred partially from recorded history but more reliably from fossils and other geological evidence. Scientists have proposed many plausible explanations for these climate changes, but since the events cannot really be modeled in detail or rep-

With global warming, newly ice-free Arctic lands would potentially become available for mining, oil and gas development, and manufacturing activities. Greater human density could affect survival rates of large mammals such as the Caribou, above.

licated for study, they can only agree about general effects, rather than local specifics.

Paleontologists and others who study the evolutionary history of life on earth have concluded that most of the species that ever inhabited the planet are now extinct. They have also estimated, as a sort of rule of thumb, that any given species, on average, persists for about a million years. Estimates of the total number of species that have existed on the planet range from tens of millions to hundreds of millions. Some of these species are known from the fossil record to have persisted much longer than a million years, and others for much shorter periods. Estimates and averages are only as good as the actual data and methods used to make them. Even if the data we have to work with are reliable, the fossil record is far from complete, and different methods of analysis continue to yield different estimates.

Because our planet is changeable, or dynamic, extinction seems to be normal and inevitable for species, much as death is inevitable for individuals. At the same time, however, evolution also generates new species from some of the old ones, as the average characteristics of a population change and "adapt" to emerging conditions. Overall, there is still life on Earth because the rate at which species evolve has exceeded the rate at which they become extinct.

No one is credibly predicting that all life on earth would end, and all species would go extinct, as a result of human-caused global warming, but many scientists are concerned that any continuing trend in climate change would increase the rate of extinctions, changing life as we know it and perhaps making life more difficult or less interesting for humans as a result. Many people want to preserve life as we know it and to prevent extinctions of other species caused by human activities. Global warming is one of many environmental changes human activities may bring about. The combined effects of human activities, along with those of geological and even cosmic events, are complex. Among the extinctions that occur during the foreseeable future, we will probably be able to blame very few solely, or even mostly, on human-caused climate change. However, if apparent trends continue, climate change will probably contribute in some way—large or small—to almost any extinction that occurs.

ECOLOGY AND CLIMATE CHANGE

It is difficult to distinguish extinctions caused mostly or mainly by climate change from those caused by other factors such as directly converting habitats to human uses. Conservation biologists have long considered habitat destruction to be the most likely cause of extinctions. Habitat has been described many ways, but it generally means an environment in which enough individuals of a particular species can survive and reproduce to keep their population from decreasing to zero. In other words, each species has a habitat, and each needs a persisting habitat to continue as a species.

Some habitats are more complicated than others, but all habitats can be thought of as having two general kinds of components. Biotic components are living things: all the other organisms that somehow affect the life of a plant or animal. Abiotic components are factors like terrain, minerals, water, sunlight, and temperature. Climate change can directly affect some of the abiotic components of a habitat. When particular places become warmer or cooler, or drier or wetter, the ability of any particular species to persist in that place also changes.

Some abiotic habitat components, such as temperature and humidity, will vary daily or seasonally. Organisms have to be able to tolerate the extremes of night and day, summer and winter, and wet and dry seasons. When the climate of a place changes to the point that one of an organism's tolerances is exceeded, a habitat literally ceases to exist.

Because of the shape of the Earth, less sunlight reaches the poles than the tropics. Habitats are limited by the climatic effects of latitude. If we could look down from space at the North Pole and see all the way to the equator, but still recognize all the land plants and animals, we would see that similar kinds of organisms are roughly arranged in a series of bands or zones centered on the pole, like a target. Working out from the center, each zone is slightly warmer than the one immediately inside it. When the average global temperature falls, the polar center of the target expands and the hottest equatorial zones shrink or even disappear. This happened during the Ice Ages, when glaciers covered much of the Northern Hemisphere. Animals and plants had to change, migrate, or become extinct. When the average global temperature rises, the polar center shrinks, and each climate zone moves toward it. The icy center may even disappear, and the next zone takes its place. Meanwhile, entirely new, hotter zones may appear at the equatorial edge.

Because the atmosphere is less dense in the mountains than at sea level, all habitats are also limited by the climatic effects of elevation. Higher elevations are colder. Seen from directly above, a tall mountain has bands of similar plants and animals, just as the whole planet does. A general trend in climate change means that these bands move down and up the mountain just as the latitude bands move toward and away from the poles.

CLIMATE-RELATED CAUSES OF EXTINCTIONS

Extinctions can occur gradually or suddenly. Large numbers of extinctions have sometimes occurred during relatively short periods of time. These "mass extinctions" resulted when a catastrophic event such as an asteroid impact suddenly made large areas of the earth's surface, or its oceans, uninhabitable. The effects produced by such catastrophes probably included sudden, drastic climate changes, but not enough evidence has been found to say with certainty how great these changes were or exactly how long they lasted.

Changing climates affect the survival prospects of individual organisms. As a result, changing climates affect the survival and reproduction rates of whole populations and species. Populations may rise or fall as climates change. Some increases or decreases will be dramatic and obvious. Others will be almost unnoticeable to us. Almost all such population changes will result from combinations of many small changes, rather than a few catastrophic ones.

As average global temperatures increase (or decrease), populations will migrate to follow shifts in local conditions. Some organisms can do this quickly and easily. Many animals already migrate to follow seasonal changes in food and water supplies. There are rare exceptions, but many individuals, such as rooted plants, cannot move at all. Their populations can migrate only as seeds are dispersed and new individuals germinate and survive in newly suitable locations. Meanwhile, the old individuals, trapped in increasingly unsuitable locations, gradually die out. When populations cannot shift to new locations quickly enough, species may become extinct. Extinctions also follow when no new locations become available or when potentially suitable locations exist but cannot be reached in time. We can easily imagine scenarios that include the extinction of plant species unable to disperse to new habitats. Because the phenomenon is so complex, scientists have been reluctant or unable to publish firm, reliable estimates of the numbers of species that could become extinct as a result of climate change, or to predict when such extinctions will occur.

Climate change is most likely to directly produce species extinctions in already extreme, barely survivable environments. These are the very cold, hot, wet, dry, or chemically unusual places in which only relatively few types of highly specialized organisms can exist. Where such extreme conditions are climate induced, even small temperature changes can be highly significant. Organisms in extreme environments are likely to be living near the limits of physiological possibility. When extreme environments become more extreme, some organisms die. When extreme environments become too extreme, nothing can survive in them—but that is only part of the story.

When extreme environments become more moderate, more species can move into them, leading to increased competition for living space and other resources. They may become "too moderate" for specialists that have lost, or perhaps never evolved, ways to compete or escape in highly diverse and densely populated environments. In other words, given a trend of global warming, hot, dry environments may become hotter and drier, crossing some survival threshold of survival for desert-adapted species. Individuals of those species will have to emigrate or die. However, some hot, dry environments might become wetter, or cooler, or both, even as average global temperatures are rising. This will allow species adapted to the new, more moderate conditions to immigrate and to compete with, prey on, or infect the existing populations in unprecedented ways.

DIRECT EFFECTS OF CLIMATE CHANGE ON SPECIES EXTINCTIONS

The direct effects of climate change are most likely to affect organisms of polar regions, mountaintops, and equatorial areas. Under a general trend of increasing temperatures, the very coldest climates—the Arctic and alpine tundras—could disappear, and along with them would likely disappear at least some of the species adapted to tolerate them. As the warmer habitats move toward the poles and up the mountains, their species will follow. Those that cannot migrate or disperse as fast as their potential habitats are shifting will either have to evolve new climatic tolerances or die out.

When abiotic factors change, some habitats may contract, even to the point of disappearing altogether. Others may expand, and new ones may appear. Overall, they can be imagined as flowing slowly across the landscape, expanding in some directions while retreating from others, sometimes forming and seemingly evaporating like puddles. The most obvious response for organisms that can move is to follow the changes in habitat or to find and occupy the new habitat. As long as enough individuals of a species can somehow keep up with these movements, their species may persist.

An expected direct effect of climate change with the potential for causing species extinction is a rise in sea level caused by the melting of polar and alpine glaciers. Large areas of low-lying coastal lands would be inundated by rising sea levels. In effect, some areas of terrestrial habitats would be converted to areas of aquatic habitats. Some low-lying oceanic islands would disappear, and along with them any land plants and animals that might be found nowhere else. Whether as a result of habitat inundation or other effects, species with very restricted ranges, called endemics, are likely to be more significantly affected by climate change than those with larger ranges.

Every species has different abiotic tolerances, so the edges of their potential habitats, based on moisture or temperature, rarely correspond exactly. Instead, these habitat edges usually overlap. Not only do they overlap, but climate change will affect each one differently, so different species habitats will move, grow, or contract at different rates. As we have seen, not all species are equally mobile. This means that two species may experience different direct, abiotic affects in the same place. These differences create the possibility of many indirect effects of climate change as species interact in new ways and places.

INDIRECT EFFECTS OF PERSISTENT CLIMATE CHANGE

Most effects on species resulting from any continuing climate change trend will be indirect. All animals rely on other species as sources of food. Many plants rely on insects and other animals to pollinate them or disperse their seeds. When different species come to depend on each other in predictable ways, their relationship is called a symbiosis. Symbioses range from pure exploitation, where only one species benefits, to cooperation or mutualism, where both species benefit. In many cases, such as those of internal parasites or intestinal bacteria, one organism actually becomes the entire habitat of another. Far more often, individuals of different species have no obvious interactions at all but do influence each other in much more subtle ways, such as by preying on another species' competitors, or its predators, or its pollinators, or by spreading its disease organisms.

The possibilities for changing species interactions are seemingly endless, but we can describe only a few examples here. Individuals of predatory species might find themselves able to range farther north, or higher into the mountains, where they will encounter potential prey species that have never seen them before. These prey animals may lack defensive or escape behaviors, and their populations may be significantly reduced. This does not mean that tropical cats like jaguars will be decimating caribou herds. Most of the land animals in the world are insects, as are most of the predators. We are hardly aware of predation at the insect level, but it is cumulatively enormous and enormously influential.

Most insects are unable to regulate their body temperatures except by seeking shelter. Flying insects have to meet minimum temperature requirements before their muscles work efficiently, allowing them to lift off. However, flying insects are highly mobile. Once aloft, they are often carried great distances by winds, sometimes to places where they normally cannot survive. However, if climates warm and their habitats move and expand, insects are likely to arrive in any newly suitable locations pretty quickly. If these pioneering insects are herbivores, they may find plants that have evolved no defenses against them. This could hasten the demise of individual plants and reduce populations that were physiologically capable of tolerating the direct effects of warmer temperatures.

Many plants rely on insects for pollination. Some plant populations could be reduced if predatory insects begin to survive in areas formerly unavailable to them because of climate factors and begin preying on the local pollinators. If pollinators become too scarce, plant reproduction could be reduced to levels that cannot maintain a population. Both the plants and the pollinators could be affected.

Polar ice caps and alpine glaciers are composed of accumulating snow. If they melt, the resulting water is fresh, not salty. There is not enough fresh water in these sources to significantly dilute the world's oceans and change the fundamental chemistry of seawater. However, fresh water is less dense than salt water, and until the two mix, fresh water entering the oceans actually floats as a surface layer. The addition of massive amounts of cold, fresh water to the Arctic, North Atlantic, and north Pacific oceans, and to the south polar regions of the Atlantic, Pacific, and Indian oceans, would affect the way currents flow and nutrients circulate in these areas. This would affect the types and distribution of plankton, and thus all the many levels of oceanic food webs in those areas. Reduced plankton production would ultimately mean less prey for aquatic predators of polar seas such as polar bears, penguins, and some toothed whales, seals, and sea lions. Added to the direct effects of reduced pack ice, such changes could lead to the extinction of animals highly specialized for life under cold polar conditions that would no longer exist.

Hot deserts have fewer rivers, lakes, and ponds, but many of them have springs and small water courses that support endemic aquatic species including fishes, amphibians, reptiles, and many invertebrates and microorganisms. If these hot deserts become even hotter or drier because of climate change, these "oases" could literally dry up. In the process, numerous rare aquatic species that cannot move to other habitats (even if they existed) would become extinct in the process.

Aquatic species endemic to small tributary streams in any watershed face various new conditions when a region becomes drier or wetter. Neither trend is automatically beneficial. If it becomes drier, the smaller tributaries become ephemeral or intermittent, forcing fully aquatic species downstream into larger, more permanent waters, where they may encounter more (and larger) predators, at least for a time. If the region becomes wetter, the small tributaries will become larger, and the larger predators may move upstream. In high, steep terrain, the physical characteristics of the newest small tributaries may make them unsuitable for colonization.

In wet tropical areas, the effect of climate change will most easily be seen if it results in changes to the flow of atmospheric moisture to the region and, as a result, to the seasonality and overall amount of precipitation. At its simplest, a rainforest with less rain will gradually become another kind of forest, having fewer species requiring high moisture or seasonal inundation by floodwaters and more that tolerate drier conditions. As in all cases, if suitable habitat disappears or appears only at an unreachable distance, some species could become extinct. The complexity and diversity of tropical forests is such that not only some tree species, but also their dependent animals (and, in turn, their own dependent animals), could become extinct in the process. Our knowledge of the flora and fauna of these regions is insufficient to support any precise estimate of the number of species present, much less the number that could be affected by any particular degree of climate alteration.

CLIMATE-RELATED EXTINCTIONS INVOLVING OTHER HUMAN ACTIVITIES

In anticipation of a continued warming trend in polar regions, various countries are already positioning themselves to take advantage of ice-free Arctic seas and increasingly temperate high latitudes. Others are bracing for possible desertification in tropical grass and scrublands. Areas likely to experience intensified human use may have higher likelihood of species extinctions.

Increasing commercial ship traffic in Arctic waters would produce the same sorts of side effects that shipping has elsewhere. Leaks and spills of fuel and cargo oil would affect the biota of littoral zones. Ballast water exchange would further redistribute aquatic species, leading to new predation and competition among aquatic species without prior experience of each other.

Newly ice-free Arctic lands would potentially become available for mining, oil and gas development, and allied manufacturing activities. This will require an influx of workers and equipment, along with creation of the physical, economic, and cultural infrastructure needed to support them. Each activity entails a direct conversion of some existing habitat to human use. This could fragment the habitats of migratory birds such as snow geese and affect survival rates for large mammals such as caribou and musk oxen.

More ship traffic, mining, and oil exploration would encourage more permanent human settlements to service, and be serviced by, these industries, leading to a greater likelihood of chemical pollution and of sewage and solid waste management issues. Human population centers would encourage the establishment of human commensals and inquilines, such as dogs and cats, rats and mice, cockroaches and houseflies. Each potentially adds a new challenge to the persistence of Arctic species.

Under a continued warming trend, farmers in Europe, Asia, and North America would experience the same northward and upward shift in habitat bands affecting uncultivated plants and wild animals. For example, grain production will likely be possible farther north, in the Canadian "Prairie Provinces." This would require "sodbusting" of existing grasslands or logging of forests to convert them into farms, reducing or eliminating their habitat value to most wildlife. All the world's major crops—corn, soybeans, wheat, rice, and cotton, along with most every other valued plant—would become economically viable in new areas while becoming impractical in others where they have been traditionally grown. The net effects on agricultural production are hard to estimate, as are the potential effects on other species.

Sri Lanka

THE DEMOCRATIC SOCIALIST Republic of Sri Lanka, formerly known as Ceylon, is a small, pear-shaped island of 25,332 sq. mi. (65,610 sq. km.) lying off the southeastern coast of India. Sri Lanka has an extraordinary diversity of wildlife and vegetation because of its location near the equator and its remarkable range of terrain and climate. Although only a minute contributor to greenhouse gas emissions, the island is vulnerable to the effects of climate change.

Sri Lanka's carbon emissions per capita are 161st out of 211 countries measured worldwide but more than doubled in the 10 years from 1990, largely in response to the country's increasing population. Like much of the rest of South Asia, Sri Lanka relies heavily on carbon-neutral biomass such as collected wood and animal waste for its domestic energy needs, particularly in rural areas. Biomass accounted for 80 percent of total residential energy consumption in 2005 and is expected to remain as high as 70 percent through 2020.

Oil consumption more than doubled between 1990 and 2005 in response to a growing demand for transport fuels. Sri Lanka imports all of its daily crude oil consumption of 87,000 barrels, and in recent years, it has further increased oil imports to avoid overreliance on hydroelectricity for industrial power. Hydropower currently provides the majority of Sri Lanka's electricity, making the country vulnerable to changing rainfall patterns. In an effort to diversify, the Sri Lankan government is developing fossil-fuel-fired power plants.

Sri Lanka's rich biodiversity includes an unusually large number of endemic species living in cloud forests, grasslands, and wetlands, as well as freshwater, coastal, and marine ecosystems. The island is both ecologically and economically vulnerable to climate change. Its famous tea plantations remain an important source of economic activity, and the island's rich cultural heritage, together with its tropical forests, beaches, and wildlife, make it a world-famous tourist destination. Climatic conditions and rich biodiversity are therefore key to maintaining Sri Lanka's economy. However, logging and population pressures continue to lead to deforestation and habitat loss. Large tracts of forest have been cut down for fuel wood or for timber export and have been replaced by rice, coconut, rubber, and coffee farms. Many species are in danger of extinction, including cheetahs, leopards, several species of monkeys, and wild elephants. Sri Lanka's coral reefs, already damaged by bleaching and the 2005 Asian tsunami, are being destroyed by human refuse and sewage and by dynamite fishing. Climate change–induced ecological stress will compound these eco-economic concerns.

Overall, the importance of environmentally sustainable behavior is underappreciated in the general population, as concerns such as poverty and the ongoing conflict between Tamil separatists and the Sinhalese government are dominant. Even so, the government of Sri Lanka has taken action to conserve wildlife. Over 13 percent of the land is protected, and the Sinharaja Forest Reserve, which protects the largest remaining stand of primary rainforest on the island, was declared a World Heritage Site in 1988. Indeed, Sri Lanka has a long history of conservation, being the first country in the world to establish a wildlife reserve.

Stanford University

STANFORD UNIVERSITY IS a private university located approximately 37 mi. (59 km.) southeast of San Francisco and approximately 20 mi. (32 km.) northwest of San Jose in Stanford, California. Stanford is situated adjacent to the city of Palo Alto, near Silicon Valley. The university enrolls approximately 6,700 undergraduates and 8,000 graduate students. The university has approximately 1,700 faculty members. Forty percent of the faculty is affiliated with the medical school, and a third serves in the School of Humanities and Sciences. Graduate studies in the Department of Geological and Environmental Sciences involve academic course work and independent research. Students are prepared for careers as professional scientists in research or for the application of the earth sciences to mineral, energy, and water resources. Programs lead to M.S., Engineer, and Ph.D. degrees. Course programs in the areas of faculty interest are tailored to the student's needs and interests with the aid of his or her research adviser. Students are encouraged to include in their program courses that are offered in other departments in the School of Earth Sciences, as well as courses offered in other departments in the university.

Launched in December 2002, the Global Climate and Energy Project (GCEP) at Stanford University seeks to find new solutions to one of the grand challenges of this century: supplying energy to meet the changing needs of a growing world population in a way that protects the environment. The primary goal of the project is to conduct fundamental research on technologies that will permit the development of global energy systems with significantly lower greenhouse gas emissions. With the support and participation of four international companies (ExxonMobil, General Electric, Schlumberger, and Toyota), the GCEP is a unique collaboration of the world's energy experts from research institutions and private industry. The project's sponsors will invest a total of $225 million over a decade or more as GCEP explores energy technologies that are efficient, environmentally benign, and cost effective.

The Stanford Climate Change Campaign, a project of Students for a Sustainable Stanford, in conjunction with People for the American Way Foundation, Global Exchange, and other student groups, has made a public commitment to lead the fight against global warming and to reduce its own carbon footprint.

The Center for Environmental Science and Policy (CESP) began as a specialized research center within the Freeman Spogli Institute for International Studies (FSI) in September 1998. It evolved as an outgrowth of the more informal Global Environmental Forum, which had existed within FSI for nearly a decade. CESP is also an affiliated center of the Woods Institute for the Environment. Formed in 2004, Woods is Stanford's principal initiative for assessing environmental science, technology, and policy on local, national, and global scales.

The center has grown considerably under the experienced leadership of a series of codirectors—Walter Falcon, Donald Kennedy, Pamela Matson, and Stephen Schneider. Leading scholars from the natural and social sciences, these individuals reflect CESP's integrative approach to research, which balances the analyses of environmental problems from both scientific and policy perspectives.

The CESP plays a crucial role in mobilizing a multidisciplinary network of scholars, students, policymakers, and leaders in understanding and helping to solve international environmental problems through science and policy research. The work of the center engages scholars from disciplines as varied as the biological and geological sciences, civil engineering, economics, and law to develop new methods for environmental assessment, negotiation, remediation, and protection.

Workshops, policy briefings, and publications link CESP with other public policy and scholarly institutions within and outside Stanford. The center houses the Program on Energy and Sustainable Development, a multiyear, interdisciplinary program that draws on the fields of engineering, political science, law, and economics to investigate how the production and consumption of energy affect sustainable development. CESP does not award degrees, but it is heavily engaged in graduate and undergraduate education. The center holds a close affiliation with Stanford's Interdisciplinary Graduate Program on Environment and Resources and also directs the Goldman Honors Program, an interschool honors program in environmental science, technology, and policy.

Stockholm Environment Institute (SEI)

THE STOCKHOLM ENVIRONMENT Institute (SEI) is a nonprofit, independent research institute specializing in sustainable development and environmental issues. SEI headquarters are located in Stockholm, Sweden, with centers in the United States and the United Kingdom. They work at the local, national, regional, and global policy levels. Their mission is to support decision making and induce change toward sustainable development around the world by providing integrative knowledge that bridges science and policy in the field of environment and development. The institute was established in 1989 following an initiative by the Swedish government to develop an international environment/development research organization. Each center has its own personality and foci of interests, and each operates with significant autonomy while participating in the five SEI research programs.

SEI's Climate and Energy Program addresses these challenges in collaboration with a global network of partners, enabling them to perform work in locally defined interests and resources. For the last two decades, projects in Africa, Asia, Europe, and Latin America have spurred innovative energy strategies that support the goals of social equity, environmental sustainability, and efficient economic development. Emissions of air pollutants to the atmosphere have had, and continue to have, significant effects on human health and well-being, crops and food security, ecosystems and biodiversity, and materials and cultural monuments.

The Atmospheric Environment (AE) Program within SEI contributes to the goal of reducing the local, regional, and global effects of the emission of pollutants to the atmosphere.

SEI's U.S. center conducts a diverse program focusing on the social, technological, and institutional requirements for a transition to sustainability. Funding is received from the United Nations, the World Bank, and numerous foundations and national governments such as the United States, Sweden, Denmark, Germany, the Netherlands, and the United Kingdom.

In addition to providing policy-relevant analyses, the center works to build capacity in developing countries for integrated sustainability planning through training and collaboration on projects. Its decision support tools are widely used: LEAP for energy planning and climate change mitigation, WEAP for water resources planning, and PoleStar for evaluating sustainable development strategies.

The center is organized into three programs: the Climate and Energy Program, which conducts energy system analyses, examines environmental consequences of energy use such as global warming, and develops policies for a transition to efficient and renewable energy technology; the Water Resources Program, which brings an integrated perspective to freshwater assessment—one that seeks sustainable water solutions by balancing the needs for basic water services, development, and the environment; and the Sustainable Development Studies Program, which takes a holistic perspective in assessing sustainability at the global, regional, and national levels.

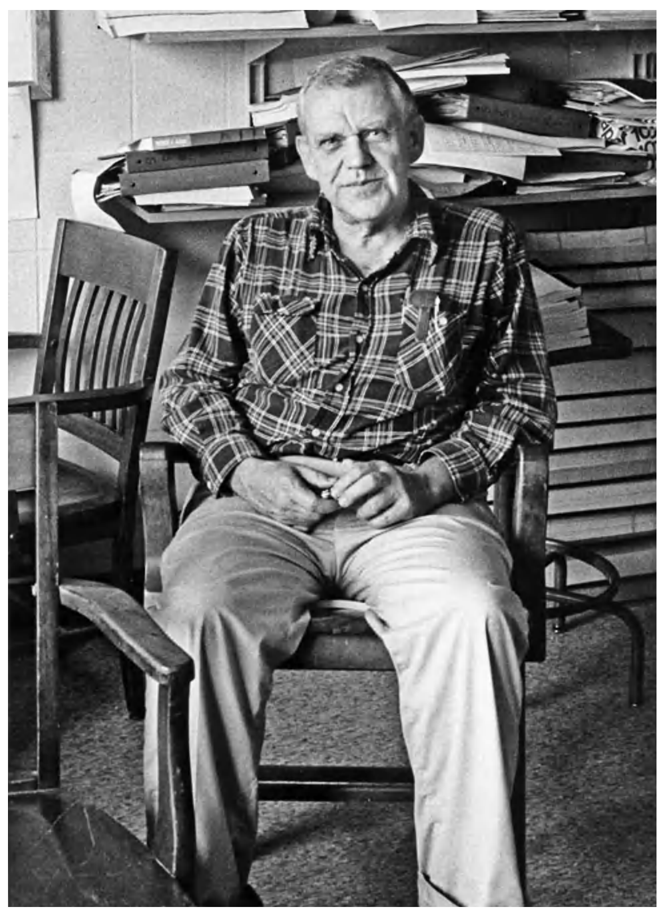
Stommel, Henry (1920–92)

HENRY STOMMEL IS an American oceanographer and meteorologist whose theories on general circulation patterns in the Atlantic Ocean made him the creator of the modern field of dynamical oceanography. Stommel carried out a series of research studies and first suggested that the Earth's rotation is responsible for the Gulf Stream along the coast of North America. He theorized that its northward thrust must be balanced by a stream of cold water moving in the opposite direction beneath it. Carl Wunsch has described Stommel as "a transitional figure, being probably the last of the creative physical oceanographers with no advanced degree, uncomfortable with the way the science had changed, and deeply nostalgic for his early scientific days." Stommel has been praised for being both a creative theorist and an acute observer who was willing to spend months at sea.

Stommel was born in Wilmington, Delaware, on September 27, 1920, into a family of extremely mixed background. His ancestors came from such different places as the Rhine Valley, Poland, Ireland, the Netherlands, England, and France, and they also had a trace of Micmac Indian. Henry's father, Walter, was a chemist born in northern Germany and trained in Darmstadt and Paris. During World War I, Walter Stommel



Henry Stommel theorized the circulation patterns of oceans and cold water moving in the opposite direction beneath it.

emigrated to Wilmington, where he was employed by Dupont Chemical. While in the United States, he married Marian Melson. Their son Henry was born shortly after the marriage. Although the reason is not completely clear, perhaps because of anti-German sentiment following World War I, the family then moved to Sweden. Henry's mother, however, soon left Sweden with Henry and returned to Wilmington. Because of his mother's decision not to see her husband again, Henry and his sister Anne grew up in a single-parent family. When Henry was 5 years old, his mother moved with the two children to Brooklyn, New York, to live with her parents and other relatives. Marian supported the entire household thanks to her job as a fund-raiser and public relations officer at a hospital. Henry and his grandfather, Levin Franklin Melson, developed a meaningful relationship in a household dominated by women.

Stommel attended New York City's public schools. He spent one year at Townsend Harris High School but finished high school at Freeport, Long Island, because his family had moved there. Thanks to his receiving a full scholarship, he was able to enroll at Yale University, from where he graduated in 1942. He remained at Yale for two years following graduation, teaching analytic geometry and celestial navigation in the Navy's V-12 program. He also spent six months at the Yale Divinity School, but his lifelong ambivalence toward religion made the ministry an unsuitable vocation for him. In 1944, renowned astrophysicist Lyman Spitzer suggested that Stommel apply for work at the Woods Hole Oceanographic Institution in Woods Hole, Massachusetts—an organization that was fast becoming a decisive part of the U.S. war effort. Stommel was recruited to work in acoustics and antisubmarine warfare but disliked his assignment and tried to be employed in other areas.

In 1948, Stommel wrote "The Westward Intensification of Wind-Driven Ocean Currents," a paper that is unanimously regarded as constituting the starting point of dynamical oceanography. In it, he explained the Gulf Stream deductively by fluid dynamics. In particular, he discovered the mechanism (the latitudinal change of the Coriolis force on the rotating Earth) that produced the westward intensification of oceanic currents. Stommel proposed a global circulation model similar to a conveyor belt: surface water sinks in the far north to supply the deep, south-flowing current, and water rises in the Antarctic region to contribute a northward flow along the eastern coasts of North and South America. His important book *The Gulf Stream* was probably the first true dynamical discussion of the ocean circulation. He put the Gulf Stream in the wider context of the general circulation and paved the way for the development of the so-called thermocline theories. Stommel also concluded that changes in density caused by cooling and evaporation at the sea surface can be responsible for deep flows in the ocean. He was thus responsible for establishing the basic factors that helped to establish theories about global circulation. His thermocline theories stressed the role of oceans and sea currents in the definition of global climate and thus anticipated debates on global warming.

In December 1950, Stommel married Elizabeth Brown. The couple had three children. Although Stommel liked working at the Woods Hole Oceanographic Institution, he did not get on well with his director Paul Fye. Therefore, he accepted an invitation to become a professor at Harvard University in 1959, lured by the prestige of the institution. He spent four unhappy years there, where his democratic ideals clashed with a rigid sense of hierarchies. After Harvard, Stommel went to work at the Department of Meteorology at the Massachusetts Institute of Technology (MIT). There he worked with the most famous meteorologists of the day, such as Jule Charney, Norman Phillips, Edward Lorenz, and Victor Starr. Stommel worked enthusiastically with these scientists to improve theories of general circulation. He also worked on other important topics such as the classification of estuaries and the effect of volcanoes on climate.

Stommel worked at MIT for 16 years as a professor of physical oceanography. He returned to the Woods Hole Oceanographic Institution when Fye retired and continued to work there until his death on January 17, 1992. Stommel established several stations for the study of ocean currents, including the PANULIRUS station (begun in 1954) in Bermuda. He was elected to the National Academy of Sciences in 1962 and received the National Medal of Science in 1989.

Stratopause

THE STRATOPAUSE IS one of the layers into which the atmosphere is divided. It is the buffer region of the atmosphere that lies between the stratosphere and the mesosphere, from a height of about 31 to 34 mi. (50 to 55 km.) above the Earth's soil. The atmospheric pressure is about 1/1000th of the pressure at sea level. In the stratopause, the temperature reaches a peak because of the heating generated by the absorption of ultraviolet radiation by ozone molecules in the stratospheric ozone layer. In this region, the catalytic cycles, which are less efficient at colder temperatures because of reduced O density, produce a significant ozone increase (~15 percent). Because of the considerable ozone presence in the stratopause, the understanding of this region is considered crucial to understanding the changes in climate and in the composition of the ozone layer. Above the stratopause, the temperature starts again to decrease with height as a result of the reduced solar heating of ozone.

The depletion of the ozone layer resulting from the emission of halogen atoms and the photodissociation of chlorofluorocarbon compounds is of particular concern to scientists, as the layer prevents the most harmful ultraviolet-B wavelengths from passing through the Earth's atmosphere. Near the stratopause, the ozone reduction is slightly smaller in the drier stratosphere because of the stronger temperature dependence of the drier atmosphere.

Studies of the temperature in the stratopause have also been important to assess the validity of global circulation models. For example, a study published in 2002 by the University of Illinois at Urbana-Champaign, and the High Altitude Observatory of the National Center for Atmospheric Research in Boulder, Colorado, showed that wintertime warming caused by sinking air masses was not as strong as the models had assumed. The study employed lidar laser measurements and balloon observations made at the Amundsen-Scott South Pole Station from December 1999 to October 2001. These measurements and observations were then used to calculate the monthly mean winter temperature profiles from the surface to about 63 mi. (110 km.). The measured temperatures during midwinter in both the stratopause and mesopause regions were 20–30 degrees Kelvin colder than current model predictions. These differences were caused by weaker than expected compressional heating associated with subsidence over the polar cap. The study showed that the greatest difference occurred in the month of July, when the measured stratopause temperature was about 0 degrees F (minus 18 degrees C) compared with the about 40 degrees F (4.4 degrees C) predicted by the models.

Stratosphere

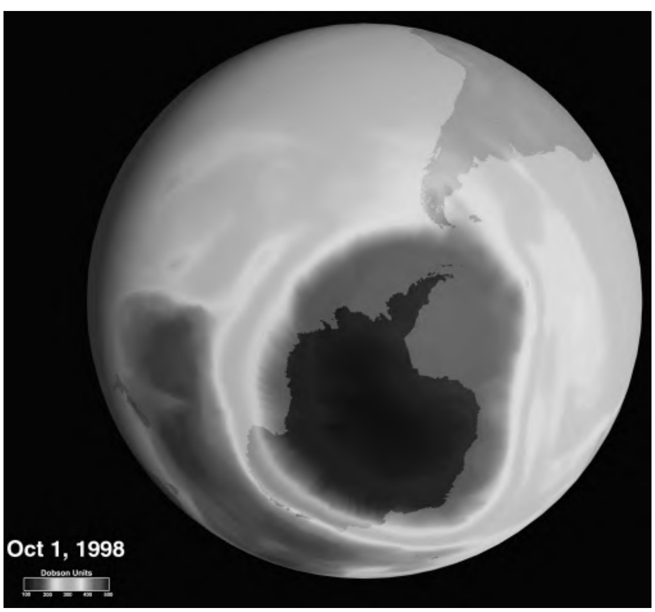
THE STRATOSPHERE IS a layer in the atmosphere that extends between about 9 to 31 mi. (15 and 50 km.) in altitude. It is characterized by a vertical temperature structure that is nearly isothermal (no temperature change with altitude) in the lowermost stratosphere and a pronounced inversion (increase of temperature with altitude) above. The stratosphere owes its name to the strong stratification, which is a consequence of this thermal structure.

The stratosphere plays an important role in the climate system. It contains the ozone layer, which shields the Earth's surface from harmful ultraviolet radiation and is responsible for the temperature of the stratosphere. Radiative processes in the infrared part of the electromagnetic spectrum also play an important role. Because, in the stratosphere, chemistry, dynamics, and radiative processes operate under very different conditions than in the troposphere, the stratosphere is susceptible to climatic forcings in a different way than the troposphere. As a consequence, stratospheric processes play an important role for climate variability and change.

The stratosphere was discovered independently by Teisserence de Bort and by Richard Assmann around 1900. It has been explored by balloon-borne observations since around the 1930s and by satellite observations since the 1970s.

The lower boundary of the stratosphere is the tropopause, the altitude of which varies with latitude (higher over the tropics than over the poles), season, and on a day-to-day scale related to weather systems. The upper boundary of the stratosphere is the stratopause. Below and above the stratosphere are the troposphere and mesosphere, respectively.

Because of its thermal structure (strong static stability), the circulation of the stratosphere is quasi-horizontal. The most important features of the zonal circulation are the vortices in the polar regions and the Quasi-Biennial Oscillation (QBO) in the tropics.



The large ozone opening over the poles (dark area). Stratospheric ozone blocks harmful ultraviolet radiation produced by the sun.

The polar vortices form over both poles during the corresponding winter season and vertically extend through the entire stratosphere. The Arctic vortex is subject to strong variability on short timescales (during so-called sudden stratospheric warmings, the vortex can break down completely within days) and on interannular timescales. The Antarctic vortex varies much less. The QBO is an oscillation of the zonal wind in the equatorial stratosphere, with changes from westerlies to easterlies and back to westerlies within approximately 28 months.

Compared with the zonal flow, the meridional circulation and associated vertical motion in the stratosphere are very weak but are, nevertheless, important. The meridional circulation is caused by planetary waves originating from the troposphere, which break and dissipate in the stratosphere and thereby deposit momentum, decelerating the zonal flow and inducing a meridional flow component. The meridional flow is compensated for by vertical motion in the tropics and in the polar areas, forming a single meridional circulation cell, which in the context of trace gas transport is often referred to as Brewer-Dobson circulation. Air enters the stratosphere in tropical areas. On passing the tropopause, the air loses almost all of its moisture; hence, the stratosphere is very dry and mostly cloud free. In the stratosphere, the air slowly moves upward and poleward toward the winter hemisphere (the summer hemisphere is dynamically quiet). In the subpolar and polar region, the air descends and can eventually enter the troposphere in conjunction with midlatitude weather systems. The stratospheric meridional circulation has a turnover time of one to three years.

Chemically, the stratosphere is characterized by a layer of ozone (O_3) formed from atomic (O) and molecular (O_2) oxygen in the presence of ultraviolet radiation. Ozone can be destroyed by catalytic processes that involve radicals of chlorine, bromine, nitrogen oxides, or hydrogen oxides. The most important source of chlorine radicals are manmade chlorofluorocarbons (CFCs), which have caused a reduction of the ozone layer since the 1970s, as well as, since the 1980s, the Antarctic ozone hole (a substantial reduction of the total stratospheric ozone amount over Antarctica). The Montreal Protocol of 1987 and its amendments have led to a strong reduction in CFC emissions worldwide. However, because of the long lifetime of CFCs, a full recovery of the ozone layer is only expected for the mid-21st century.

The anthropogenic greenhouse effect, as well as ozone depletion, causes a cooling of the stratosphere, whereas volcanic eruptions lead to warming. The stratosphere plays an important role for climate at the Earth's surface. Perturbations of the stratospheric circulation can propagate downward and affect weather at the ground. This provides a pathway through which some of the forcings can affect climate. For instance, it is now believed that part of the climate effect of strong volcanic eruptions operates via the change in stratospheric circulation induced by the heating effect of volcanic aerosols. Similarly, changes in solar irradiance could affect climate via stratospheric ozone chemistry and their subsequent effects on circulation.

Sudan

SUDAN IS A sub-Saharan African (SSA) country that has been combating global warming for many decades. Similar to other SSA countries, Sudan can expect an increase in temperature of 0.4–0.9 degrees F (0.2–0.5 degrees C) per decade, which may lead to the climate becoming drier. In Sudan, rainfall is predicted to decrease by 25 percent over 30 years, leading to desertification in a country that is already 50 percent desert.

Since the 1930s, the desert in Sudan expanded between 31 and 124 mi. (50 and 200 km.), which has led to severe water shortages. It has been predicted that 350 to 600 million people will face water shortages in Sudan by the middle of the 21st century. Water shortages, especially in western Sudan, have led many herders from northern Sudan to migrate to southern areas onto farmers' lands in search of water. This conflict over water, which is a precious resource in Sudan, has led to violence and to 2.4 million people being displaced in 2003. Increases in livestock, which has degraded the land, and deforestation (loss of 12 percent of forests over the last 15 years) have also contributed to continuing desertification. The drying climate has threatened the food security of 1.7 million people, as 90 percent of the people in Sudan depend exclusively on rain-fed agriculture.

Positive adaptive measures have, however, been taking place since 1992 in drought-prone western areas of Sudan, such as the Bara Province. In this area, rangeland rehabilitation measures are being taken through community participation to manage land and water resources and promote agroforestry and sand dune fixation. This has helped prevent overexploitation of resources and restore the productivity of rangelands.

Although Sudan is facing many challenges because of climate change, it hardly contributes to worldwide greenhouse gas emissions. For instance, in 1998, Sudan's total carbon dioxide emission was 3,597 thousand metric tons (tmt) compared with 515,001 tmt for SSA and 24,215,376 tmt for the world. Non–carbon dioxide emissions for Sudan in 1995 were 132 tmt compared with 5,345 tmt for SSA and 141,875 tmt for the world. Even though Sudan hardly contributes to global warming, the government of Sudan intends to adapt to the consequences of the problem. It has prepared the National Adaptation Plans for Action, which highlight several policy measures to adapt to climate change. These include increasing irrigation and low-water crops, water management and conservation technology, sustainable forest resource consumption, and reduction of livestock. The government of Sudan has also ratified the United Nations Framework Convention on Climate Change.

Sulphur Dioxide

SULPHUR DIOXIDE (SO_2) is an important component of the atmosphere, present as the result of both natural and human activity. Although it is a primary pollutant in its own right, causing respiratory irritation and damage to plants, it is the secondary pollutants produced from SO_2 that are particularly important in connection with global climate change. Sulphur dioxide is notorious as the cause of acid rain, but it is also a precursor to the formation of clouds. Hence, its release to the atmosphere is a major contributor to global dimming, a process that is thought to offset some of the effects of global warming.

There are, therefore, important implications of SO_2 release for the global climate change agenda. The reduction in SO_2 pollution in recent decades, stimulated by health concerns and by the effects of acid rain, is removing an unexpected and previously unidentified protection against increasing global temperatures. This illustrates the complexity of climate science that compounds the social and political responses to the threat of climate change.

Once in the atmosphere, SO_2 is rapidly oxidized, ultimately producing sulphuric acid. Although this transformation is well known in the formation of acid rain, it also has broader climatological significance. The liquid sulphuric acid forms as an aerosol (tiny droplets suspended in the air), and this sulphuric acid aerosol attracts water vapor, which dissolves in the acid. In this way, the gas-to-liquid conversion of SO_2 to sulphuric acid brings about the nucleation of clouds: sulphuric acid aerosol is a cloud condensation nucleus (CCN).

Clouds play important roles in the atmosphere and in the climate, principally acting to transport water (and energy) between regions and to affect the Earth's radiation balance. Clouds have a very strong tendency to reflect sunlight (they have a high albedo) and also absorb energy from the sun, so that the amount of cloud present in the atmosphere affects the amount of sunlight reaching the surface: more clouds result in a dimmer planet. This dimming effect of clouds is well documented.

SULPHUR DIOXIDE AND CLIMATE CHANGE

Furthermore, the influence of SO_2, and subsequent aerosol formation, has been observed directly during volcanic eruptions. For example, the 1991 eruption of Mount Pinatubo in the Philippines released an estimated 20 megatons (20,000,000 tons) of SO_2 into the atmosphere. The force of the explosion injected a large fraction of this material, along with dust particles, directly into the stratosphere, from which removal via rainout is very slow. The aerosol and clouds that formed as a consequence of this lasted for many years, with measurable effects on global temperatures. In the year following the eruption, the global average temperature reduced by 0.9 degrees F (0.5 degrees C), and even in 1993 the temperature was depressed by as much as 0.45 degrees F (0.25 degrees C).

In the lower atmosphere, the rate of SO_2 gas-to-liquid conversion is increased in the presence of other materials, notably particles such as soot, and this has an important effect on cloud condensation. The typically hydrophobic—water-repelling—surfaces of soot particles catalyze the chemical reactions that convert SO_2 to sulphuric acid, so that the soot ends up coated with a water-loving, hydrophilic layer. The simultaneous emission of SO_2 and soot (e.g., from burning coal or diesel fuel) therefore increases the concentration of cloud condensation nuclei in the air, affecting both the amount and nature of cloud formation.

Because there are many more cloud condensation nuclei under these conditions than in the clean atmosphere, clouds form with smaller, more numerous droplets. More numerous particles means that the clouds reflect more light, and smaller droplets take longer to form raindrops. Hence, the clouds formed on sulphate/soot aerosol CCN are longer lived and have a higher albedo than ordinary clouds. In this way, SO_2 emissions in combination with soot increase the amount of incoming sunlight reflected away from the Earth, effectively dimming the planet's surface.

Sulphur dioxide pollution–related global dimming is thought to explain the slight global cooling trend in the period from 1950 to the late 1970s. With the recent, legislation-driven decrease in emissions of SO_2 and soot particles from industry and transport in industrialized nations, there has been a steady rise in the amount of sunlight reaching the earth. It is suspected that reducing this form of pollution is removing an effect that has been offsetting the full force of anthropogenic global climate change.

Sulphur Hexafluoride

SULPHUR HEXAFLUORIDE (SF_6) is the most powerful of all the greenhouse gases recognized by the Kyoto Protocol and evaluated by the Intergovernmental Panel on Climate Change. Although its concentration in the atmosphere is low, the combination of a high global warming potential and a very long lifetime make emissions of SF_6 a considerable concern. It is primarily used as an electrical insulator in the high-voltage distribution network, and major industrial users are beginning to restrict the use and emission of SF_6.

The Kyoto Protocol requires developed nations to cut their emission of six greenhouse gases. The Intergovernmental Panel on Climate Change periodically assesses these gases and estimates a global warming potential (GWP) for each. The gasses, with their respective GWPs, are as follows: CO_2 (1), CH_4 (21), N_2O (310), PFC (9200), HFC (11,700), and SF_6 (23,900). In this list, HFC and PFC are groups of chemicals, and the value quoted is for the member of the group with the highest GWP. Despite the low atmospheric concentration of SF_6 (5.6 parts per trillion), its extremely high global warming potential and long lifetime (probably in excess of 1,000 years) mean that present emissions will have an effect on climate for a long time to come.

As SF_6 gas is denser (heavier) and more electrically insulating than either dry air or dry nitrogen, it is an ideal electrical insulating material. The gas is used extensively in electrical applications, and its principal use is in the electrical generation and high-voltage distribution industry. There are two specific advantages of SF_6 in these applications. First, its highly insulating character means that less space is needed between high-voltage components, so that equipment can be made significantly smaller than is possible when air or nitrogen are use as insulators. Second, gas-insulated switch gear using SF_6 rather than air demands a controlled environment, and the equipment is consequently more robust with regard to environmental pollutants and weathering than would be the case with simpler air-insulated equipment. In addition to these advantages, the gas is unreactive, nontoxic and nonflammable. In the United States, the electric power distribution industry works on a voluntary basis with the SF_6 Emissions Reduction Partnership for Electric Power Systems to identify and implement technologies for reducing SF_6 emissions.

Another large-scale use of SF_6 is in magnesium metal manufacturing and casting. Magnesium metal is extremely reactive in air, particularly when hot or molten. The high density and low chemical reactivity of SF_6 make it a suitable choice as a protective gas layer preventing contact of the molten, highly reactive metal with oxygen and water in the air. A voluntary SF_6 Emission Reduction Partnership for the Magnesium Industry exists in the United States in association with the U.S. Environmental Protection Agency, which, together with the International Magnesium Association, is committed to eliminating SF_6 emissions from the industry by 2011.

SF_6 is also used in certain medical applications, including eye surgery and ultrasound scanning. Once again, it is the gas's high density and low toxicity that are used. In eye surgery, the gas is commonly used to form a plug to seal the retina during surgery. Its high density means that the gas stays in place and does not enter the blood at an appreciable rate. The density of the gas also makes it an excellent contrast agent in medical ultrasound scanning.

Similar to the perfluorocarbons, SF_6 is also used in the semiconductor industry, and there is concern about the growth of this industry leading to uncontrolled increases in the amount of SF_6 released to the atmosphere.

Paradoxically, because of its high chemical stability, low toxicity, and low natural abundance, SF_6 has been extensively used by atmospheric scientists as a tracer gas to understand the movements and mixing of air. The gas has, for instance, been injected into the exhaust plumes from power stations in an attempt to understand the origins of acid rain. In the United Kingdom, SF_6 tracer experiments have demonstrated that power stations are capable of delivering acid rain pollution to Scandinavia. For similar reasons, SF_6 is used to trace the movements of air within ventilation and air conditioning system tests. Recently, the gas was released on the London Underground in an attempt to understand the way toxic gases would spread throughout the system in the event of a terrorist attack.

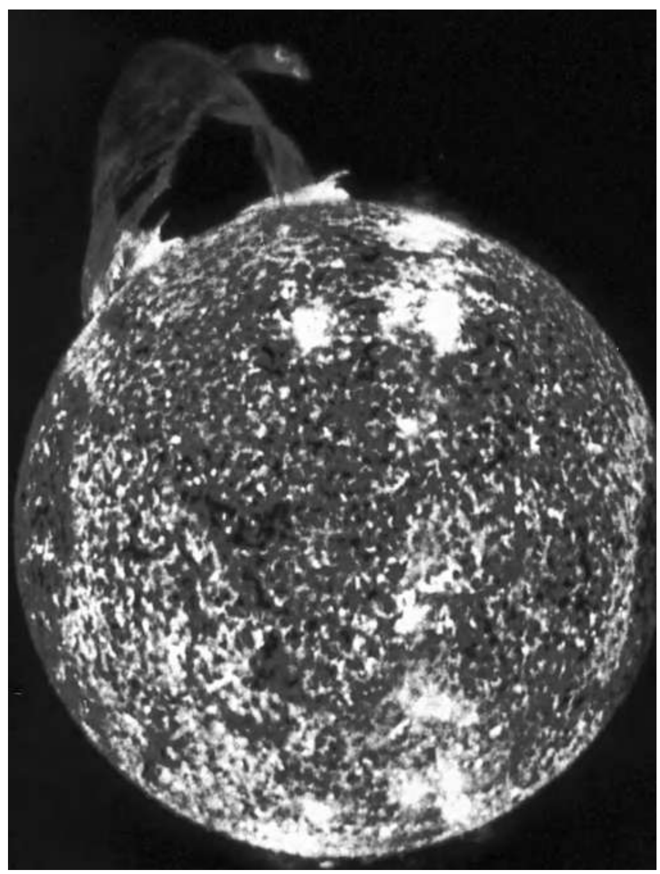
Sunlight

SUNLIGHT IS THE electromagnetic radiation given off by the sun. It is passed through the atmosphere to the Earth, where the solar radiation is reflected as daylight. Sunshine results when the solar radiation is not blocked. Sunlight is the primary source of energy to the Earth. It provides infrared, visible, and ultraviolet (UV) electromagnetic radiation with different wavelengths. Small sections of the wavelengths that are visible to the human eye are reflected as rainbow colors. Sunlight may be recorded using a sunshine recorder. Electromagnetic waves are waves that are capable of transporting energy through the vacuum of outer space and that exist with an enormous continuous range of frequencies known as the electromagnetic spectrum. The spectrum is divided into smaller spectra on the basis of interactions of electromagnetic waves with matter.

The longer-wavelength, lower-frequency regions are located on the far left of the spectrum, and the shorter-wavelength, higher-frequency regions are on the far right. Two very narrow regions within the spectrum are the visible light region and the X-ray region. The visible light region is a very narrow band of wavelengths located to the right of the infrared region and to the left of the UV region. Though electromagnetic



Sunlight is Earth's primary source of energy, providing infrared, visible, and ultraviolet electromagnetic radiation.

waves exist in a vast range of wavelengths, human eyes are only sensitive to the visible light spectrum. The visible portion of the solar spectrum lies between 400 and 700 nm. and separates the UV region of shorter wavelengths from the infrared region of longer wavelengths. A combination of waves results in white light. Red has the longest visible wavelength, whereas violet has the shortest. Waves longer than red are known as infrared, and waves shorter than violet are called UV.

The sun is the closest star to the Earth and the most closely studied. It is at the center of the solar system and accounts for about 99.8 percent of the mass of the solar system. The planets revolve around the sun. The sun is composed of hydrogen, helium, and other trace elements and goes around the center of the Milky Way galaxy at a distance of about 26,000 light years from the center of the galaxy. The amount of solar energy incident on the Earth's atmosphere is about 342 Watts per sq. m.r, based on the surface area of the Earth. Although the Earth's surface continuously radiates energy outward to space, only part of the surface area receives solar radiation at a time. Most of the solar energy incident on the Earth is in the UV region of shorter wavelengths. The sun is the source of heat that sustains life on Earth and controls the climate and weather. Only the sun's outer layers, which consist of the photosphere, the chromosphere, and the corona, can be observed directly. These three regions have different properties from one another, with regions of gradual transition between them. The sun has basically the same chemical elements as are present on the Earth. However, the sun is so hot that all of these elements exist in the gaseous state. Energy generated in the sun's core takes a million years to reach its surface. Solar energy is created deep within the core of the sun, where nuclear reactions take place.

SUNLIGHT AND THE DANGER OF SKIN CANCER

Every living thing exists because of the light from the sun. Sunlight is important in photosynthesis. For humans, UV light in small amounts is beneficial because it helps the body produce vitamin D from the UV region of sunlight. However, excessive exposure to sunlight is dangerous, as it can cause sunburns, skin cancer, and aging. UV light wavelengths are short enough to break the chemical bonds in skin tissue, and when the skin is exposed to sunlight, most skin will either burn or tan. The skin undergoes certain changes when exposed to UV light to protect itself against damage. The epidermis thickens, blocking UV light, and the melanocytes make increased amounts of melanin, which darkens the skin, resulting in a tan. Melanin absorbs the energy of UV light and prevents the light from penetrating deeper into the tissues. Sensitivity to sunlight varies according to the amount of melanin in the skin. Darker-skinned people have more melanin and therefore have greater protection against the sun's harmful effects. The amount of melanin present in a person's skin depends on heredity as well as on the amount of recent sun exposure. Albinos have little or no melanin. The more sun exposure a person has, the higher the risk of skin cancers, including squamous cell carcinoma, basal cell carcinoma, and malignant melanoma. Actinic keratoses (solar keratoses) are precancerous growths also caused by long-term sun exposure.

UV light, although invisible to the human eye, is the component of sunlight that has the greatest effect on human skin. Sunlight deficiency could increase blood cholesterol by allowing squalene metabolism to progress to cholesterol synthesis rather than to vitamin D synthesis, as would occur with greater amounts of sunlight exposure. Larger amounts of UV light damage the body's DNA and alter the amounts and kinds of chemicals that the skin cells make. UV light may also break down folic acid, sometimes resulting in a deficiency of that vitamin in fair-skinned people. UV light is classified into three types, UVA, UVB, and UVC, depending on its wavelength. Although UVA penetrates deeper into the skin, UVB is responsible for at least three quarters of the damaging effects of UV light, including tanning, burning, premature skin aging, wrinkling, and skin cancer. The amount of UV light reaching the Earth's surface is increasing, especially in the northern latitudes. This increase is attributable to chemical reactions between ozone and chlorofluorocarbons that are depleting the protective ozone layer, creating a thinner atmosphere with some holes. The key to minimizing the damaging effects of the sun is avoiding further sun exposure. It should be noted that damage that is already done is difficult to reverse.

Suriname

LOCATED IN THE northeast of the South American mainland, Suriname, formerly a Dutch colony, has a land area of 63,251 sq. mi. (163,270 sq. km.), with a population of 458,000 (2006 est.) and a population density of 7 people per sq. mi. (2.7 people per sq. km.). With 97 percent of the land covered in forests, and a relatively small timber industry, there is little arable land available.

For electricity production, in 2001, 64.2 percent of the country's electricity came from hydropower, with the remaining 35.8 percent coming from fossil fuels. Much of the hydropower comes from a number of hydroelectric plants in the country. Although most provide electricity for the government, some were constructed to provide electricity for specific businesses, such as the Brokopondo Reservoir for the nearby Alcoa aluminum plant. Most of the fossil fuels used in Suriname come from petroleum, with liquid fuels being responsible for 95 percent of the carbon dioxide emissions from the entire country. On account of this reliance on liquid fuels, in spite of being largely undeveloped, Suriname had a per capita rate of carbon dioxide emissions of 4.5 metric tons per person in 1990, rising steadily to 5.1 metric tons in 2003.

The effects of global warming on Suriname include a greater possibility of flooding, with the increased risk of insect-borne diseases such as malaria and dengue fever. There is also the risk of alienating some of the arable land in the country, possibly making it dependent on imported food. Furthermore, the rising water temperature is already having an effect on the leatherback turtles at the Galibi Nature Reserve. The Suriname government took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992, ratifying it four years later, with the government ratifying the Vienna Convention in 1997. On September 25, 2006, Suriname became the 163rd country to ratify the Kyoto Protocol to the UN Framework Convention on Climate Change.

Sustainability

THE LANGUAGE OF sustainability emerged during the 1970s, though the concept was introduced as sustainable development in 1980 in the World Conservation Strategy and was popularized in 1987 by the World Commission on Environment and Development (also known as the Brundtland Commission after its Norwegian chairperson Gro Harlem Brundtland). Today there are numerous definitions of sustainability, but the important question to ask is, What is to be sustained? Is it the planet, particular environments, individual species, current lifestyles, certain rates of economic growth, a specific level of profit?

Sustainability, especially as constructed in mainstream definitions of sustainable development, is very similar to the concept of conservation espoused by the American forester, Gifford Pinchot, in the late 19th century. Conservation emphasized using natural resources wisely, not depleting nonrenewable resources, ensuring that all American men received a fair share of the distribution of benefits, and that consideration be given to the needs of their descendents. Sustainable development globalizes the discourse. The World Commission on Environment and Development report in 1987 defined sustainable development as "development that meets the needs of the present without compromising the ability of future generations to meet their own needs." This definition is used today in many parts of the world by governments, businesses, environmental groups, and educators. The history of the concept, and the specific term, mean that it may be interpreted as a repackaging of environmental management. The managerial focus and faith in technological progress evident in this definition of sustainability mean that it is critiqued by more radical sustainability advocates.

In Australia, the term ecologically sustainable development emerged as a unique approach as a result of the power of major environmental groups in Australia in the early 1990s. In 1992, ecologically sustainable development was defined as "using, conserving and enhancing the community's resources so that ecological processes, on which life depends, are maintained and the total quality of life, now and in the future, can be increased." This terminology and definition, which arose as a result of the political power of environmental groups in the early 1990s in Australia, highlights the dependence of all life on ecological processes (thermodynamics, hydrological cycles, nutrient cycles, and so on).

The Australian definition leans toward what has been termed strong sustainability, meaning that humans should not be substituting human-made capital for natural capital. In contrast, weak sustainability advocates substitution provided the total store of capital is not diminished. Critics of the weak sustainability approach point out that this is what has been happening for thousands of years, leading to the destruction of the environment. Other critics reject the notion of turning nature into "natural capital" and therefore do not engage in the strong versus weak sustainability debates.

CONFERENCES ON SUSTAINABILITY

The concept of sustainable development was the basis for a massive conference in Rio de Janeiro in 1992 that was chaired by Maurice Strong and attended by 178 governments, including 118 heads of state. The United Nations Conference on Environment and Development (UNCED, otherwise known as the Earth Summit) was the five-year follow-up to the release of the Brundtland Report. The conference attempted to move from debates about the notion of sustainability and sustainable development to working out how to implement this idea. The idea of expanding the global economy, although controversial, was accepted within sustainable development discourses because development was seen as being necessary to overcome poverty. Sustainable development was intended to allow economic growth to continue but to make this growth greener. Growth was seen as essential for developing countries and also for developed countries, so as to facilitate trade and help the poorer countries of the world. This concept of sustainability was compatible with that of the newly founded business organization, the World Business Council for Sustainable Development, which was influential in shaping the idea of sustainable development and how it would be implemented.

Implementation has been the focus of subsequent conferences in New York (1997) and Johannesburg (2002) and in the ongoing work of the United Nations Commission on Sustainable Development. Many countries, states/provinces, and local governments, as well as some businesses, have also introduced departments focused on implementing sustainability within their organization. Implementation is challenging because there are many barriers to implementing sustainable development. These include corporate cultures, countervailing market signals, and jurisdictional issues. Another issue is that although the temporal emphasis within the concept of sustainability is apparent, the spatial or geographical scale is unclear. This has led to various scales of analysis and implementation, including concepts such as sustainable lifestyles, sustainable cities, and sustainable regions. The UNCED Conference in 1992 produced five important documents including Agenda 21, which was a 40-chapter document outlining the actions needed to implement sustainable development. Importantly, chapter 28 highlighted the important role of local government in implementing the concepts introduced at the global level. This led to the development of Local Agenda 21 (LA21). At the Johannesburg Conference in 2002, LA21 was relaunched as Local Action 21, which is the second decade of this program containing a focus on action and implementation.

FUTURE PLANNING

There are also different ways of conceptualizing sustainable development vis-à-vis sustainability. Some authors present sustainability and sustainable futures as being the goals to be reached by a process called sustainable development. Other authors maintain a distinction between sustainable development and ecological sustainability on the basis of their approach to existing structures and institutions. Sustainable development is seen as more of a reformist approach by advocates who primarily support the existing institutions but want them to be greener, whereas those activists and authors who emphasize sustainability or ecological sustainability often question the structures that perpetuate unsustainable practices.

Today it is impossible, given the adoption of legislation related to sustainability, not to be planning for sustainability. However, many of the differences in various concepts of sustainability can be attributed to the relative weight given to the economic, social, cultural, and environmental components of sustainability. The differences are also caused by the perception of how these components fit together.

There are two main approaches to conceptualizing sustainability, with numerous variations on these approaches. The dominant, mainstream representation of sustainable development that emerged from the Brundtland Commission, and that has been adopted by many governments and business groups throughout the world, is the balanced approach. Although the notion of balance has been largely discredited in scientific ecology, it is still a powerful metaphor within the environmental literature. In many models of sustainable development, balance is achieved by the construction of three circles of equal size to represent the economy, society, and environment. At the intersection of these three equal-sized circles is sustainable development. In contrast, more radical advocates of sustainability may posit a hierarchical approach, in which the hierarchy may vary between models. It often includes ecological considerations at its base, followed by society—because there would be no society without an environment, and then a smaller economy—because there would be no economy without society. Variations may include the use of thermodynamic processes to support biochemical cycles that allow ecosystems to flourish, eventually reaching human social and individual scales.

Some environmental groups avoid using the term sustainable development, partly because of its perceived cooption. Other groups use the term sustainability, whereas some groups attempt to avoid this language altogether. The challenge for sustainability advocates is to be able to implement something that moves humankind and the rest of the planet away from a state of being unsustainable at a rate that is needed to avoid catastrophe.

Sverdrup, Harald Ulrik (1888–1957)

HARALD ULRIK SVERDRUP is a Norwegian meteorologist and oceanographer known for his studies of the physics, chemistry, and biology of the oceans and considered as the founding father of modern physical oceanography. Sverdrup explained the equatorial countercurrents and helped develop the method of predicting surf and breakers. A unit of water flow in the oceans was named after him by oceanographic researchers: 1 sverdrup (Sv) is equal to the transport of 1 million cubic meters of water per second. The American Meteorological Society honored him with the Sverdrup Gold Medal, which recognizes researchers for outstanding contributions to the scientific knowledge of interactions between the oceans and the atmosphere.

Sverdrup was born on November 15, 1888, in Sogndal, Sogn, Norway, into an ancient and respected family of university lecturers, lawyers, politicians, and Lutheran ministers. His father Johan was a teacher and, following the family tradition, became a Lutheran minister of the State Church of Norway. In 1894, his father became minister in the island district of Solund, about 40 mi. (64 km.) north of Bergen, and then moved to Rennsö near Stavanger. In 1908, he became professor of church history in Oslo. Because of his father's different jobs, Sverdrup spent much of his boyhood in various sites in western Norway and was taught by governesses until he was 14 years old. At that age, he went to school in Stavanger. During his adolescence, Sverdrup experienced conflicts between his interest in natural science and the religious background of his family. It was particularly difficult for him to reconcile the concept of evolution with his religious upbringing.

SVERDRUP'S FORMAL TRAINING

As he was not aware of the possibility to study science at university, he first opted for the classical curriculum in 1903. Within this field, his major interest became astronomy. Sverdrup left the gymnasium with honors and spent a year in Oslo preparing for university preliminary examinations. Military service was compulsory at the time, so he decided to combine it with his scientific education, enrolling at the Norwegian Academy of War. This training was combined with the study of physics and mathematics. The physical training that he received while at the academy was extremely useful for his survival during his later long arctic expeditions.

When Sverdrup entered university, he decided to major in astronomy. In 1911, he was offered an assistantship with Professor Vilhelm Bjerknes, the preeminent Norwegian meteorologist and founder of the Bergen School, which allowed him to enter one of the brightest scientific circles in the country. The Bergen School was supported by an annual grant that Bjerknes received from the Carnegie Institution of Washington almost from its founding. Sverdrup initially planned to continue his research in astronomy, but he became increasingly interested in meteorology and oceanography and thus changed his major. When, in 1912, Bjerknes went to Germany to work at the University of Leipzig as professor and director of the new Geophysical Institute, Sverdrup followed him, remaining in Germany from January 1913 to August 1917. He also continued his thesis for the University of Oslo and received his doctorate in June 1917 on a published paper on the North Atlantic trade winds.

CAREER HIGHLIGHTS

In July 1918, Sverdrup joined Roal Amundsen's expedition in the Arctic, on the *Maud*, as a chief scientist. Although the planned duration of the expedition was from three to four years, it lasted for seven and a half years. Sverdrup did not return to Norway until December 22, 1925. He was enthusiastic about the experience and defined the most interesting period as the eight months between 1919 and 1920 spent in Siberia, living with nomadic reindeer herders, the Chukchi. Sverdrup's arctic expedition was interrupted for six months between 1921 and 1922, when the meteorologist had the chance of spending a profitable period of time at the Carnegie Institution. From the arctic expedition, Sverdrup gained better understanding of the basic physical oceanography of currents. He argued that the effect of the Earth's rotation, a fundamental aspect of the dynamics of the oceans, is best observed in the polar regions, because it reaches its greatest level there. On his return to Norway, Sverdrup married Gudrun Bronn Vaumund.

By 1926, Sverdrup was a well-established scientific researcher and was offered the chair of meteorology at Bergen, which had been previously held by Bjerknes. The Carnegie Institution had also offered Sverdrup a permanent position twice, but the Norwegian scientist refused the American offer and took up the position at Bergen. In this capacity, Sverdrup edited the scientific report of the *Maud*. He also continued to collaborate with the Carnegie Institution. In 1931, he led the scientific group in the Wilkins-Ellsworth North Polar Submarine Expedition, during which valuable information was gathered despite its failure to achieve the chief goal of the expedition, the submarine exploration of the Arctic in the *Nautilus*.

In 1936, Sverdrup accepted the position of director of the Scripps Institute of Oceanography in La Jolla, at the University of California, remaining there for almost 12 years. During his tenure as director, Sverdrup expanded the Scripps Institute, making it an institute with a research program, and developing closer ties between Scripps and the University of California, Los Angeles. During World War II, Sverdrup was involved in the U.S. war effort, although he did not directly work for the University of California Division of War Research. He worked on problems related to forecasting surf conditions for military beachhead assaults. His current and wave forecasting methods were applied by military weathermen to predict landing conditions for Allied invasions.

Sverdrup was a central figure in the postwar development of oceanography and allied sciences. He served on many scientific committees after the war, and his contributions to science were increasingly recognized. He was elected to the National Academy of Sciences in 1945. He joined the Executive Committee of the American Geophysical Union in 1945 and presided over the American Geophysical Union Oceanography Section. In 1946, he became president of the International Association of Physical Oceanography. He chaired the Division of Oceanography and Meteorology at the 1946 Pacific Science Conference. Sverdrup returned to Norway in 1948, where he worked as a professor of geophysics at the University of Oslo until his death on August 21, 1957.

Swaziland

THE KINGDOM OF Swaziland is landlocked, with its neighbors being South Africa and Mozambique. It has a land area of 6,704 sq. mi. (17,363 sq. km.), with a population of 1,141,000 (2006 est.) and a population density of 153 people per sq. mi. (59 people per sq. km.). Some 11 percent of the land is arable, with much of it used for subsistence farming, and also for growing maize, cotton, rice, sugar cane, and citrus fruits. In addition, 62 percent of the country is used as meadows or pasture for low-intensity grazing of cattle, sheep, and goats. About 6 percent of the country is forested, with a significant logging industry.

Because the country is largely undeveloped, there is a relatively low use of electricity, with a significant component being used for heating in winter. Electricity production in Swaziland comes from fossil fuels (55.8 percent) and hydropower (44.2 percent), with most of it imported from South Africa. In terms of its carbon dioxide emissions, Swaziland ranks 144th in the world, with emissions of 0.5 metric tons per person in 1990, falling to 0.1 metric tons per person in 1993 but rising steadily to 0.92 metric tons per person by 2003. All the carbon dioxide emissions in Swaziland are attributed to the use of solid fuels, with most of the electricity generated and also the residential and business heating done by coal or wood. This has resulted in a significant per capita emission of carbon monoxide.

As a result of global warming and climate change, Swaziland has seen the effects of water shortages for some of its crops, such as rice, and desertification of some areas previously used for farming. The Swaziland government took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992, signing the Vienna Convention in the same year. On January 13, 2006, the country accepted the Kyoto Protocol to the UN Framework Convention on Climate Change, being the 155th country in the world to do so, with it coming into force on April 13, 2006.

Sweden

SWEDEN IS ONE of the few nations expected to meet or exceed its target according to the Kyoto Protocol and is lauded as one of the countries that has adopted the most stringent measures to address global warming on the basis of emission levels and trends and climate policy. Since 2000, greenhouse gas emissions in Sweden have been an average of 3.7 percent below levels in 1990 and are expected to be 4 percent lower in 2010. This meets Sweden's national target of reducing emissions by 4 percent between 1990 and 2012.

A traditional windmill in southern Sweden. Sweden has invested heavily in the development of wind and water power plants.

Sweden has committed to becoming the world's first oil-free nation by 2020. The Swedish Government's Commission on Oil Independence proposed measures necessary to eliminate Sweden's dependence on fossil fuels for transport and heating and promotes the use of renewable alternatives. In 1970, 77 percent of Sweden's energy came from oil, but this amount decreased to 32 percent by 2003. Nuclear power will be phased out, and Sweden has invested heavily in the development of wind and water power plants. Innovative programs including the use of boilers that use wood-based pellets have dramatically decreased the use of oil for home heating, and tax exemptions enabling drivers to use ethanol-based fuel have increased compliance among residents. Sweden's climate strategy involves partnerships between the business community, scientists, and politicians.

Recent modelling scenarios indicate an increase in annual mean temperature in Sweden of between 4.5–8.1 degrees F (2.5–4.5 degrees C) by 2100, with a greater increase in temperature and rate of precipitation during the winter than the summer. Specific effects include flooding resulting from increased precipitation and heavier rainfall. Summer drought and water shortages are expected in southern Sweden because of changes in precipitation rates and increased evaporation. Although the flora and fauna of Sweden may be enriched by a number of southern species, northern species and those indigenous to the Baltic Sea region will be displaced.

Agricultural yields are likely to benefit from warmer temperatures, with extended growing periods and better conditions for cultivation leading to increased harvest yields of around 20 percent and an increased number of commercial crops. A warmer climate would result in elevated levels of pests and disease, leading to the more frequent usage of pesticides. Anticipated changes in temperature and salinity in the Baltic Sea are expected to have an adverse effect on species of importance to the fisheries sector such as Baltic herring, cod, salmon, turbot, and plaice. Species composition is expected to shift as new fish and shellfish species are introduced from the south. Reduced sea-ice cover may also have an adverse effect on reproduction for flatfish, whereas warm-water species such as pike, perch, and carp may benefit from higher water temperatures.

Joanna Kafarowski
University of Northern British Columbia

Switzerland

SWITZERLAND HAS A long-standing tradition of environmental awareness and protection and has been active in bringing the debate on climatic change to the forefront of international environmental affairs. Switzerland was a strong supporter of the Intergovernmental Panel on Climate Change from its inception in 1988 and an important negotiator for the UN Framework Convention on Climate Change, leading *inter alia* to the Kyoto Protocol. Climate research is high on the agenda of Swiss academia, with recognized expertise in paleoclimate reconstructions, climate modeling, and impacts studies. In 1987, the Swiss Academy of Science set up a unique scientific platform at the interface of science and policy (ProClim, the Swiss Forum on Climate and Global Change) to facilitate the transfer of knowledge to decision makers and to the media.

The keen awareness of Switzerland to climatic change is the result of many climate-driven changes in the Alpine environment already being perceptible, such as the retreat of mountain glaciers. The climate of Switzerland is rendered complex by the interactions between the Alpine topography and atmospheric flows and the competing influences of a number of contrasting climate regimes that converge into the region (the Mediterranean, continental, Atlantic, and polar systems). Temperatures have risen by up to 3.6 degrees F (2 degrees C) in many parts of Switzerland since 1900—well above the global average 20th-century warming of about 1.3 degrees F (0.7 degrees C).

Future climatic change in the Alps will be a complex aggregate of decadal- to century-scale forcing factors related to the North Atlantic Oscillation, the Atlantic Multidecadal Oscillation, and the anthropogenic greenhouse effect. Regional climate models suggest that by 2100, Swiss winters will warm by 5.5–9 degrees F (3–5 degrees C) and summers by 11–12.5 degrees F (6–7 degrees C); in parallel, precipitation is projected to increase in winter and to sharply decrease in summer. Strong heat waves similar to the 2003 European event are likely to become the norm by 2100, and both drought and intense precipitation are projected to increasingly affect the country.

The effects of climatic change on Switzerland will change the natural environment and economic activities. Alpine glaciers may lose between 50–90 percent of their current volume, and the average snow line will rise by 492 ft. (150 m.) for each degree of warming. Hydrological systems will respond in quantity and seasonality to changing precipitation patterns and to the timing of snowmelt in the Alps, with a greater flood potential in spring and drought potential in summer and fall. More extreme events will trigger frequent slope instabilities, and at high elevations, melting permafrost will compound these problems. The distribution of natural vegetation will change as plants seek new habitats with similar climatic conditions to those of today. A rapidly warming climate will result in a loss of mountain biodiversity, as not all species are capable of adapting to change. The direct and indirect effects of a warming climate will affect important economic sectors such as winter tourism, hydropower, agriculture, and the insurance industry, which will be confronted with more frequent natural disasters. Climate-related health risks (allergies, pollution) are expected to increase, with consequent economic effects resulting from prolonged morbidity and absenteeism.

University of Geneva, Switzerland

Syria

LOCATED IN THE Middle East, the Syrian Arab Republic has a land area of 71,479 sq. mi. (185,180 sq. km.), with a population of 19,929,000 (2006 est.) and a population density of 267 people per sq. mi. (103 people per sq. km.). Some 28 percent of Syria is arable land, with a further 43 percent used as meadows or pasture, much of it for low-intensity grazing of sheep. Only a very small part of the country is woodland.

In terms of its per capita carbon dioxide emissions, Syria ranks 93rd in the world, with emissions of 2.8 metric tons per person in 1990, gradually falling to 2.7 metric tons per person by 2003, after which emissions experienced a significant rise to 3.72 metric tons per person in 2004. Fossil fuels make up 64.5 percent of electricity generation in the country, and hydropower contributes to the remainder, with dams located on the Euphrates River. In 1973, the Syrian government built the Tabaqah Dam on the Euphrates to create a new reservoir called Lake Assad to help with the irrigation of the region, and there have been other, smaller projects in recent years.

About 70 percent of the country's carbon dioxide emissions come from liquid fuels, with 19 percent from gaseous fuels, 7 percent from gas flaring, and 4 percent from the manufacture of cement. Solid fuels are not used in the country. By sector, 42 percent of the carbon dioxide emissions come from the generating of electricity, with 32 percent from manufacturing and construction, and 12 percent from transportation. In terms of the effects of global warming and climate change, Syria has experienced a higher average temperature, which has resulted in some level of desertification and the widespread alienation of marginal arable land as the country draws heavily on its water reserves. One positive benefit, although short term, has been that in the Jabal and Nusariyah mountains, parallel to the coastal plain, there has been a rise in temperature, which has led to the melting of the snows, helping with the irrigation of the heavily populated eastern slopes of the mountain range.

The Syrian government of Hafez al-Assad took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992. The government of his son Bashar al-Assad accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on January 27, 2006, with it entering into force on April 27, 2006.

Tajikistan

TAJIKISTAN IS LOCATED in Central Asia, east of China. It is a landlocked country dominated by the Pamir and Alay mountain ranges, with the highest peak being over 7,200 m. (23,600 ft.) high. The valley floors are considered a continental climate zone, whereas the mountains range from semiarid to polar. Climate change has begun to affect the lives of many of the country's seven million residents, particularly those who live in the mountain zones.

According to modeling scenarios published by the government, Tajikistan should see an average temperature increase of 3.2–5.2 degrees F (1.8–2.9 degrees C) by the year 2050. Mean monthly temperature increases varied within the models, but at least one showed a sharp increase in February and March temperatures of 8.5–8.8 degrees F (4.7–4.9 degrees C) over historical averages. Precipitation should increase by 3–26 percent by 2050 in most regions, with several models showing an average increase of 14 percent in the mountains and 18 percent in the valleys. More frequent rainfall will increase soil erosion in the main agricultural sectors.

Six percent of Tajikistan is covered with glaciers, and they are receding at an increasingly worrisome pace. Several thousand small glaciers will vanish entirely by 2050, and the major glacier fields will shrink by 15–20 percent. Over the course of the 20th century, the massive Garmo glacier retreated by 4.3 mi. (7 km.) and shrunk in area by 2.3 mi. (6 sq. km.); the 43.5 mi.-long (70-km.) Fedchenko glacier has retreated 0.6 mi. (1 km.) in length and lost 0.85 mi. (2 sq. km.) of thickness in recent years.

Water flow in the major river basins is expected to decrease by an average of 7 percent by 2050. With increased snowfall in the mountains and the melting of glaciers, the spring floods are anticipated to increase in duration. At the same time, reduced water flow will have a severe effect on irrigation and hydroelectric power production. Mountain villages are already feeling the effects of the changing climate. Over the last few years, mountain communities have seen increased snowfall, which leads to the closure of mountain roads for longer and longer periods and causes severe flooding and landslides when the snows melt. New precipitation patterns, characterized by unusually heavy downpours, have led to flash flooding and crop loss as fields are washed away.

Tajikistan is not a major contributor to global emissions, expelling just 5.1 million metric tons of CO_2 in 1998. Of this, 67 percent came from liquid fuels, 29 percent from gaseous sources, and 4 percent from solid fuels. The government of Tajikistan has developed a national mitigation plan as part of their participation in the UN Framework Convention on Climate Change, pledging to support sustainable agricultural practices, the development of renewable energy sources, the reduction of greenhouse gas emissions, and the protection and development of carbon sinks for mitigation.

Tanzania

TANZANIA, SITUATED IN east Africa just south of the equator, is a country characterized by high environmental, ecosystem, and cultural diversity. Much of Tanzania is also characterized by low-lying plains extending in from the coastal area in addition to the low-lying island archipelagos dominated by the islands of Mafia, Pemba, and Zanzibar. Inland there is the Eastern Arc Mountain chain, which is formed from heavily metamorphosed pre-Cambrian basement rocks, periodically uplifted by faulting and weathering over millions of years.

The mountains rise to 8,350 ft. (2,600 m.) in altitude, although maximum altitudes of 2,200 to 2,500 m. are more typical and cover an area of 2,085 sq. mi. (5,400 sq. km.). Farther west there is a high plateau of gently undulating terrain commonly between 4,920 and 6,561 ft. (1,500 and 2,000 m.). To the north of Tanzania, the landscape is dominated by the quite recent (2 million years old) volcanic chain that includes Kilimanjaro and Mount Meru.

Rainfall patterns in Tanzania are associated with the passage of the Intertropical Convergence Zone (ITCZ), which migrates from approximately 10 degrees S during January to 10 degrees N during July. The southeast trade winds are driven by annual oscillation of the ITCZ, bringing monsoonal rainfall to the east of Tanzania. Wet and dry seasons are clearly defined: Northern Tanzania experiences a rainy season from March to May and from October to December, whereas southern areas have one long rainy season from November to May. The elevational gradient on the eastern slopes of the Eastern Arc Mountains is relatively steep, whereas the western sides are relatively gently sloping. It is estimated that forests and woodlands cover 45 percent of Tanzania. The widespread flora on mountain islands led to the view of a continent-wide, archipelago-like center termed Afromontane; however, the distinct flora of the Eastern Arc Mountains suggests that they are floristically different from other African mountains. The altitudinal distribution of forest types comprises three major vegetation categories: upper montane forest, upper montane herb and shrub, and montane forest. Much of the coastal area is characterized by a coastal forest ecosystem that has been fairly heavily degraded, and the central part of the country is dominated by savanna bordered to the west by the Eastern Arc Mountains; these make up one of the world's hot spots of biodiversity because of their great variety of plant and animal species and their unusually high number of endemic species.

Relatively few palaeoecological records have been generated from Tanzania, with those records that have been produced being largely associated with the Rift Valley lakes located in the west of the country—the Empaki Crater Lake and an interesting ice core from the permanent ice on Kilimanjaro. One record from the Eastern Arc Mountains indicates relatively little ecosystem change over the past 40,000 years; this is in marked contrast with those records from the lowland lakes, which show expansion of montane forest into present savannah environments under the cold dry climate of the last glacial period. The Holocene, similar to other places in East Africa, is marked by human effects from around 4,000 years ago, and particularly after around 2,000 years ago as the agricultural transformation took place. Superimposed on this era are numerous climate change events, such

Lions in Tanzania stay close to their water source. Lion attacks have increased in rural Tanzania, the increase mirroring the dramatic rise in population, which grew by nearly 50 percent between 1988 and 2002 and encroached on the lions' habitat.

as the shift to more arid condition centered around 4,000 years ago and detected as a rapid increase in dust from Mount Kilimanjaro. The complicated picture of human-induced effects within a background of changing climate is something to be explored by generating new records on environmental history in a much underresearched part of the world.

Tata Energy Research Institute (TERI)

THE ENERGY AND Resources Institute (TERI) began in 1974 as the Tata Energy Research Institute. Motivated by concerns about finite, nonrenewable energy resources and pollution, Darbari Seth, a chemical engineer working for Tata Chemicals, proposed a research institute dedicated to the collection and dissemination of information regarding energy production and utilization. R.J.D. Tata, then chairman of the Tata Group, actively supported the institute, and TERI was formally established in Delhi in 1974. By 1982, TERI had expanded to include research activities in the fields of energy, environment, and sustainable development. As the scope of activities continued to widen, TERI maintained its acronym, although it was renamed the Energy and Resources Institute in 2003. Now, TERI's staff of over 700 conducts research and provides professional support to governments, institutions, and corporations worldwide. TERI's global leadership in efforts to mitigate the threat of climate change has been further endorsed by the election of its director-general, Dr. Rajendra K. Pachauri, as chairman of the Intergovernmental Panel on Climate Change in April 2002.

Although spawned by the Tata Group, the largest conglomerate in India accounting for 96 companies operating in over 40 countries and exporting to 140 countries, TERI operates as a not-for-profit, nongovernmental organization. TERI's work is sponsored by over 900 organizations (Tata Group included), and more than 200 organizations from 43 countries serve as partners in TERI projects.

The Energy and Resources Institute currently operates through divisions that include energy–environment technology, environmental and industrial biotechnology, biotechnology and management of bioresources, regulatory studies and governance, resources and global security, action programs, information technology and services, sustainable development outreach, and policy analysis. Examples of TERI-led research projects vary widely and include microbial bioremediation of oil spills and oil sludge deposits; design and dissemination of biomass gasifiers; wasteland reclamation and biodiesel production through Jatropha Curcas, a nonedible, oil-bearing crop; e-waste recycling; green buildings; and ecovillages.

The Asian Development Bank declared TERI a clean energy knowledge hub in 2006. As evidence of its dedication to clean energy, TERI established the Green Rating for Integrated Habitat Assessment, the first of its kind in India. Other work in this area includes research and training initiatives to advance large-scale use of renewable and clean energy, energy efficiency, and response to climate change in Asia and the Pacific region. Although large-scale projects with international cooperation remain key to many of TERI's goals, TERI also promotes empowering disadvantaged populations and generating employment through small-scale entrepreneurial endeavors.

The institute established the TERI University in 1998. It became a deemed university in India in 1999. The TERI University offers degree programs only at the master's and Ph.D. levels, and faculty and students participate in research conducted by the institute.

TERI continues to collect, generate, and make available a wide range of publications on issues related to its areas of research and training. Given its long and successful history of publication, the institute established TERI Press.

During its relatively brief existence, TERI has expanded to include research, training, and support efforts throughout India, and it claims to be the only institution in a developing country to have established a significant presence in North America, Europe, the larger Asian continent, Japan, Malaysia, and the Middle East.

Technology

TECHNOLOGY IS DEFINED as applying science to manipulate or change the human environment. Although it is usually thought to involve some form of machinery or physical equipment, technology can just as effectively be intangible in form, such as with management technology, which provides different ways of understanding how resources, including people, may be organized for more efficient production or operation. Historically, technology changed and developed very slowly around the world. However in more recent years, the improvements in infrastructure—and particularly in communications—have meant that technological advances have increased at an ever-quicker rate. Meanwhile, the dissemination of that technology has spread around the world, although there are still many hundreds of millions of people too poor to benefit from it. Nevertheless, for most people, especially in the Western world, life and society have been transformed completely by the technologies that have emerged over the last two decades.

Because the rate of change of new technological innovation continues to accelerate, it seems likely that life and society in the future will be at least as difficult to predict now as it would have been a few decades in the past. Because of its prevalence in society, its ability to reduce the time needed for generally undesirable domestic tasks, and its ability to improve leisure opportunities, among other attributes, most people welcome technology and believe it to be beneficial to their lives. However there are still individuals and groups of people who may, perhaps for ideological or religious reasons, reject the use of technology. Because global climate change has come to be associated with the use of technology and the energy required to power so much of it, technology as a whole has come to be regarded by some people as an enemy that must be resisted and eradicated. In the extreme case, there are people who believe that only by returning to a form of society in which all forms of technology are rejected can humanity survive the forthcoming environmental crisis.

Philosophers such as Michael Foucault, meanwhile, consider technology to be a tool most commonly used by the powered elites of society to suppress the masses. They would point out that the introduction of technology is customarily followed by the imposition of restrictions that prevent the majority of people from accessing the benefits of that technology. For example, internet technology in China is regularly used to spy on the activities of ordinary people and keep their discussions heavily monitored. This is an instance of technology being used to suppress people and to maintain the existing architecture of power. In contrast, it is possible to argue that the very same technology actually represents a liberation of people because of the many new ways it enables people to communicate with each other and to share information.

Most people tend toward a more moderate position, recognizing the better lifestyle that some aspects of technology provide and being unwilling to abandon these forms, while accepting the need for greater efficiency in the use of resources. They would be unwilling to voluntarily choose to forego the use of that technology to cause some future effects to abate. In other words, people will not vote for significant reductions in the use of personal technologies to reduce future damage caused by climate change. To change their minds, some activists believe that it is necessary to startle or scare people into realizing what sort of changes are likely in the future. Those more skeptical of those future changes, meanwhile, accuse such activists of regularly committing this act and concluding, as a result, that all calls for changes in behavior are overstated and, possibly, politically motivated. This argument has been successfully deployed, in that it has muddied the waters of debate and, hence, reduced the likelihood of future changes in behavior.

THE ROLE OF TECHNOLOGY IN ABATING CLIMATE CHANGE

Technology can be employed to abate current and future climate change in a number of ways. At a large or macrolevel, there are plans to place enormous mirrors into orbit around the earth so that they reflect light energy from the sun back out into space, reducing atmospheric temperature. At a medium or mesolevel is the attempt to develop new and cleaner technologies in terms of energy production, which would reduce carbon emissions. At a microlevel, there are the efforts to reduce resource use inefficiencies by such means as recycling waste products, turning off unattended electronic devices, and generally developing technologies to mitigate future climate change. The extent to which it is possible to abate future climate change by action at the microlevel is not clear, and many estimates vary widely.

Clearly, turning off unused computers or televisions that are idle will save some energy and reduce carbon emissions, but many people believe that this amount of saved energy will be dwarfed by the increased amount of emissions resulting from the rapid and rather dirty industrialization occurring in India and

Concurrent with the rise of technology is the growth of cities, such as Hong Kong, China, above. One of the principal causes of increased atmospheric heat is the presence of cities, especially large cities, across most of the inhabited world.

China, in particular. Indeed, there is an argument that because the effects elsewhere are so great, there is no point trying to reduce emissions on a personal level. This argument does not bear rational examination: in the first place, the reduction of the rate of acceleration of global warming must of itself be a necessary and important thing; second, the people and governments of India and China (and most of the rest of the world) are also aware of the problems of global climate change and are willing to do what they can to bring about changes in their own lives.

Other arguments suggest that changes at the microlevel can have significant changes in the extent of future climate change. The noted skeptical environmentalist Björn Lomborg, for example, has argued that one of the principal causes of increased atmospheric heat is the presence of cities, especially large cities, across most of the inhabited world. Cities are built or have organically grown, in general terms, to maximize population density and, as such, are dry areas without much greenery or standing water. Further, many of the buildings or infrastructure within cities are dark in nature and, as a result, absorb a great deal of energy in a needless fashion. The result is that cities are several degrees F/C or more hotter than surrounding areas. This problem fuels increased use of air conditioning systems and other energy use (e.g., for refrigerators and other cooling devices), which leads to a vicious cycle. Lomborg argues that low-technology solutions can reduce the urban effect: paint buildings white, introduce more water areas, replace some tarmac with grass, and so forth. Taking these steps may reduce the temperature in the local city areas by several degrees. This would have a knock-on effect, too, as in many cases political priorities are determined by urban electorates. As a consequence, demonstrating that technology—even comparatively low-technology solutions—can lead to a measurable improvement in quality of life, which might then lead to more positive sentiment toward the use of technology to improve future lifestyles.

THE SEARCH FOR ALTERNATIVE ENERGY SOURCES

Because it is the use of hydrocarbon fuels that leads to carbon dioxide emissions and is the largest contributor to global climate change, it follows that finding alternative forms of energy that do not emit carbon to the same extent would represent the best means of abating future climate change. Further, the world's reserves of hydrocarbon fuels are finite, and there is a need to develop alternatives if current and projected lifestyles are to be maintained in the future. It is not clear exactly when the reserves of oil will be depleted under current trends of usage, as it is possible (although increasingly less likely) that areas of significant previously unexploited reserves will be found, and probably more importantly, improvements in technology have made it possible to extract profitably existing reserves that have to date been too difficult or expensive to obtain. In addition, as the price of oil increases in general—and continues to increase as demand increases—with respect to supply, more and more known but problematic reserves will become commercially viable. Already, using oil-soaked earth in parts of Canada that were previously prohibitively expensive to process has become viable because of the effect of supply and demand. Other difficult-to-access reserves will, likewise, become more viable.

Nevertheless, although the figures are controversial and contested, it seems likely that all oil reserves will be exhausted within about 120 years, based on current rates of consumption. It is possible, although far from certain, that peak oil production has already been reached. Although declining supply relative to demand will stimulate some increased efficiency of use of oil, it is nevertheless clear that new forms of energy will need to be developed within the next few decades. Clean technologies such as wind and wave power are expected to make up an increasing part of a portfolio of alternative sources of energy. They already contribute significantly to the energy production of some European countries, although there are problems with nimbyism—or not in my back yard-ism—as people complain that wind turbines are unsightly and noisy. Solar panels have been used with moderate success in many parts of the world, particularly those areas with high levels of sunshine. However improvements in this technology are still needed. Photovoltaic cells have been used to collect power from the sun, and water pipes have been heated by placing them in the sun, but there is a need for more integrated solutions to ensure that a higher level of efficiency is achieved and also to reduce initial start-up costs, which may be high. This is likely to come about through regulation rather than market influences.

Other technologies that might be developed include the tapping of geothermal energy, which has been used for thousands of years in a nonsystematic manner, in the form of hot springs. There remains considerable scope for the further development of the use of geothermal energy on a more systematic basis. Hydroelectricity is a further form of alternative energy and it has been used effectively on many rivers. Countries such as China plan a massive increase in the number of hydroelectric stations, with attendant dams, on the rivers passing through its territory. This includes plans for as many as 12 dams on the River Mekong, for example. However this form of energy is problematic because of the effect on people living downstream of reduced flow of water and because of the effect of building large dams on the populations living in the vicinity, many of whom must be resettled—some of them forcibly. The ownership of a river passing through the territory of more than one country is also a problematic issue.

The one means of producing energy that is available without the consideration of geography is that of nuclear power. The technology involved is to employ certain heavy elements such as plutonium and uranium, which undergo atomic decay on a largely predictable manner, releasing considerable amounts of energy at the same time. A more advanced approach is to employ nuclear fission, which involves causing atoms to collide with each other so as to release more subatomic particles such as neutrons and, hence, more power. The amount of power, which is converted to electricity, that may be released through these processes is limited only by the availability of the appropriate heavy elements. These elements are scarce, and the existing amounts are controlled, although not always effectively. There is a need for control because of the radioactive nature of the substances involved, which makes them very dangerous to life, as well as the possibility that they may be used to create highly destructive nuclear bombs.

Many governments are planning to increase, perhaps quite significantly, their reliance on nuclear power. This causes problems because of the threat of an accident releasing nuclear material, as happened at Chernobyl in the Ukraine, causing thousands of deaths. The use of power plants in known earthquake zones is of particular concern. In addition, depleted uranium or other material, which is no longer productive, remains dangerously radioactive for many thousands of years, and it is not clear where that waste may be safely stored over the long term. There is also the potential problem that nations that develop nuclear power plants might also employ this knowledge and technology to develop nuclear weapons. One consequence of this is that there is widespread public concern about the use of nuclear energy and opposition to it in democratic countries. Even so, improvements in the technology of safety suggest that more governments will wish to augment their nuclear power production capacity and begin building new plants, knowing that it takes several years or more between deciding to construct such a plant and when power from it is ready to enter the grid.

MACROLEVEL TECHNOLOGY APPROACHES TO CLIMATE CHANGE ABATEMENT

Various macrolevel technologies have been suggested as a means of reducing climate change. These are generally very expensive and time-consuming to create and maintain and, hence, tend to be regarded as something of a last-ditch attempt. These technologies include placing large mirrors or reflective dust in space to absorb or reflect away the sun's energy, or to use huge series of tubes leading to the ocean floor, through which excess heat energy may be circulated. Many of these ideas derive from the United States, which has a long tradition of optimism in terms of technology and also large firms and organizations possessing the kind of capital necessary to develop and, in time, implement such solutions. Because none of these solutions has, to date, been operationalized, it is not yet clear whether all or any of them will in fact be viable. Nevertheless, it is becoming clear that companies are starting to realize the market opportunities emerging for green or clean technologies. At the individual level, technology will be consumed by households to meet their own mandated requirements; for example, in terms of recycling or energy use reduction. At the state level, in contrast, public-sector support of megaprojects can provide sustained funding for a number of years sufficient to underwrite very large research and development operations. Because these technologies are not yet proven to be feasible and may be extremely expensive in practice, it would be much more cost-effective to make extensive use of micro- and mesolevel technologies immediately rather than waiting for a last-ditch attempt to maintain the planet as a place for human life. This will require some sacrifices in the short and medium terms.

TECHNOLOGY AND REGULATION

The Montreal Protocol of 1987, which helped to resolve the problem of atmospheric ozone depletion, demonstrated the ability of states to work together to solve transboundary environmental issues effectively. Market-based attempts to achieve similar goals, for example, through creating markets in tradable carbon emission permits, have foundered without a strong institutional shaping of the rules of the market and supervision of its activities. Technologists around the world have created numerous efficiencies that would help abate future climate change but that will only be implemented when state regulation requires it to be introduced. Just as the numbers of deaths from road traffic accidents was reduced (proportionate to the amount of traffic) after governments introduced legislation requiring safety belts to be worn, so too have buildings become more resistant to earthquakes after stricter building codes were introduced. In countries such as Germany, new regulations about energy production enable households under certain conditions to produce and sell their own power, such as that generated from solar power, online, for example. Good regulations provide appropriate incentives to encourage people to behave in the desired way and disincentives to dissuade people from behaving in undesired ways. The extent to which this can affect behavior and make measurable changes to energy use may be seen in California, where state-level legislation, transparently introduced over a sustained period, has ensured that energy use per capita has not increased in a number of years, despite the significant amount of electronic consumer goods owned per household.

John Walsh
Shinawatra University

Tennessee

TENNESSEE IS 42,143 sq. mi. (109,150 km.) in size with inland water making up 926 sq. mi. (2,398 sq. km.) Tennessee's average elevation is 900 ft. (274 m.) above sea level, with a range in elevation from 178 ft. above sea level on the Mississippi River to 6,643 ft. (2,025 m.) at Clingman's Dome. The variety of topographic features includes mountains, forested ridges, cultivated valleys, rugged plateau with valleys cut by streams, and the Highland Rim (an upland plain surrounds the Nashville Basin, and the Tennessee River separates the Highland Rim from the relatively flat coastal plain in the western part of Tennessee that extends almost to the low-lying area on the Mississippi River, which forms Tennessee's western border). The major rivers are the Mississippi, the Tennessee River, and the Cumberland River, along with many tributaries. Natural lakes and reservoirs store water.

Tennessee has hot summers, mild winters, and abundant precipitation, with variations based on region. West Tennessee (the Gulf Coastal plain), Middle Tennessee (Highland Rim and Nashville Basin is made up of the Highland Rim [mountains] and East Tennessee [mountainous high region]). Average July temperatures range from less than 70 degrees F (21 degrees C) in the Blue Ridge region to 80 degrees F (27 degrees C) in Nashville and Memphis, and even summer nights can be warm and muggy in central and western Tennessee, with cooler temperatures in the eastern mountains. Average January temperatures range from freezing in the eastern mountains to 42 degrees F (22 degrees C) in the southwestern region. The highest temperature recorded in the state is 113 degrees F (45 degrees C) on August 9, 1930, and the lowest temperature recorded in the state is 32 degrees F (0 degrees C) on December 30, 1917. The average annual precipitation is 52 in. or 132 cm. (ranging from 60 in. or 152 cm. in mountain areas to 45 in. or 114 cm. in protected ridges and valleys). Severe blizzards rarely hit Tennessee, but some snow falls every year. West Tennessee receives about 5 in. (13 cm.), and the east can expect twice as much. The precipitation is made up of a combination of rain, snow, and sleet. Heavy rain falls in March and April, causing rivers to overflow their banks.

Tobacco is grown in much of the state. Western Tennessee is the largest agriculture region, with crops of cotton, corn, soybeans, tobacco, and others. Livestock (cattle, sheep, hogs, and poultry) predominates in the Nashville Basin, as well as dairy farming. Crops grown in the region are used to feed the livestock, except tobacco, which is a cash crop. Tennessee's electricity is generated by coal-fired, nuclear power, and hydroelectric plants.

Although climate models vary on predicted temperature increase for Tennessee, estimates range from 1–5 degrees F (1.8–9 degrees C) in all seasons. Precipitation is estimated to increase only slightly in winter, perhaps 10–30 percent in spring and autumn and by 10–50 percent in summer. This increased rainfall could increase flooding (already a concern in the mountains in eastern Tennessee, in unregulated streams, and in growing urban areas near Chattanooga, Nashville, and Memphis).

With changes in climate, the extent of forested areas in Tennessee could change little or decline slightly, though the types of trees would be likely to change. Pine and scrub oaks would replace eastern hardwoods. The success of tree planting in environmental restoration areas (as in around mines) might decrease. Increased temperatures could pose a risk of wildfires. The agriculture may change little, however, with cotton yields unaffected and corn and hay yields possibly increasing.

If rainfall and runoff increase in the Tennessee region, then higher stream flows and lake levels could benefit hydropower production, enhance recreational opportunities, and improve water availability for water supplies. Increased water flow would dilute pollutants, though increased runoff including pesticides and fertilizers may shift levels of contamination higher, with the river basins in western Tennessee being especially susceptible.

Flooding increases the possibility of contamination of water supplies by sediment erosion, increased levels of pesticides and fertilizers, and runoff from grazing, mining, and urban areas.

Human health risks include, but are not limited to, contracting certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents. Warmer temperatures would increase the incidence of heat-related illnesses and lead to higher concentrations of ground-level ozone pollution causing respiratory illnesses (diminished lung function, asthma, and respiratory inflammation).

On the basis of energy consumption data from the Energy Information Administration, State Energy Consumption, Price, and Expenditure Estimates, released June 1, 2007, indicate Tennessee's total CO_2 emissions from fossil fuel combustion for 2004 were 125.38 million metric tons CO_2, made up of contributions from: commercial sources (3.72 million metric tons CO_2), industrial sources (20.41 million metric tons CO_2), residential sources (4.41 million metric tons CO_2), transportation sources (44.93 million metric tons CO_2), and electric power sources (51.90 million metric tons CO_2).

Tennessee joined the Climate Registry, a voluntary national initiative to track, verify, and report greenhouse gas emissions, with acceptance of data from state agencies, corporations, and educational institutions beginning in January 2008. The Tennessee Environmental Council is including climate change strategy in their meetings.

Tennessee participates in a program called Rebuild America—an organization committed to assisting state and local government and school systems to implement energy-saving improvements. The Tennessee Valley Authority (TVA) has developed a program called Green Power Switch that enables customers to purchase 150-kilowatt-hour blocks of renewable energy (making up about 12 percent of a typical household's monthly energy consumption). In addition, TVA must meet federal and other environmental statutes and regulations for air and water quality as well as managing the disposal of wastes (including hazardous materials). These regulations are becoming more stringent with clean air requirements and reducing greenhouse gas emissions.

Federal and state agencies are responsible for conservation inducing forest management and environmental protection including protecting against soil erosion and water and air quality.

Tertiary Climate

THE TERTIARY PERIOD (ca. 66.4 to 1.8 million years ago [Ma]) was an interval of enormous geologic, climatic, oceanographic, and biologic change. It spans the transition from a globally warm world of relatively high sea levels to a world of lower sea levels, polar glaciation, and sharply differentiated climate zones. Over the past decade, however, it has become increasingly clear that Tertiary climatic history was not a simple unidirectional cooling driven by a single cause but a much more complicated pattern of change controlled by a complex and dynamic linkage between changes in atmospheric CO_2 levels and ocean circulation, both probably ultimately driven by tectonic evolution of ocean-continent geometry. Although satisfactory explanations for many aspects of Tertiary climate history are available, many areas remain incompletely understood.

The early Tertiary (Paleocene and most of the Eocene epochs, ca. 66–50 Ma) was characterized by a continuation of Cretaceous warm equable climates extending from pole to pole. Global temperatures may have been as much as 18–22 degrees F (10–12 degrees C) higher than present, and pole-to-equator temperature gradients were about 9 degrees F (5 degrees C) during the Paleocene, as compared with about 45 degrees F (25 degrees C) today.

The Paleocene-Eocene boundary (about 54 Ma) was marked by a geologically brief episode of global warming known as the Paleocene-Eocene thermal maximum (PETM), characterized by an increase in sea surface temperatures of 9–11 degrees F (5–6 degrees C), in conjunction with ocean acidification, a decline in productivity, and a large and abrupt decrease in the proportion of isotopically heavy terrestrial sedimentary carbon in the oceans. The PETM is thought to have lasted only about 170,000 to 220,000 years, with most of the temperature and isotopic change occurring in the first 10,000 to 20,000 years. Its causes remain unclear, but it was probably associated with dissolution of methane hydrates on the ocean floor, which would then have caused greenhouse warming. Possible triggers for this hydrate release include an increase in volcanism, leading to an increase in atmospheric CO_2 and consequent sudden initiation of greenhouse warming; a change in ocean circulation; or massive regional submarine slope collapse.

Global temperatures warmed still further during the early Eocene, reaching their highest levels of the past 65 million years during an interval sometimes called the early Eocene climatic optimum (52–50 Ma). Global cooling began during the early middle Eocene (ca. 50 Ma) and accelerated rapidly across the Eocene-Oligocene boundary (ca. 34 Ma), at which time Antarctic continental glaciation began. This shift is frequently referred to as a change from a greenhouse to an icehouse climate regime, and it was one of the most fundamental reorganizations of global climate known in the geological record.

Initiation of Antarctic glaciation has long been attributed to the tectonic opening of Southern Ocean gateways, especially the Drake Passage between South America and the Antarctic Peninsula, which allowed establishment of the Antarctic Circumpolar Current and the consequent isolation of the southern continent from warmer low-latitude waters. This has been questioned recently, however, as a result of the redating of the formation of these gateways, as well as modeling results that point to a greater role for reduced atmospheric CO_2.

Most estimates of early Cenozoic atmospheric pCO_2 range between two and five times the present values in the middle to late Eocene and then decline rapidly during the Oligocene to reach approximately present levels in the latest Oligocene. This decline in CO_2 may, in turn, have been at least partly a result of the tectonic uplift of the Tibetan plateau, beginning around 40 Ma, leading to increased rates of chemical weathering. Levels of CO_2 remained relatively constant throughout the Miocene, suggesting that the substantial climate changes during this time were driven by other factors, including changes in weathering or ocean circulation.

Global temperatures warmed again in the late Oligocene, followed by a brief (ca. 200,000 years) but deep glacial interval at the Oligocene-Miocene boundary (ca. 24 Ma). Temperatures then stabilized or slightly increased (punctuated by several more brief glacials), leading to what is sometimes referred to as the mid-Miocene climatic optimum around 17 to 15 Ma, during which time deep water and high-latitude sea surface temperatures were 11–18 degrees F (6–10 degrees C) warmer than at present. The causes of this warming are not clear, but they may have been related to increased northward oceanic heat transport in the North Pacific brought via intensified currents primarily triggered by narrowing of the Indonesian Seaway in the western equatorial Pacific.

Another major cooling occurred between 14.2 and 13.7 Ma and is associated with increased production of cold Antarctic deep waters and a growth spurt of the East Antarctic Ice Sheet, leading to an increased latitudinal temperature gradient and drying in midlatitudes. A further episode of aridity occurred between 8 and 4 Ma. This cooling trend continued into the Quaternary period, with a short warming interval in the early to mid-Pliocene (ca. 5–3.2 Ma), characterized by warmer sea and air temperatures across at least much of the North Atlantic region.

Northern Hemisphere ice sheets first expanded about 3.5 Ma, with a major pulse of growth occurring 2.5 Ma, at which time the Earth is usually said to have passed over a thermal threshold initiating the latest so-called Ice Age, in which mode the planet is still today. The initiation of Northern Hemisphere glaciation has been attributed to completion of the formation of the Central American Isthmus at around 3.5 Ma, which deflected warm low-latitude currents flowing westward from Africa northward into the Gulf of Mexico and through the Florida Straits to join the Gulf Stream. This strengthened Gulf Stream then transported more moisture to high latitudes, where it supplied an increase in snowfall, leading to increased albedo and temperature decline.

Texas

IN A POST–WORLD War II climate of mass consumption, urban disinvestment, and the emerging dominance of the automobile as the preferred mode of transportation, Texas and its economy grew dramatically. Fleeing postindustrial urban decay and the loss of manufacturing economies, millions of Americans and immigrants flocked to the wide-open and nonunionized spaces of the southwest United States. Home to almost 25 million residents, the State of Texas ranks second only to California in population and is experiencing the largest net population growth of any state in the nation.

Driven by this continuing growth in population, diversifying economic development, persistent low-density suburban development, almost exclusive reliance on the automobile for transportation, and a warming climate, the demand for cheap and plentiful energy—and attendant emissions of greenhouse gases—is growing rapidly. Texas leads the United States in greenhouse gas emissions—40 percent of the national total—largely because of its reliance on existing coal-burning power plants.

In a recent study analyzing urban sprawl, Fort Worth/Arlington and Dallas metro areas rated 10th and 13th on the list of the nation's 83 most sprawling urban areas. Having increased by 30 percent over the past 10 years, the 2000 Environmental Protection Agency ozone National Ambient Air Quality Standard report estimated that Texas vehicle miles traveled would increase between 2007 and 2030 by over 44 percent, and Dallas/Fort Worth, Houston, and San Antonio metropolitan regions would remain in nonattainment for ground-level ozone. These urban areas are experiencing significant population growth, continuing sprawl development, and increasingly severe highway congestion that contribute significantly to their climate change effect.

The consequences for Texas of impending climate change are serious, especially given the already extreme nature of much of its regional weather.

CONSEQUENCES OF CLIMATE CHANGE

Texas exhibits a wide variety of climates within its boundaries, from subtropical in the southeast to high desert in the north and west. Although all regions are likely to experience an increase in mean annual temperature (both daily maximums and minimums) and increasing shortages of freshwater, other challenges faced by the state from climate change differ as a function of geography. Texas's 370 mi. (595 km.) of coastline will experience higher sea levels and resulting beach erosion, saltwater infiltration, and subsidence. Increased water temperatures in the Gulf of Mexico may result in more frequent and widespread algal blooms toxic to indigenous fish and plant species. Warmer ocean and Gulf waters will also contribute to the intensity, if not the frequency, of coastal storms and hurricanes.

Climate change also will result in a redistribution of rainfall across the state, significantly affecting agricultural economies and freshwater supplies available to increasingly urban populations. As it continues to drain its aquifers, Texas increasingly relies on freshwater captured in surface reservoirs. A future that is markedly warmer and drier in many regions of the state will jeopardize these supplies (as demonstrated by the drought that gripped the state in recent years). Increasing temperatures will contribute to already pronounced urban heat islands, resulting in increased frequency of heat-related illnesses and deaths, as well as in increased severity of isolated weather events, especially thunderstorms bearing isolated, flooding rains.

Agricultural and forestation patterns and productivity, staples of regional and state economies, will be disrupted not only by the changes in rainfall, increased uncertainty in available irrigation water, and higher mean temperatures but also by a changing variety of natural weeds and pests that will migrate northward as the climate warms. Infestations of insects new to Texas crops will result in reduced crop productivity and, as farmers try to respond, a likely increase in the number and environmental toxicity of herbicides and pesticides.

RENEWABLE ENERGY SOURCES

Although it confronts serious climate challenges across the state, Texas is also blessed with sources of renewable energy that have only begun to be exploited. It is famous for its scorching summers and sunshine that will "peel the chrome off a trailer hitch." The largest portion of its electricity needs are generated by coal-fired and nuclear power plants. Recently, the state backed away from approving the construction of as many as 11 new coal-fired power plants and is in the process of redefining its energy policies. As technological advances reduce the price and increase the efficiency of solar energy-generation devices, Texas, especially in its western reaches, will be able to capitalize on the abundant radiant energy provided by the sun. In addition, wind-generated electricity is being produced in increasingly economical quantities by west Texas wind farms. Although a transmission infrastructure is evolving to supply the state's urban demand, Texas ranks first in wind power generation among U.S. states. It is also the country's leading producer of biodiesel transportation fuel. Its leadership role was highlighted by the success of country music icon Willie Nelson in promoting locally produced BioWillie biodiesel fuel, primarily marketed for the long-haul trucking industry.

LOCAL ACTION

In the absence of a meaningful climate protection policy at the federal or state levels, many Texas cities have joined municipalities in other states in a variety of nongovernmental organization–led initiatives to reduce their carbon footprints and to lobby for action on climate change and related environmental issues at both the state and federal levels. Among other actions taken by Texas municipalities, 17 Texas cities—including Austin, Dallas, and San Antonio—have signed the U.S. Conference of Mayors Climate Protection Agreement

The Dallas metro area is rated 13th on the list of the nation's 83 most sprawling urban areas. Texas is home to almost 25 million residents, and is experiencing the largest net population growth of any state in the United States.

committing their respective cities to carbon dioxide reductions similar to those contained in the Kyoto Protocol. Both Austin and San Antonio are also members of the Cities for Climate Protection, a global campaign of local and regional entities led by the International Council of Local Environmental Initiatives Local Governments for Sustainability. Through process implementation and performance monitoring, these cities are committed to a rigorous accounting and reduction of their greenhouse gas emissions.

Thailand

LOCATED IN SOUTHEAST Asia, Thailand has a land area of 198,115 sq. mi. (513,115 sq. km.), with a population of 62,828,700 (December 2006) and a population density of 317 people per sq. mi. (122 people per sq. km.). Bangkok, the capital and the largest city, has a population of 6,593,000 and a population density of 9,418 per sq. mi. (3,630 per sq. km.). Traditionally, the economy of Thailand has been agricultural, and 34 percent of the land is arable, with an additional 2 percent used as meadows and pasture. With the increase in the tourist industry, as well as manufacturing, the importance of agriculture has declined, but it remains the country's major employer. Some 30 percent of the country is forested, with the timber industry being heavily regulated, although there are regular allegations of illegal logging.

Thailand has a relatively low per capita rate of carbon dioxide emissions—1.8 metric tons in 1990, rising steadily to 4.28 metric tons per person by 2004. Some 92.3 percent of the electricity in the country comes from fossil fuels, with most of the remainder drawn from hydropower. The heavy use of automobiles, and also private generators, has led to 56 percent of the carbon dioxide emissions from the country being from liquid fuels, with 15 percent from gaseous fuels and 21 percent from solid fuels. Some 8 percent of Thailand's carbon dioxide emissions come from the manufacture of cement.

In terms of the sector causing the carbon dioxide emissions, 38 percent comes from the generation of electricity, with air conditioning—especially for the tourist sector—being a very important part of the demand. Some 33 percent comes from transportation, with the traffic problems in Bangkok often leading to a pall of smog in the city. Some 25 percent of carbon dioxide emissions come from manufacturing and construction, with the remaining 3 percent from residential use.

Thailand can best be described as tropical and humid for the majority of the country during most of the year. The area of Thailand north of Bangkok has a climate determined by three seasons while the southern peninsular region of Thailand has only two. In northern Thailand the seasons are clearly defined. Between November and May the weather is mostly dry; however, this is broken up into the periods November to February and March to May. The later of these two periods has the higher relative temperatures, although the northeast monsoon does not directly affect the northern area of Thailand, it does cause cooling breezes from November to February. The other northern season is from May to November and is dominated by the southwest monsoon, during which time rainfall in the north is at its heaviest.

The southern region of Thailand really has only two seasons— the wet and the dry. These seasons do not run at the same time on both the east and west side of the peninsula. On the west coast the southwest monsoon brings rain and often heavy storms from April through October, while on the east coast the most rain falls between September and December.

Overall the southern parts of Thailand get by far the most rain with around 2,400 millimeters

Driving during a monsoon in Thailand. The Boxing Day tsunami in Thailand in 2004, which resulted in the deaths of an estimated 8,200 people, including many hundreds of foreign tourists, has been partially blamed by some experts on climate change.

every year, compared with the central and northern regions of Thailand, both of which get around 55 in. (1,400 mm.).

Thailand has been heavily affected by global warming and climate change. An increase in flooding in southern Thailand has resulted in a rise in the prevalence of insect-borne diseases such as malaria and dengue fever. The Boxing Day tsunami in 2004, which devastated the Phi Phi Islands and other islands along Thailand's Indian Ocean coastline, such as Ko Tapu, and resulted in the deaths of an estimated 8,200 people, including many hundreds of foreign tourists, has been partially blamed by some experts on climate change. The gradual bleaching of coral reefs in that region, and also in the Gulf of Thailand, is certainly attributable to global warming.

The Thai government took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992. It signed the Kyoto Protocol to the UN Framework Convention on Climate Change on February 2, 1999, and it was ratified on August 28, 2002, entering into force on February 16, 2005.

Thermocline

THE THERMOCLINE IS the region of the ocean where temperature decreases most rapidly with increasing depth. It separates the warm, well-mixed upper layer from the colder, deep water below. A thermocline is present throughout the year in the tropics and middle latitudes. It is more difficult to discern in high latitudes, where temperature is more uniform with depth. The presence of a very shallow thermocline in the eastern equatorial Pacific Ocean has important implications for global climate.

The thermocline exists because the ocean absorbs most of the sun's heat in a shallow layer near the surface. The heat absorbed from the sun increases the temperature of the surface relative to that of the deep ocean, maintaining the thermocline. This is in contrast to the atmosphere, where a much larger portion of incident solar radiation passes through to the Earth's surface.

Two important properties of the thermocline are its depth and its strength, or how rapidly temperature decreases with increasing depth. The thermocline's depth is influenced by the winds at the surface of the ocean. In the Atlantic and Pacific oceans, surface winds push warm surface water away from the equator toward the poles, bringing the thermocline close to the surface at the equator.

Water that diverges at the equator accumulates in the subtropics, increasing the depth of the thermocline there. The thermocline is generally (82 to 656 ft. (25 to 200 m.) deep in the equatorial regions and up to 3,281 ft. (1,000 m.) deep in the subtropics.

The thermocline is strongest in the tropics and weakest in high latitudes. This reflects the fact that the surface temperature of the ocean generally decreases from the tropics to the poles, whereas the temperature of the deep ocean is nearly the same at all latitudes. As a result, the temperature contrast between the upper ocean and the deep ocean is greatest in the tropics. The temperature can drop by as much as 18 degrees F (10 degrees C) in less than 164 ft. (50 m.) in the tropical thermocline.

In the extratropical oceans, the strength and depth of the thermocline vary from season to season. There is a main thermocline throughout the year between 656–3,281 ft. (200–1,000 m.). During summer, the sun heats the ocean's surface more strongly than in winter. Most of the additional heat is absorbed in a very shallow surface layer, generating a sharper "seasonal" thermocline above the main thermocline. The seasonal thermocline is similar to the tropical thermocline in terms of its strength and depth. It erodes in the winter as the surface cools relative to the temperature in the main thermocline.

TROPICAL OCEANS

The existence of a strong and shallow thermocline in the tropical oceans has important implications for climate. In the equatorial Pacific Ocean, westward surface winds lead to an accumulation of warm surface water in the west, depressing the thermocline there and raising it to near the surface in the east. The shallow thermocline in the east enables cold, nutrient-rich water to be mixed upward into the surface layer. Every few years the thermocline in the eastern equatorial Pacific deepens in association with an El Niño event. The mixing of cold, nutrient-rich thermocline water into the surface layer is reduced, the surface temperature of the eastern equatorial Pacific Ocean increases, and biological productivity decreases. The warmer surface temperatures associated with El Niño affect atmospheric circulation in the tropics and alter weather patterns throughout the world.

The depth of the eastern equatorial Pacific thermocline has varied significantly in association with changes in global climate. For example, during the early Pliocene period (between 4.5 and 3 million years ago; the most recent period with global temperatures significantly higher than today), the eastern Pacific thermocline was much deeper than it is today, much like it is during a modern El Niño event.

Thermodynamics

THE SCIENCE OF thermodynamics, a branch of physics, aims to describe transformations in energy. Thermodynamics comprises three laws. The first holds that energy can neither be created nor destroyed. Energy in various forms may be transformed into heat (thermal energy) and heat may be transformed into another form of energy so long as the total energy in the system remains constant. The second law states that entropy, a measure of the amount of energy dissipated as heat, increases over time in a closed system. The conversion of energy into heat increases the entropy of a system and the dissipation of heat likewise increases the entropy of a system. The third law states that as temperature approaches absolute zero, the theoretical minimum temperature in the universe, entropy approaches a maximum.

The first law of thermodynamics accounts for the relative constancy of the climate, averaged over long durations. Were Earth simply a reservoir nergy in the form of sunlight, it would heat up to a very high but finite temperature. Earth does not heat up to this magnitude because it radiates heat back into space. The dissipation of energy as heat, according to the second law of thermodynamics, describes the Earth's shedding of radiant energy received from the sun as heat. This law, functioning as a heat accountant, is at the heart of understanding the role of heat in determining the climate. The third law of thermodynamics does not operate as long as the Sun generates energy. Rather, the third law anticipates the end of the universe. The Sun will one day burn out. Bereft of its heat, Earth's climate will be eternally cold, as its temperature approaches absolute zero. Not only will the Sun be extinguished, but all stars in the universe will one day burn out. The heat from these stars will dissipate in all directions in the universe, bringing the temperature, uniform throughout the universe, near absolute zero.

The science of thermodynamics traces the origin of energy in the solar system to the Sun. Energy from the Sun is the basis of Earth's climate, but not all sunlight reaches Earth. The thermosphere lies 190 mi. (306 km.) above Earth's surface, and is the outermost layer of the atmosphere. It absorbs ultraviolet light so efficiently that its temperature rises as high as 570 degrees F (299 degrees C). This conversion of the sun's radiant energy into thermal energy obeys the second law of thermodynamics. The next layer of the atmosphere, the mesosphere, is 50 mi. (80 km.) above earth. Its temperature, cooler than the thermosphere, is 200 degrees F (93 degrees C). Carbon dioxide (CO_2) in the mesosphere absorbs infrared light as heat, and that light radiates from Earth back into space. CO_2 molecules absorb a portion of this light before it reaches space. The larger the number of CO_2 molecules, the more heat they will absorb. The heating of the atmosphere by the absorption of infrared light causes the Greenhouse Effect, the warming of Earth's climate. Beneath the mesosphere is the ozone rich stratosphere, roughly 15 mi. (24 km.) above Earth. The ozone in the stratosphere blocks some 90 percent of sunlight from reaching Earth. Ozone, like the thermosphere, absorbs ultraviolet light. Beneath the ozone layer is the troposphere, a variable layer 5 mi. (8 km.) thick at the poles and 20 mi. (32 km.) thick at the equator. The troposphere holds water vapor, which absorbs both infrared and ultraviolet light, heating the atmosphere. These layers of the atmosphere both absorb and radiate heat. The heat that they radiate either scatters into space or reaches Earth.

Earth absorbs sunlight, chiefly at the equator. This sunlight, in the form of heat, moves to the poles through the currents of the oceans and air. This distribution of heat from an area of greater concentration (the equator) to a region of lesser concentration (the poles) obeys the second law of thermodynamics. Heat supplies the energy for the movement of the oceanic and air currents, which in turn transform the potential energy of stasis into the kinetic energy of motion. On an idealized Earth on which the oceans and air distributed heat evenly throughout the planet, heat would reach thermodynamic equilibrium, the point at which entropy would be at a maximum. Earth is much less efficient than this idealized model. For all the motion of the oceanic and air currents, heat nevertheless concentrates at the equator, which is always warmer than the poles. The waters at the equator hold enormous amounts of heat. Because the oceans liberate their heat slowly, heat accumulates at the equator and is slowly transferred toward the poles.

In accord with the second law of thermodynamics, entropy would increase as heat moves from equator to poles, but the Sun continuously adds heat to Earth, keeping the equator warmer than the poles. Entropy does not increase because the equator remains warmer than the poles. Without the oceanic and air currents, heat would accumulate at the equator and would not circulate to cooler regions of Earth. The currents therefore perform an important function in carrying heat from the equator to temperate and cold latitudes.

Earth and the atmosphere reflect roughly one-third of the sunlight they receive and radiate the other two-thirds into space. Earth sheds the same amount of heat as it receives, keeping earth on average at 60 degrees F (16 degrees C). By contrast outer space, which has no atmosphere to absorb heat, is much colder at minus 454 degrees F (minus 270 degrees C). Earth absorbs sunlight as ultraviolet and visible light and continually radiates it back into space as infrared light.

Earth also reflects light back into space. The oceans reflect half the sunlight they receive, whereas ice and fresh snow reflect 90 percent. In accord with the second law of thermodynamics, entropy decreases when Earth absorbs heat, and increases when the oceanic and air currents diffuse heat to other regions of the planet. Similarly entropy increases when Earth reflects light back into space, thereby dissipating heat.

Entropy is least in equatorial waters because they retain heat and slowly liberate it to other regions of Earth. Heat is not evenly-distributed in equatorial waters, as thermodynamic equilibrium would suggest. In holding heat, the oceans at the equator moderate the climate, keeping lands near them warmer than inland stretches of territory.

The land warms four times faster than the oceans; the air warms faster still. Land and air also radiate heat faster than the oceans. The climate of a desert underscores the rapidity of heating and cooling on land. Temperatures in a desert rise rapidly during the day, often surpassing 100 degrees F (38 degrees C). At night a desert cools with equal speed, dipping as low as freezing. In accord with the second law of thermodynamics, entropy decreases as a desert absorbs heart and increases as it dissipates heat.

Warm climates hold heat not only in water and land, but also in air. Warm air holds more moisture than cool air in the form of water vapor, a greenhouse gas. Water vapor holds more heat than CO_2, methane, other greenhouse gases. Water in all three phases absorb and emit heat. Ice absorbs the least heat and reflects the most sunlight back into space. Liquid water and water vapor are efficient reservoirs of heat.

The laws of thermodynamics work because Earth and its atmosphere absorb and radiate heat. One might argue that the absorption and radiation of heat give Earth its distinctive characteristics and its ability to sustain life.

Thermohaline Circulation

THERMOHALINE CIRCULATION IS global oceanic circulation generated by buoyancy fluxes resulting from heat and freshwater exchange between the ocean, atmosphere, cryosphere, and land. External forcing leading to an increase in water density (i.e., cooling or salinity rise) causes the sinking of more dense water (so-called thermohaline convection) and compensating transport of more light shallower waters of the upper mixed layer and thermocline. This process forms thermohaline overturning, which is one of the principal mechanisms of meridional heat transport in the world's ocean and global coupled ocean-atmosphere system.

Thermohaline circulation is characterized by two regimes, as was first pointed out by Henry Stommel. They are caused by thermal and haline effects and, in turn, account for large-scale temperature and salinity distribution in the World Ocean and, hence, influence the global climate. In general, in recent climate conditions, just thermal overturning circulation prevails in the world oceans, because global thermohaline circulation is formed mostly by the sinking of cold high-latitude waters and the compensating transport of warm shallower water. In general, there are two principal sources of deep and bottom waters. They are in the North Atlantic and Antarctic regions, respectively. These sources produce North Atlantic deep water (NADW), the core of which is at 1.2 to 1.5 mi. (2 to 2.5 km.), and Antarctic bottom water (its core deepens below 2.5 mi. [4 km.]). Haline circulation prevails in some specific regions of the world oceans, such as in the semiclosed Black and Red seas. The effect of salinity changes on the density field is also enhanced in subtropical oceanic regions, especially in the subtropical Atlantic, which is close to the Sahara desert. There, the upper mixed layer depth is mostly controlled by thermohaline convection as a result of salinity effects.

Thermohaline and superimposed wind-driven forcing has caused recent large-scale general oceanic circulation. The relative importance of these two sources for integral volume transport of principal large-scale oceanic currents varies from one region to another. In the North Atlantic, for instance, thermohaline and wind-driven shares in the general circulation of the upper 1.5 mi. (2 km.) layer are discussed in a recent study by Alexander Polonsky.

Global warming may cause, in principle, a change in circulation regime as a result of ice/glacier melting and increased freshwater input into the polar zone of the North Atlantic. This may lead to surface water lightening and blocking of thermohaline overturning. The Gulf Stream should dramatically weaken as a result of that. Such a regime has been called thermohaline catastrophe because it should be accompanied by strong climate shift in the North America and Europe. It is expected that a new climate will be much more severe and will be accompanied by much more frequent and strong North Atlantic cyclones because even just eddy meridional heat transport prevails in the midlatitude atmosphere, and it must now compensate for the reduced meridional thermohaline heat transport in the ocean after thermohaline catastrophe. However, as follows from recent multimodel simulations published by Ronald Stouffer and coauthors, the likelihood of thermohaline catastrophe happening in the next 100 years is quite small, taking into account recent tendencies of ice/glacier melting.

As follows from the simulation results of Stefan Rahmstorf, during the Last Glacial Maximum (about 21,000 years ago), thermohaline circulation was characterized by more shallow meridional cell and reduced meridional heat transport in the North Atlantic. The core of NADW was at about 1 km. In general, this was the result of severe ice conditions in the North Atlantic, where NADW has being produced. Different paleodata analyzed recently by Jean Lynch-Stieglitz and coauthors (2007) confirm in part such a scenario.

There is some evidence that blocking thermohaline circulation in the North Atlantic occurred about 8,200 years ago, just after the last glacier period. Most likely, it was a result of a plume of freshwater from juvenile lakes that rose in the end of a glacier period. Another possibility is the relatively fast melting of an armada of icebergs spreading from a Greenland glacier. However, it has not been proven by the analysis of deep ocean sediments provided by Christopher Ellison and coauthors (2006).

Thermosphere

THE EARTH IS surrounded by a blanket of air, called the atmosphere. The atmosphere is a thin layer of gases that envelope the Earth. The gases are held close to the earth by gravity and the thermal movement of air molecules. Life on Earth is supported by the atmosphere, solar energy, and the magnetic fields. Five layers have been identified in the atmosphere, using thermal characteristics, chemical composition, movement, and density. The atmosphere is divided into the troposphere, the stratosphere, the mesosphere, the thermosphere, and the exosphere. The thermosphere, from the Greek word (thermos) for heat, is the fourth atmospheric layer from Earth, separated from the mesosphere by the mesopause. It begins about 50 mi. (80 km.) above the Earth and is the layer of the atmosphere directly above the mesosphere and below the exosphere. The lower part of the thermosphere, from 50 to 342 mi. (80 to 550 km.) above the Earth's surface, contains the ionosphere, which is the region of the atmosphere that is filled with charged particles. Beyond the ionosphere, extending out to perhaps 6,214 mi. (10,000 km.), is the exosphere.

The Earth's thermosphere is the layer of the atmosphere that is first exposed to the sun's radiation and so is first heated by the sun; it is the hottest layer of the atmosphere. Within the thermosphere, temperatures rise continually to well beyond 1,832 degrees F (1,000 degrees C). In the thermosphere, ultraviolet radiation causes ionization. At these high altitudes, the residual atmospheric gases sort into strata according to their molecular mass. Thermospheric temperatures increase with altitude as a result of the absorption of highly energetic solar radiation by the small amount of residual oxygen present. Temperatures in the thermosphere are highly dependent on solar activity. Radiation causes the air particles in this layer to become electrically charged, enabling radio waves to bounce off and be received beyond the horizon.

The few molecules that are present in the thermosphere receive extraordinary amounts of energy from the sun, causing the layer to warm to high temperatures. Air temperature, however, is a measure of the kinetic energy of air molecules—not of the total energy stored by the air. The air is so thin that a small increase in energy can cause a large increase in temperature. Because the air is so thin within the thermosphere, such temperature values are not comparable to those of the troposphere or stratosphere. Again, because of the thin air in the thermosphere,

The Northern Lights occur in the thermosphere, which is the fourth atmospheric layer from Earth. It is the first layer of the atmosphere that is exposed to the sun's radiation, so it is the hottest layer of the atmosphere.

scientists cannot measure the temperature directly. Instead, they measure the density of the air by how much drag it puts on satellites and then use the density to determine the temperature.

Although the measured temperature is very hot, the thermosphere would actually feel very cold to humans because the total energy of the few air molecules residing there would not be enough to transfer any appreciable heat to our skin. In addition, it is so near vacuum that there is not enough contact with the few atoms of gas to transfer much heat. A normal thermometer would read significantly below 32 degrees F (0 degrees C). The dynamics of the lower thermosphere are dominated by the atmospheric tide, which is driven, in part, by the very significant diurnal heating.

The atmospheric tide dissipates above this level because molecular concentrations do not support the coherent motion needed for fluid flow. The International Space Station has a stable orbit within the upper part of the thermosphere, between 199–236 mi. (320–380 km.). The Northern Lights also occur in the thermosphere.

Worldwide, it is estimated that 50,000 thunderstorms occur every day, and over 18 million occur per year.

Thunderstorms

A THUNDERSTORM IS a localized storm that is produced by a cumulonimbus cloud and always contains thunder and lightning. Thunderstorms form in conditionally unstable environments, meaning there is cold, dry air aloft over warm, moist surface air. This causes the air to become buoyant and allows for rising air motion. A lifting mechanism is also needed to start the air moving. Such lifting mechanisms include surface heating, surface convergence, lifting caused by mountains, or lifting along frontal boundaries.

The heat and the humidity of the summertime can often produce what are called ordinary thunderstorms or air mass thunderstorms. These are the type of thunderstorms that seem to suddenly pop up, last less than an hour, and are rarely severe. A severe thunderstorm is defined by the National Weather Service as having three-quarter-inch diameter hail or surface winds exceeding 58 mi. (93 km.) per hour or producing a tornado. Ordinary thunderstorms also do not usually have excessive vertical wind shear, meaning that the wind speed or direction does not change greatly with height. They usually go through a series of stages from birth to decay. The first stage is known as the cumulus stage and is dominated by updrafts. The updrafts bring in warm, moist air, which then cools and condenses as it rises. When the clouds further develop and precipitation starts to fall, a downdraft is produced. This marks the beginning of the mature stage, which is the most intense stage. During this stage, the strong updraft is still present, supplying the warm, moist air, but the strong downdraft is also evident. The gust front is located at the boundary of the updraft and the downdraft. This is an area where the wind velocity changes rapidly. Eventually, the downdraft will cut off the supply of warm, moist air in the updraft. When this occurs, typically 15 to 30 minutes after the mature stage, the thunderstorm will start to weaken and enter the dissipating stage as a result of the deprivation of energy from the updraft.

If the vertical wind shear increases, this allows for the thunderstorm to tilt. Therefore, the downdraft is less likely to cut off the updraft, which allows the thunderstorm to persist longer. Sometimes the downdraft can slide underneath an updraft, which can produce multiple cell thunderstorms or simply multicell storms. If the vertical wind shear becomes extremely strong, the shear can produce a large rotational thunderstorm known as a supercell. Supercell thunderstorms are large storms that last longer than an hour and are often severe and can produce tornadoes. The strong wind shear creates horizontal spin, which can then rotate vertically when the updraft encounters the vortex.

Thunderstorms can occur as a line of multiple-cell thunderstorms known as squall-line thunderstorms. These usually form along or slightly ahead of a cold front. The line of thunderstorms can extend over 500 mi. (805 km.) and often exhibit severe characteristics. When thunderstorms occur in a large circular pattern, they are known as a mesoscale convective complex, or MCC. An MCC is a large, convectively driven system that usually lasts more than 12 hours and covers more than 38,610 sq. mi. (100,000 sq. km.) Many thunderstorms are embedded within the MCC and often form during the summer in the Great Plains. As warm, moist air is brought in from the Gulf of Mexico, the tops of the very high clouds cool rapidly by emitting radiation into space. This makes the atmosphere very unstable and allows for the MCCs to generate and persist. Because MCCs are usually located underneath weak upper-level winds, they tend to travel very slowly, which can cause locally heavy rains and flooding events.

All thunderstorms have lightning—the electrical discharge—and thunder—the resulting shockwave produced by the extreme heating. Lightning has a temperature of approximately 54,000 degrees F (29,982 degrees C), which is five times hotter than the surface of the sun. Lightning occurs during the mature stages of thunderstorms and can appear within a cloud and travel from one cloud to another or from cloud to ground. Most lightning strikes are within a cloud.

Worldwide, it is estimated that 50,000 thunderstorms occur every day, and over 18 million occur per year. Thunderstorm frequency is most common in the tropics, especially near the Intertropical Convergence Zone, which is an area of low pressure near the equator. Thunderstorms occur with lower frequency in drier regions near 30 degrees N/S, which is dominated by the subtropical high pressure, as well as in the polar regions. In the United States, thunderstorm activity is predominantly found in the southeast, with a maximum located over Florida. Florida has over 90 days of thunderstorms per year as a result of the convergence of wind from the Gulf of Mexico and the Atlantic.

Thunderstorms release a massive amount of latent heat energy through condensation. This is a major mechanism for the Earth to transfer heat from areas of energy surplus near the equator to areas of energy deficit toward the poles. It is generally agreed that increased greenhouse gas emissions are causing global temperatures to rise. With increased global surface temperatures, it is expected that more clouds will be produced with increased evaporation rates. However, the potential effects of increased cloud coverage and what it means for potential rainfall and thunderstorm activity is not fully understood.

The degree to which the increased aerosols and clouds will reflect solar energy back into space is the main discrepancy. Some scientists think that global warming will increase evaporation rates, thereby producing more precipitation. Others have speculated that with the increased clouds and aerosols in the atmosphere, this will greatly reduce the amount of radiation reaching the earth. As a result, this will make the lower and midlevels of the atmosphere warmer, therefore reducing evaporation rates. Because the thermal gradient, that is, the difference in temperature, will be reduced from the surface to the atmosphere, the reduced evaporation rates could then potentially make for drier conditions.

Togo

THIS WEST AFRICAN country, officially the Togolese Republic, is located between Ghana and Benin, with a northern border with Burkina Faso. It has a land area of 21,925 sq. mi. (56,790 sq. km.), with a population of 6,585,000 (2006 est.) and a population density of 280 people per sq. mi. (108 people per sq. km.). Some 38 percent of the country is arable, with a further 4 percent used for meadows and pasture and another 28 percent of the land forested.

For the electricity production in Togo, 97.9 percent comes from fossil fuels, with 2.1 percent coming from hydropower. These generate 102 million kilowatt-hours (kWh; in 2001), with 520 kWh, largely drawn from hydropower, more imported from Ghana. Although before World War I the Germans tried to establish Togoland (as it was then called, including part of what is now eastern Ghana) into a model colony, the country has remained relatively poor, with its carbon dioxide emissions being 0.2 metric tons per person in 1990, rising gradually to 0.38 metric tons per person in 2003. About 68 percent of the country's carbon emissions come from liquid fuels, with the remainder coming from the manufacture of cement. By sector, 37 percent comes from manufacturing and construction, with 35 percent from transportation and 14 percent from electricity and heat production. The high figure for transportation is because there is only one train line, going from the capital, Lomé, to Blitta, with very few other forms of public transport.

The coastal part of Togo, around Lomé, is low lying, and as such, it is at risk from global warming and climate change. The rising average temperatures are also likely to lead to increased desertification in the north of the country. The Togo government ratified the Vienna Convention in 1991 and took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992. The government accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on July 2, 2004, with it coming into force on February 16, 2005.

Tonga

LOCATED IN THE South Pacific, the Kingdom of Tonga has a land area of 289 sq. mi. (748 sq. km.), with a population of 100,000 (2006 est.) and a population density of 396 people per sq. mi. (153 people per sq. km.). The country consists of 169 islands, but only 36 of these are permanently inhabited. With 24 percent of the country listed as arable, some 6 percent is used for meadows and pasture, with 12 percent of the country being forested; Tonga has a very restricted timber industry program.

Tonga also has a low per capita rate of carbon dioxide emissions, with 0.8 metric tons per person in 1990, rising to 1.12 metric tons by 2003, ranking Tonga 136th in the world in terms of emissions. Although the electricity production in the country is low, it is all generated from fossil fuels. With all the country's carbon dioxide emissions coming from liquid fuels, this accounts for not just electricity production but also the use of automobiles and small household or business generators.

Global warming and climate change are already having a major effect on Tonga, with the flooding of parts of the country, including a number of the uninhabited islands, and the very real risk of large parts of the country being lost as the water level rises. In addition, there is a problem over the alienation of arable land, deforestation leading to soil erosion, and off-shore coral reef bleaching and loss of marine life.

The Tonga government took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992 and ratified in 1998, in the same year as the ratification of the Vienna Convention. The current Tonga government has not expressed a position on the Kyoto Protocol to the UN Framework Convention on Climate Change.

Toronto Conference

SCIENTISTS FROM VARIOUS international organizations, such as the World Meteorological Organization in Geneva, met with their peers in groups at various locations for three years. Following the signing of the United Nations Vienna Convention on the Protection of the Ozone Layer (1985) and the Villach Conference (1985), these meetings helped to develop the basis for further action. From the discussions at these meetings, a scientific accord on the main aspects of how much climate warming can be expected emerged. The confluence of this emerging consensus and other events led to the Toronto Conference in 1988.

The scientists' efforts gained the support of the United Nations, the World Meteorological Organization, the Canadian government, and other international organizations. The scientists then came together in Toronto, Canada, from June 27 to 30, 1988. In attracting national policymakers as well as 300 scientists from 46 countries and organizations, this conference became the first such international conference to combine science and policy.

Entitled the International Conference of the Changing Atmosphere: Implications for Global Security, the meeting highlighted atmospheric issues in a comprehensive way. The concern for the potential damage to the planet was compared with the consequences of nuclear war, and the scientific consensus at the conference astonished its chair, Stephen Lewis, who was then Canada's ambassador to the United Nations. Lewis also brokered the strongly worded final declaration. Identifying the existing situation as "an unintended, uncontrolled, globally pervasive experiment," the Conference Statement claimed that the consequences of this experiment would be second only those of a global nuclear war.

Recognizing that attempts to address issues affecting the atmosphere as a whole had been fragmentary to date, the Toronto Conference took a more global approach. The initiative was to integrate the existing Vienna Convention (1985) and the 1979 Geneva Convention on Long-Range Transboundary Air Pollution and to provide a basis for including issues that had not yet been addressed or recognized. Such an integrated approach to considering the atmosphere as a whole would conceivably permit a more complex approach to interrelated issues and solutions. As such, this initiative raised the possibility of a comprehensive Law of the Air.

RECOMMENDATIONS

The comprehensive approach and wide representation enabled attention to be paid to the scientific, economic, and social concerns. The attendees generated specific calls for action to governments, industry, and nongovernmental organizations. Working groups within the conference made specific recommendations to address a wide range of issues that were related and relevant to the health of the global atmosphere.

Issues that were recognized were those that arose both directly out of usage of the atmosphere and indirectly, through human effects on land and water. The atmospheric effects of the manner and form of human settlement—including the increasing urbanization of populations and acid rain—were directly relevant. Indirect atmospheric effects resulted from the full range of human activities including food production, industry, energy usage, trade, and investment.

Changing climate and human effects on coastal and marine resources were also pertinent. Human decision making involving forecasting, uncertainty, futures, and geopolitical issues—higher-order considerations resulting from the integration of programs and legal issues—were also addressed.

The precise form of a global pact was debated, with the Canadian government favoring the concept of an International Law of the Air. Canadian Prime Minister Brian Mulroney pointed out that the groundwork for such an approach exists in the Montreal Protocol to protect the ozone layer and in the impending international protocol on nitrogen oxide control. Norwegian Prime Minister Gro Brundtland recommended a global convention on protection of the climate.

The meeting recommended a global pact to protect the atmosphere and a world atmosphere fund to facilitate global solutions, which recognized differential issues in usage and effects. For instance, the different historical consumption of and contribution to the atmosphere of already industrialized nations and those in the process of industrializing would be balanced by having the fund financed in part by taxes on fossil fuels consumed in industrialized nations. The proposed atmosphere fund would then be used partly to provide economic assistance to developing countries pursuing environmentally friendly strategies such as reducing deforestation.

The delegates concluded that immediate action is imperative to address ozone depletion, global warming and sea-level rise, and acidification by atmospheric pollutants. The potential role of nuclear power as a clean energy source was debated, but no official recommendations emerged. Reduction of other greenhouse gases, substances that deplete the ozone layer, and acidifying emissions were recommended.

Specifically on the issue of global warming from greenhouse gases and climate change, the conference reached a consensus on the likelihood of a rise in the global mean temperature of between 2.7–8 degrees F (1.5–4.5 degrees C) by about 2050, but not on whether such warming has begun. The conference statement called for a 20 percent cut in present (1988) levels of global carbon dioxide emissions by the year 2005, about half of which could be achieved through conservation, leading to an eventual cut of 50 percent. This statement was possible as a result of the participation of governments that voluntarily committed to cutting carbon dioxide emissions by 20 percent by the year 2005. This became the so-called "Toronto target" for greenhouse gas emissions and went beyond the emissions targets recommended by most later international conferences, as well as the 1992 UN Framework Convention on Climate Change and the core goal of Kyoto.

The Toronto Conference was also influential in other developments. The Intergovernmental Panel on Climate Change (IPCC), an international grouping of over 300 of the world's best climate scientists, charged with peer reviewing and reporting on the latest international science, effects, and responses to climate change, had been formed just before the conference. The conference was instrumental in promoting the IPCC and in the eventual appointment of Swedish scientist Bert Bolin to head it.

PUBLIC AWARENESS

Discussions at the conference also led to the allocation of resources to the World Climate Programme and other global research institutions, to the support for technology transfer solutions, to the advocacy of reduction of deforestation, and to raising public awareness of issues related to the atmosphere.

As a follow-up to June's Toronto Conference, a smaller meeting of legal and policy experts was held in Ottawa, Canada, from February 20 to 22, 1989, to begin developing an international accord for the protection of the atmosphere. The 80 participants, acting in a personal capacity, constituted a broad spectrum of experts and officials from developed and developing countries, nongovernmental organizations, and academic institutions and discussed the legal and institutional framework for dealing with emerging atmospheric problems, agreed where possible on the basis of an umbrella convention framework, and identified areas of possible disagreement.

With the 1982 Law of the Sea as a precedent, the meeting recommended that one or more international conventions such as a Law of the Atmosphere and a narrower Climate Change Convention with appropriate protocols were urgently needed, especially to limit greenhouse warming. The statement from this meeting presented early drafts of the proposed documents.

The Law of the Atmosphere approach was criticized as being more unrealistic than the narrower Climate Change Convention and did not receive much attention from subsequent negotiators. In carrying the ideas from the Toronto Conference forward, the Ottawa meeting proposed broad terminology for atmosphere and atmospheric interference; discussed the obligation of nations to protect the atmosphere, recognizing the relationship between the atmosphere and other aspects of the environment; recognized the need to balancing of development internationally; and proposed an international notification process for harmful activities, liability, compensation, and dispute resolution mechanisms, as well as details of the Atmospheric Trust Fund.

Features that were eventually included in the 1992 Climate Convention included the approach of a framework treaty that deals with the central issues with protocols for particular details. This would be similar to the Vienna Convention with the Montreal Protocol. Two years after the Toronto Conference, the IPCC issued assessments that provided the basis for the United Nations Framework Convention on Climate Change in 1992, followed by the Kyoto Protocol in 1997.

Tourism

THE RELATIONSHIP BETWEEN tourism and global warming is a paradoxical one: global warming has become a threat to tourism, yet tourism remains a major cause of global warming. This vicious circle is well known to all stakeholders of the tourism industry, but implementing meaningful change has proven difficult because of three types of resistance: politico-economic resistance (from policymakers in regions and countries that rely heavily on tourism as a source of income), commercial resistance (from the tourism industry itself), and sociocultural resistance (from tourists who are not ready to change their behavior).

Several factors account for the considerable development of tourism since World War II: growing affluence, longer holidays, cheaper transportation, the availability of preorganized packaged tours, and the development of an industry catering both to mass tourists and to independent travellers. The subsequent increase in demand has resulted in an exponential rise in visitor numbers, both domestically (within countries) and internationally (especially from developed countries to developing countries). Although domestic tourism is statistically much more important (e.g., it accounts for 99 percent of all U.S. tourism and for 85 percent of all Australian tourism), international tourism is easier to measure (through a simple head count at borders); in addition, international tourism corresponds much more to the mainstream imagery of tourism: an island-hopping cruise in the Caribbean, a romantic holiday in Paris, a big game safari in Kenya. According to the World Tourism Organization, the number of international tourists increased from a mere 25 million in 1950 to 800 million in 2005. This number is predicted to double and to reach 1.8 billion by 2020, as more and more people want to travel. They may well know that they contribute to global warming and climate change, and some may feel a pang of guilt and remorse, but their desire to travel is stronger.

Climate is a key resource for tourism: favorable climatic conditions are key attractions for tourists, be it to ski in the mountains, to relax on a beach, or to experience nature. As soon as climatic conditions fluctuate and become less predictable, the tourism demand is affected and tourist flows move elsewhere: tourism, as a geographic phenomenon, is fickle and versatile. The mass media occasionally run stories about tourism hot spots that are victims of climate change and see their tourism appeal decrease; examples abound from all across the world, from less snowfall and shorter skiing seasons in Aspen, Colorado, or in Chamonix in the French Alps, to damage to coral reefs and rising ocean

Warmer temperatures at ski resorts: As soon as climatic conditions fluctuate and become less predictable, the tourism demand is affected and tourist flows move elsewhere; tourism, as a geographic phenomenon, is fickle and versatile.

water in Australasia, not to mention hurricanes that affect island resorts and the cruising industry.

These media stories are not just anecdotes or isolated incidents: they are part of a wider concern already well documented in the tourism literature, both in the academic literature (with seriously researched case studies, a nascent modelization of the relationship between climate change and tourism, and an increasing number of specialists, such as the Canadian Daniel Scott, the Dutch Bas Amelung, and the French Jean-Paul Ceron) and in the professional literature (industry publications such as professional bodies' reports and newsletters, as well as travel guides for tourists).

ENVIRONMENTAL AWARENESS AND TOURISM

International tourism organizations endeavor to raise awareness, to harness energies, and to articulate realistic plans of action. In 2003, the World Tourism Organization held its first Summit on Climate Change and Tourism. This resulted in the so-called Djerba Declaration on Tourism and Climate Change, whose signatories encouraged all governments to act to control climate change. The Djerba Declaration also asked the travel industry to adjust its activities to minimize climate change, and it invited consumer associations and the media to further raise public awareness, both at destinations and in generating markets. Taking place in 2007 in Davos, Switzerland, the Second International Conference reviewed and emphasized the key aims and intentions of the Djerba Declaration, strengthening its urgency and exploring concrete ways for tourism to respond to climate change, while still ensuring tourism development as a tool of economic growth and sociocultural well-being. At another level, in 2007 the World Travel and Tourism Council launched an international campaign on the same topic, calling for an open and mature dialogue on issues of tourism, climate change, and the environment; the campaign ran full pages in major publications such as *The Daily Telegraph*, *Newsweek*, and *The Wall Street Journal*, as well as travel trade media around the world.

Tourism professionals are aware of their responsibilities with regard to the environment, but they also know how much tourism contributes to the world economy. In 2007, the tourism industry globally represented 231.2 million jobs, which corresponded to 8.3 percent of total employment; that is, one in every 12 jobs worldwide. By 2017, this figure is expected to rise to 262.6 million jobs. Through their statements and declarations, tourism policymakers at all levels (local, regional, national, and supranational) and from all sectors (public, private, and voluntary) show that they understand the seriousness of the situation with regard to global warming and climate change, but one cannot ignore the fact that tourism is one of the world's largest economic sectors.

Tourism is not just about holidays and recreation, it is a powerful economic force that cannot be obliterated; rather, it has to be managed by implementing ways to maximize its benefits and minimize its costs. Through the concept of sustainable tourism, sustainable development has now become a key agenda in tourism, covering a range of social, cultural, and environmental issues, including references to climate change and global warming, yet solutions and ways forward are difficult to find. Simply controlling the number of international flights and limiting the amount of international tourists may not be a viable alternative at all: such a short-term measure could have devastating effects on many regions and countries whose economies are dependent, if not overreliant, on tourism income; for instance, small island states such as the Maldives, the Netherlands Antilles, and the Seychelles.

In 2007, global tourism generated over $7 trillion, and this number is likely to double within the next decade. The ongoing democratization of tourism means that more and more people can afford to travel and readily do so, even when they are aware of the effect on climate change and global warming; their arguments are usually twofold: first, that their own individual contribution is minimal, and second, that tourism is only one cause of climate change and global warming, among others. Many factors account for the ongoing increase in tourists' numbers: technological developments (epitomized by the superjumbo A380, with its capacity of 850 passengers), market deregulation (leading to more competition, which keeps prices low, especially in the airline industry), and the multiplication of specialized niche markets (such as sports tourism, senior tourism, gay tourism, or industrial tourism, making the demand more fragmented but also easier to target and satisfy). Neither financial penalties (tourism ecotaxes, imposed on airlines or at the destination) nor ethical appeals (campaigns asking would-be tourists to reconsider because of their carbon footprint) are proving effective deterrents for what is increasingly regarded as a right and not a privilege. Even the most vocal critics of tourism like to travel to conferences (business tourism) and go away on holidays (leisure tourism), which weakens the arguments of the antitourism lobby.

THREATS TO TOURISM

Climate change poses several risks to tourism; not only direct risks (climate variability affecting immediate demand as well as tourists' comfort and safety in the short term) but also indirect risks (such as causing damage to ecosystems or reducing water supplies, which may jeopardize tourism in the long term). This is ironic, inasmuch as tourism as a whole is partly responsible: by definition, tourism relies on methods of travel that generate air pollution (greenhouse gas emissions from vehicles that transport tourists, especially aircraft), so by its very existence, tourism heavily contributes to climate change. Rather than attempting a difficult—if not impossible—balancing act, specialists have identified two strategies. The first strategy involves innovation (e.g., with regard to sources and production of energy) and disseminating best practice in terms of sustainable development (e.g., through benchmarks and rewards). This first approach takes tourism in its wider industrial context, applying to tourism some policies and measures from other sectors, such as building and manufacturing.

The second strategy involves analyzing how climate change affects tourism to proactively restructure the tourism industry itself, both in terms of tourism demand and tourism supply; for instance, extremely hot temperatures in summer in seaside destinations may lead to a decrease of the demand in summer but to higher rates in other warm times of the year, such as warmer winter periods. As seasonality has always been a plague of the tourism industry, this climate change may eventually prove beneficial, though it will require adapting and revisiting established patterns. This second approach considers tourism as a specific and idiosyncratic system, although some related sectors, such as agriculture, local transport, and the entertainment industry, are likely to be affected too (a phenomenon conceptualized as backward linkages). The two strategies are not mutually exclusive: they can be combined, as they are both underpinned by a mix of idealism and pragmatism (adaptation and mitigation are two concepts used by scholars and policymakers alike).

Because of the intrinsic diversity of the tourism industry (exemplified by differing tourists' needs and expectations, from a backpacking teenager touring Europe to jetsetters staying in exclusive resorts), there may not be a one-size-fits-all solution. Case studies of destinations ranging from the Fijian archipelago to Banff National Park in Canada show that each region needs to develop its own methodologies and planning scenarios to anticipate changes in tourism demand and distribution, while remembering that it is not only the complex tourism system that is affected by global warming and climate change but also the local communities. Collaboration between partners and agencies is always heralded as a necessary mechanism; a good illustration is the official cooperation between the World Tourism Organization and the World Meteorological Organization: in 2006, an Expert Team on Climate and Tourism was jointly set up by both agencies. Such meetings of experts can result in sharing intelligence to help with research projects, as there is a wide recognition that decisions need be evidence based. The tourism industry is aware of the problems posed by global warming and climate changes, and it wants to be part of the solution.

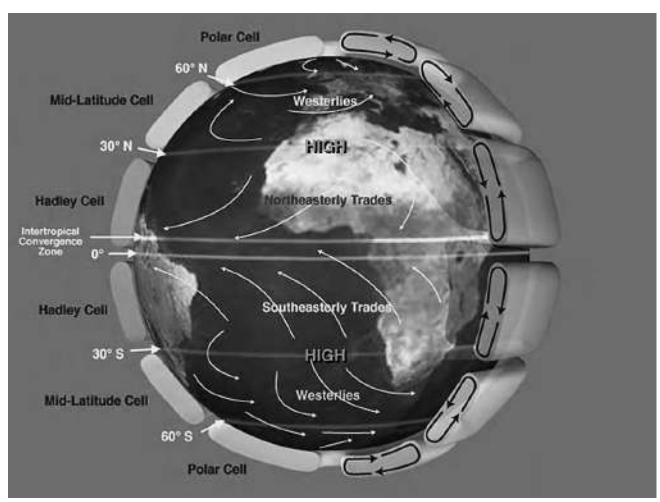
Trade Winds

THE TRADE WINDS are a large-scale component of Earth circulation, occupying most of the tropics straddling the equator between approximately latitude 30 degrees N and latitude 30 degrees S, with a seasonal shift of the entire trade wind belt system about 5 degrees of latitude northward during summer (July) and southward during winter (December).

In the Northern Hemisphere, warm equatorial air rises and flows north toward the pole, the Coriolis Effect (caused by the Earth's rotation) deflects the current, and as the air cools, it descends, blowing southwestward from the northeast. In the Southern Hemisphere, warm equatorial air rises and flows south toward the pole, the Coriolis effect deflects the current, and as the air cools, it descends, blowing northwestward from the southeast. The rising air is associated with deep atmospheric convection, heavy precipitation, and weak wind speeds, with an influence on global weather patterns Air heated by the sun rises and releases moisture through rain and thunderstorms. Once the air cools, it descends as drier air. In the equatorial low, the air rises and travels aloft to the subtropical highs, where it then sinks.

Mariners called these reliable wind currents for sailing the trade winds, or westerlies. The name trade winds comes from an old sailing term meaning that the winds could be counted on to blow steadily from the same direction at a constant speed. The trade



A NASA graphic of climatic zones and trade winds. In the tropics, the easterly trade winds dominate.

winds, or easterlies, carried air from east to west at low latitudes and are less regular over land areas than they are over the oceans. The trade winds meet at the Intertropical Convergence Zone. The doldrums (downward branch of the Hadley Cell, named for George Hadley, whose 1735 paper linked rising air and the Earth's rotation in causing the trade winds) are the calm winds at the Intertropical Convergence Zone in the area between latitude 5 degrees N and latitude 5 degrees S, where a sailing ship might not move because of the calm winds. In satellite imaging, the Intertropical Convergence Zone appears as a band of clouds. The strength and position of the Intertropical Convergence Zone influences tropical and global weather patterns.

Air temperature differences across the Earth's surface (both land and water) create winds, with warm air being lighter than cold air. Near the equator, the sun heats the sea surface, causing the warm air at the surface to rise and be replaced by the trade winds blowing from subtropical high pressure systems into equatorial low-pressure troughs. The trade winds blow steadily for days and are among the most consistent on earth. When trade winds move over warm tropical waters, they pick up moisture and bring heavy rainfall to the windward-facing slopes of mountainous areas, contrasting with the downward motion of dry air that creates desert areas on land. Because the area of Earth between the Tropic of Cancer and Tropic of Capricorn, lying at approximately 23 degrees latitude on either side of the equator, receives more solar heat than the rest of the earth, the warm air creates clouds and rain with thundershowers there almost every day.

The influence of the trade winds on weather and climate is seen with El Niño, La Niña, and the development of hurricanes/cyclones. The differences in pressure and temperature between the two sides of the Pacific are caused by the trade winds; air blowing from east to west pushes water, making the sea level higher in the western Pacific, and makes cold water rise toward the surface, making the eastern Pacific approximately 14 degrees F (7.7 degrees C) cooler than the western Pacific.

During El Niño years, the eastern Pacific sea surface is warmer, and the Intertropical Convergence Zone is closer to the equator, causing rainfall over the Pacific. The warm surface temperature is associated with reversed air pressure patterns and decreasing strength of trade winds, so more water stays in the eastern Pacific off the coast of South America. With the rain pattern shift eastward, the western Pacific can become drier over India and much of southeast Asia. A similar pattern sets up in the Atlantic, resulting in extreme drought in the eastern United States and reduced tropical storm development in the Atlantic Ocean.

During La Niña years, the trade winds are stronger than normal, causing more cold water to rise to the ocean surface. The cooler surface temperature is associated with a rain pattern shift westward. The eastern areas thus become drier, with an increased probability of flooding from monsoons in both India and much of southeast Asia.

Hurricanes (Atlantic) and cyclones (Indian Ocean) are tropical storms of low-pressure cells. Formation of hurricanes in the Atlantic comes from solar heating of water off the West African coast along the Intertropical Convergence Zone, with high cumulus cloud formation in the low-pressure area along the edge. These systems are pushed westward by the trade winds, and the rotation is set in motion by the Coriolis Effect. A similar pattern sets up in the Pacific, causing cyclones.

Transportation

TRANSPORTATION CAN BE simply defined as the movement of people, goods, and services from one place to another. Its system consists of the fixed facilities, flow entities, and control systems that permit the free flow and efficient movement of people and goods from place to place across geographical boundaries. Basically, there exist three forms of transportation: the road, water, and air transport.

The road transport systems are made up of the vehicular transport system and the rail transport system. The vehicular transport system comprises the different grades, sizes, and types of automobiles, and the rail transport system comprises the train systems of transportation. Water transportation also comprises the different shapes and sizes of water vehicles, known primarily as ships, boats, ferries, canoes, and so on. Air transport, in turn, comprises the different grades, shapes, and sizes of airplanes and helicopters.

FOSSIL FUELS

Each one of these means of transportation runs on fossil fuels of crude oil distillates and coal, apart from modern train systems in developed countries, which may run on automated power. These fuels are subjected to internal cycles of combustion, giving gaseous by-products of carbon dioxide (CO_2), carbon monoxide, and sulphur dioxide. Methane and nitrous oxide are also emitted by cars. World over, the greenhouse gas contribution of transportation is very high as a result of factors that include an increase in the number of vehicles, volume of passengers, and freight traffic. The percentage contribution of CO_2 from transportation alone varies from state to state and country to country. In 1990, Japan's contribution was put at about 19 percent, and that of the United States surprisingly doubled between 1960 and 2001. Specifically, it is reported that emissions of CO_2 in the United States jumped from 2 billion metric tons in 1960 to almost 5.7 billion metric tons in 2001, accounting for over a 100 percent increase, with over 20 percent of this emission linked to transportation. Transportation is also reported to account for 40 percent of volatile organic compounds, 77 percent of carbon monoxide, and 49 percent of nitrogen oxide emissions in the United States. In Canada, also, it is reported that transportation is the largest single anthropogenic source of outdoor air pollution. On average, each of the several million vehicles registered across the country emits approximately 5 tons of air pollutants and gases annually. This trend in record is the same for all industrialized nations and several developing nations, such as Nigeria in West Africa, because of an increased population and a rapid rate of economic growth, bringing about increased use of automobiles and other means of transportation. This increase has brought with it increasing emissions of air pollutants and greenhouse gases because of the type of engines in use and the nature of the fuels in place.

In general, it is reported that combustion engines emit nitrogen oxides (NO_x), carbon monoxide, and unburned hydrocarbons capable of chemical transformation in the atmosphere, creating other gaseous matter such as ozone. Ozone is a triatomic molecule consisting of three atoms of oxygen; it is an allotrope of oxygen but is much less stable. Its instability makes it a strong oxidizing agent, having the ability to decompose to oxygen in the atmosphere within 30 minutes. In its physical undiluted state, at standard temperature and pressure, it is a pale blue, odorless gas. In the troposphere, ozone acts as a greenhouse gas and has a radiative forcing of about 25 percent that of CO_2. Around the Earth's surface, it poses a regional air pollution problem damaging human health and agricultural crops.

More so, residual fuel oils, particularly the heavy oil used aboard ships, contain sulphur, which reacts with atmospheric water and oxygen to produce sulfate particles and sulphuric acids, also known as acid rain. It lowers soil and freshwater pH, resulting in damage to our natural environment, and also causes chemical weathering. Its ability to increase the reflection of part of the sunlight that should come into the Earth's surface creates a cooling effect. Road traffic on its own is a major contributor to environmental degradation and global warming. It clearly provides the largest net contribution to warming through its large emissions of CO_2 and significant emissions of ozone and soot. Soot particles emitted by diesel engines have the ability to absorb sunlight, thus heating up the climate. Total warming from road traffic is reported to be about 0.19 Watts per sq. m. (W/m^2), forming about 7 percent of the total climate forcing, as a result of an increased concentration of ozone, soot, and greenhouse gases.

Air traffic, as a sector in the transportation industry, also shows a trend toward increased environmentally unfriendly emissions. Airplanes fly in the upper edges of the atmosphere, where the air is rarefied and the planes release large quantities of greenhouse gases. CO_2, the main constituent in the exhaust gases, slowly descends into the lower altitude. However, the large number of planes flying across the sky has caused the average amount of these greenhouse gases to increase. CO_2 and other greenhouse gases get cut up in the stratosphere, where they become much more potent than at the Earth's surface, blocking radiant energy from reaching the planet. Thus, the global warming effect of air traffic pollution in the stratosphere is very high. In addition, the NO_x emitted have an especially large effect on ozone formation. A more recent research report on air traffic suggests that the occurrence of ice clouds, called cirrus clouds, at flying altitudes is increasing in areas with heavy air traffic because the trails of vapor left by aircraft at high altitude under certain meteorological conditions can expand. These clouds, found at altitudes of between 5 and 7.5 mi. (8 and 12 km.), have a warming effect on the climate because their greenhouse effect is stronger than their cooling effect through the reflection of light. This is a result of the low temperatures at this height.

Moreover, the various gases emitted by engines of transportation units pose serious challenges to the environment. CO_2, the most popular of the greenhouse gases, is a colorless, odorless gas with a covalent bond between its atomic constituents. It is the most potent greenhouse gas, being highly atmospherically stable and having a life of over a hundred years, with a strong ability to absorb radiations below the visible light spectrum, thus trapping heat attempting to escape from the Earth's surface and causing an increase in the temperature of the planet's surface. It has a radiative forcing of 1.5 W/m^2 and is regarded as the most powerful greenhouse gas because of its long atmospheric stability period.

The presence of a ton of CO_2 put into the atmosphere thus has a deleterious environmental warming effect for over a hundred years. With the increasing anthropogenic emission of this gas from transportation and other sources, the global warming effect of CO_2 on the environment has never been ignored. It is heavily concentrated in the atmosphere.

Methane (NH_4), in contrast, is a covalent compound, colorless and odorless. It is not as stable as CO_2 but has a stronger effect as a greenhouse gas than CO_2. Its stability period in the Earth's atmosphere is 10 years. It absorbs infrared radiation and affects tropospheric ozone. Methane may not be as popular a greenhouse gas as carbon dioxide, but its effects on the climate are stricter than it, and methane has been rated the second most potent greenhouse gas, after CO_2, with the exception of water vapor because of its short life and the quantity of it found in the Earth's atmosphere.

Another gas emitted from the burning of fossil fuels is nitrous oxide. It is a colorless, nonflammable, sweet-smelling gas having two nitrogen and one oxygen atoms covalently bonded together. When released into the atmosphere, nitrous oxide is the third largest greenhouse gas contributor to global warming, and has more effect than an equal amount of CO_2. It is reported that nitrous oxide is 296 times stronger a greenhouse gas than CO_2. It attacks ozone in the stratosphere, increasing the amount of ultraviolet light entering the Earth's surface. This ultraviolet light has deleterious effects on the human immune system, as well as the eye, and on the skin. It causes sunburn, inflammation, immunosuppression, tanning, and the accelerated aging of the skin.

GASEOUS POLLUTANTS

Other gaseous pollutants from transportation (mentioned earlier) are carbon monoxide and sulphur dioxide. Carbon monoxide is a colorless, odorless, and tasteless gas, formed by the thermal composition of excess carbon with oxygen. It is made up of a carbon atom covalently bonded to an oxygen atom. It is also released from the exhaust of motor vehicle engines, having gone through an incomplete internal combustion process of burning excess fossil fuels in the presence of oxygen. It is a toxic air pollutant. Its reaction in the atmosphere with some atmospheric constituents like the hydroxyl radical (OH^-) can increase the amounts of atmospheric methane and tropospheric ozone, thus causing an indirect forcing effect. It has the ability to combine with oxygen in the atmosphere to give CO_2, thereby contributing to greenhouse effects and global warming. Apart from this environmental degradation, CO has deleterious effects on human health.

Exposure to excess carbon monoxide can lead to heart and respiratory problems and has an effect on pregnancy, the central nervous system, and the heart—to mention a few adverse effects. Sulphur dioxide, in contrast, is a covalently bonded chemical compound made up of an atom of sulphur and two atoms of oxygen. It is anthropogenically produced from the combustion of coal and petroleum, which is commonly used by cars. It is a colorless gas with the smell of burning sulphur and is able to undergo serial combination to form sulphuric acid, which is an acid rain with corrosive tendencies found in the atmosphere. Sulphur dioxide is also toxic and has caused damage to humans in times past. However, its effects as a regulatory measure on the global warming effects of the greenhouse gases is limited by its lifespan on the Earth's surface, which is not more than a week.

With the present system of transportation still in use the world over, the rate of emissions of these harmful gases will continue to be on the increase, and their deleterious effects will become severe, as anthropogenic emissions of CO_2, methane, and nitrous oxide from industry and transportation are among the major causes of global warming. Gaseous pollutants of carbon monoxide and sulphur dioxide also contribute to dangerous effects on humans and the environment. However, various reports of the Intergovernmental Panel on Climate Change exist, each pointing to the damaging effects of such greenhouse gases as carbon dioxide, methane, and nitrous oxide. The contribution of transportation to the emission of these gases is high, and determining what must be done to reduce these emissions must be a global exercise that involves scientific contribution. Transportation effects on global warming and environmental pollution cannot be reduced without a redesign of the present system of engines vis-à-vis the available fuel systems. The emissions from modes of transportation can only increase as the numbers of vehicles, airplanes, ships, and other transport units migrating from one place to another increase.

Trexler and Associates, Inc.

TREXLER CLIMATE AND Energy Services, Inc. (TC+ES) was founded as Trexler and Associates, Inc. (TAA) in the year 1991 by Dr. Mark C. Trexler, formerly of the World Resources Institute in Washington, D.C. TC+ES is based in Portland, Oregon. TC+ES was the company that wrote the first contracts for carbon offset, and designed the first methane carbon offset project for a coal mine.

Until 1997, the company was the only one serving the private sector in climate change mitigation services. That same year, TAA worked with Stonyfield Farm and its New Hampshire facility, helping the company to become the United States' first "greenhouse gas (GHG) neutral" facility. In 2000, TAA assisted Shaklee Corporation in its application to the Climate Neutral Network for the pilot certification of "Climate Neutral". The Climate Neutral Network awarded these certifications to companies who submitted worthy applications; it was to close down in 2007.

In 2002, TAA became partly run by Japan's Sumitomo Corporation. Sumitomo was established in 1919 as Osaka Hokko Kaisha Ltd., and adopted the English name Sumitomo Corporation in 1978.

Since its founding, TC+ES has worked with over 100 companies, large and small, in over 20 nations. Some of its better-known clients include the Chevron Research and Development Corporation, Fannie Mae, Nike Inc., Stonyfield Farm Inc., The Nature Conservancy, and the U.S. Department of Energy, and other institutions.

Services provided by TC+ES include achieving GHG neutrality, building ghg competitive advantage, customized price curve development, GHG inventory support, internal cost curve development, mitigation portfolio development, power plant siting and offset strategies, project design document (pdd) services, risk and opportunity assessment, and Sarbanes-Oxley compliance.

The company frequently publishes papers and reports regarding environmental strategizing and financial planning for companies interested in incorporating environmental responsibility.

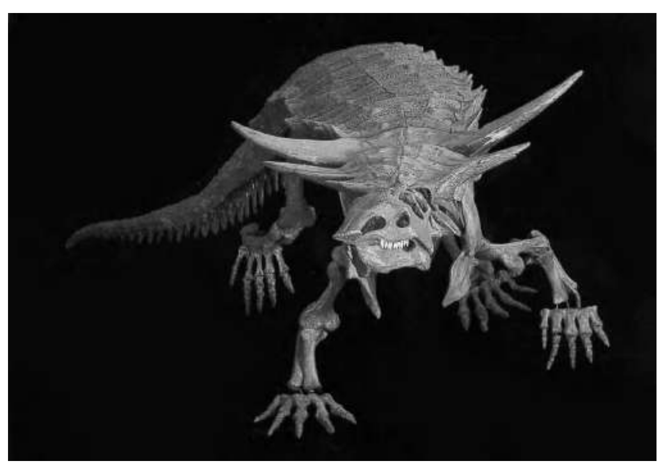
Triassic Period

THE TRIASSIC PERIOD is the geologic time period that extends from about 251 to 199 million years ago. This is the first period of the Mesozoic era, following the Permian and preceding the Jurassic period. Both the start and end of the Triassic are marked by major extinction events. During the Triassic period, both marine and continental life showed an adaptive radiation, beginning from the starkly impoverished biosphere that followed the Permian-Triassic extinction. The first flowering plants may have evolved during the Triassic, as did the first flying vertebrates, the pterosaurs. The Triassic period is further separated into Early, Middle, and Late Triassic epochs.

During the Triassic period, almost all the Earth's land mass was concentrated into a single supercontinent centered more or less on the equator, known as Pangaea. This supercontinent began to rift during the Triassic period but had not yet separated.

The Triassic climate was generally hot and dry, forming typical red bed sandstones and evaporites. There is no evidence of glaciation at or near either pole. The polar regions were moist and temperate—a climate suitable for reptile-like creatures. Pangaea's continental climate was highly seasonal, with very hot summers and cold winters. It probably had strong, cross-equatorial monsoons. The interior of Pangaea was hot and dry during the Triassic period. This may have been one of the hottest times in Earth history. Rapid global warming at the very end of the Permian may have created a super hothouse world that caused the great Permo-Triassic extinction.

The Permian-Triassic extinction event, also known as the Great Dying, was an extinction event that occurred 251.4 mya (million years ago). This was the Earth's most severe extinction event, with up to 96 percent of all marine species and 70 percent of all terrestrial vertebrate species becoming extinct. There are several proposed mechanisms for the extinction event, including both catastrophic and gradualistic processes, similar to those theorized for the Cretaceous extinction event. The former include large or multiple impact events, increased volcanism, or sudden release of methane hydrates from the seafloor. The latter include sea-level change, anoxia, and increasing aridity. Evidence that an impact event caused the Cretaceous-Tertiary extinction event has led naturally to speculation that impact may have been the cause of other extinction events, including the Permian-Triassic extinction. Several possible impact craters have been proposed as possible causes of this extinction event, including the Bedout structure off the northwest coast of Australia and the so-called Wilkes Land crater of east Antarctica. In each of these cases, the idea that an impact was responsible has not been proven and has been widely criticized. If impact was a major cause of this extinction event, it is possible or even likely that the crater no longer exists. Seventy percent of the Earth"s surface is



Aetosaur bones from the Triassic period in the Petrified Forest in Arizona. The Triassic climate was generally hot and dry.

sea, so an asteroid or comet fragment is over twice as likely to hit sea as to hit land. There is evidence that the oceans became anoxic toward the end of the Permian. There was a noticeable and rapid onset of anoxic deposition in marine sediments around east Greenland near the end of the Permian. The most likely causes of the global warming that drove the anoxic event were a severe anoxic event at the end of the Permian, causing sulphate-reducing bacteria to dominate the oceanic ecosystems and causing massive emissions of hydrogen sulfide, which poisoned plant and animal life on both land and sea. These massive emissions of hydrogen would have severely weakened the ozone layer, exposing much of the life that remained to fatal levels of ultraviolet radiation.

Pangaea's formation would also have altered both oceanic circulation and atmospheric weather patterns, creating seasonal monsoons near the coasts and an arid climate in the vast continental interior. Marine life suffered very high but not catastrophic rates of extinction after the formation of Pangaea—rates almost as high as in some of the Big Five mass extinctions. The formation of Pangaea seems not to have caused a significant rise in extinction levels on land, and in fact, most of the advance of Therapsids and the increase in their diversity seems to have occurred in the late Permian, after Pangaea was almost complete. Thus it seems likely that Pangaea initiated a long period of severe marine extinctions but was not directly responsible for the Great Dying and the end of the Permian.

The possible causes, which are supported by strong evidence, appear to describe a sequence of catastrophes, each one worse than the previous. The resultant global warming may have caused perhaps the most severe anoxic event in the oceans' history. The oceans became so anoxic that anaerobic sulphur-reducing organisms dominated their chemistry.

University of California, San Diego

Trinidad and Tobago

THE ISLANDS OF Trinidad and Tobago, located in the Caribbean close to the South American coast, have a land area of 1,979 sq. mi. (5,128 sq. km.), with the island of Trinidad accounting for 1,864 sq. mi. (4,769 sq. km.), and Tobago the remaining 116 sq. mi. (300 sq. km.). The country has a population of 1,333,000 (2006 est.), of whom 96.3 percent live on the island of Trinidad, which has a population density of 660 people per sq. mi. (254 people per sq. km.). Some 69 percent of the population live in urban areas. With 15 percent of the land being arable, 9 percent is under permanent cultivation, with 2 percent being used as meadow or pasture. Some 44 percent of the country is forested, with efforts being made by the government to conserve the forests.

Much of the economy of Trinidad and Tobago comes from the petroleum industry, with petroleum and petroleum products making up the vast majority of the country's exports. The country also has coal deposits. The consumption of these deposits has led to an increase in greenhouse gases, with the result that Trinidad and Tobago has one of the highest carbon dioxide emissions per capita in the world. Although data published by the U.S. Department of Energy's Carbon Dioxide Information Analysis Center puts it at 9th in the world, Trinidad is the fifth highest independent country. Its emissions were 13.9 metric tons of carbon dioxide per capita in 1990, and with the exception of a low figure for 1993, emissions levels have risen significantly since then, reaching 22.1 metric tons per capita in 2003. The emissions are largely from gaseous fuels (72 percent), with 16 percent from liquid fuels, 10 percent from gas flaring, and 2 percent from the manufacture of cement. Not only is the heavy use of petroleum a major contributing factor but there is also poor public transport on Trinidad, resulting in widespread use of automobiles.

There is also extensive use of air conditioning for private houses and businesses. The effect of global warming can be seen by rising water temperatures detrimentally affecting the population of leatherback turtles, as well as affecting other Caribbean nations far more significantly. The government of Trinidad and Tobago has also been worried about the effects of global warming on the tourism industry, as well as the problems that might be posed to yachting and the cruise liners operating in the Caribbean.

The government of Patrick Manning took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992, and 2 years later, Trinidad and Tobago was represented at the Global Conference on the Sustainable Development of Small Island Developing States held in Barbados. On January 7, 1999, the Trinidad government of Basdeo Panday signed the Kyoto Protocol to the UN Framework Convention on Climate Change, with it being ratified exactly 3 weeks later, but only entering into force on February 16, 2005.

Tropopause

THE TROPOPAUSE IS the boundary region dividing the troposphere, the lowest layer of the atmosphere, from the overlying stratosphere. Since the tropospheric and stratospheric air masses have rather distinct features, in correspondence to each surface location, the tropopause height is the level in the vertical where abrupt changes in the physical and chemical properties of the atmosphere are observed.

Three different definitions are typically adopted. The thermal tropopause is related to the change of the sign of the vertical derivative of the temperature (lapse rate), which is negative in the troposphere and positive in the stratosphere.

The World Meteorological Organization defines the tropopause as the lowest level where the absolute value of the temperature lapse rate decreases to 2K/km. or less, with the average lapse rate between this level and all higher levels within 1.2 mi. (2 km.) not exceeding 2K/km. The dynamical tropopause is defined in terms of sharp changes in the potential vorticity (much higher in the stratosphere), which measures stratification and rotation of the air masses. An abrupt increase (decrease) with height of the ozone (water vapor) mixing ratio indicates the presence of the chemical tropopause. In spite of the necessity of choosing phenomenological thresholds, the three definitions of the tropopause are quite consistent.

TROPICAL TROPOPAUSE

Typically, the tropopause height decreases with latitude, being around 3.7 mi. (6 km.) near the poles and 11 mi. (18 km.) near the equator. Whereas radiative and convective processes with time scale of the order of one week to one month basically determine the properties of the tropical tropopause, in the midlatitudes a relevant role is played also by baroclinic-fuelled extra-tropical cyclones, having a typical time scale of a few days, in such a way that the tropopause readjusts its height in such a way as to act effectively as a stabilizing mechanism limiting the growth of the weather perturbations. The tropopause is not a hard boundary: exchanges of tropospheric and stratospheric air occur through various mechanisms, including vigorous thunderstorms and midlatitude perturbations.

The globally averaged tropopause height tends to increase if the troposphere warms up and/or the stratosphere cools down, and the height change is approximately proportional to the difference between the tropospheric and stratospheric temperature changes. Therefore, the mean tropopause height can act as a robust indicator of climate change. Recent climate simulations have shown that the estimated increase after 1979 of about 492 ft. (150 m.) may be primarily explained by anthropogenic causes, namely the stratospheric cooling driven by ozone depletion and the tropospheric warming driven by increases in the greenhouse gases concentration. Considering natural processes, episodic, short-lived strong reductions of the globally averaged mean tropopause height are caused by large explosive volcanic eruptions, which warm the troposphere and cool the stratosphere.

Troposphere

ON THE BASIS of thermal characteristics, the atmosphere is normally subdivided into four major vertical layers: the troposphere, stratosphere, mesosphere, and thermosphere. The troposphere makes up the lowest of these layers, extending from the surface to a global average height of 7.5 mi. (12 km.). Coined in 1908 by French scientist Leon Philippe Teisserenc de Bort, the name troposphere is derived from the Greek word tropos, meaning to turn, mix, or change. The term aptly describes the extensive vertical mixing and stability changes of this layer, which generates clouds, precipitation, and other meteorological events. For this reason, the troposphere is commonly referred to as the weather sphere.

The depth of the troposphere is relatively thin, yet it contains approximately 80 percent of the atmosphere's mass. Because the atmosphere is compressible, air molecules are more compact closer to the surface, thereby increasing the density and pressure of the air at lower altitudes. The relationship between density and pressure with altitude is nonlinear, decreasing at a decreasing rate with increasing altitude. In the lower troposphere, the rate of pressure decrease is about 10 mbars. for every 330 ft. (100-m.) increase in elevation.

Temperature in the troposphere generally decreases with height, contrasting considerably between its lower and upper boundaries. Temperature in this layer is largely affected by the radiant energy exchanges from the underlying surface and insolation intensity. The global average temperature at the surface is 59 degrees F (15 degrees C) but decreases to around minus 82 degrees F (minus 63 degrees C) at the top of the troposphere. On the basis of mean tropospheric depth, the average rate of temperature decrease is 3.6 degrees F per 1,000 ft. (6.5 degrees C per km.), a measurement known as the normal lapse rate. This rate represents average global conditions, deviating substantially depending on latitude, time, and local modifications. The actual temperature change with height is the environmental lapse rate, which is measured remotely, using satellites, or directly, using Radiosondes (a balloon-borne instrument package). Eventually, temperature ceases to decline with height, transitioning into a zero lapse rate region (or isothermal layer), where temperature is neither increasing nor decreasing. This shift demarcates the boundary between the troposphere and the stratosphere, known as the tropopause.

The mean height of the tropopause can have considerable spatial and temporal variability. In the tropics, the depth of the troposphere is around 16 km. (10 mi.), but near the poles, the depth dwindles to about 8 km. (5 mi.) or less. The tropopause also varies seasonally, with higher heights occurring during the summer than the winter. Warm surface temperatures occurring at low latitudes and high sun periods encourage vertical thermal mixing, thereby extending the depth of the troposphere. Accordingly, the environmental lapse rate in these regions continues to remain positive (i.e., temperature decreases with height), and tropopause temperatures are typically lower in the tropics than for high latitudes. Occasionally the tropopause is difficult to discern because of extensive mixing between the upper troposphere and the lower stratosphere.

This situation is common in portions of the midlatitudes, usually defining the location of jet streams (a narrow belt of high-velocity winds often in excess of 185 km. per hour (115 mi. per hour) that steer midlatitude cyclones. Because the height of the tropopause is dependent on the average temperature of the troposphere, temperature changes in this layer can influence the location of extratropical storm tracks and cloud depth.

Embedded frequently within the troposphere are thin sublayers in which the temperature actually increases with height, known as temperature inversions. Radiation inversions result from nocturnal surface cooling. Under certain ambient conditions (e.g., cloudless nights), terrestrial radiation loss to space is enhanced and the ground (and air above) cool rapidly, thereby establishing a shallow inversion layer. Conversely, subsidence inversions occur from mid-upper tropospheric processes that produce areas of sinking air that are being warmed by compression; hence, lower tropospheric temperatures are actually colder than those aloft. This setting tends to stabilize the air, inhibiting vertical mixing and cloud growth.

A semipermanent sublayer of the troposphere is the planetary boundary layer (PBL), a section directly influenced by surface daily conditions. Comprising typically the lowest 1 km. (3,300 ft.) of the troposphere, the PBL is characterized by turbulence generated by frictional drag from the surface beneath and rising thermals (heated air parcels). The depth of the PBL amplifies and diminishes with the daily solar cycle, such that the greatest thickness is during the day when the atmosphere is most turbulent.

Evidence suggests that the troposphere has undergone a significant rate of warming during the past century. The tropospheric temperature trend in the latter half of the 20th century is estimated at a 0.18 degree F (0.10 degrees C) increase per decade, similar to the surface temperature rate change. Higher temperatures mean increased surface evaporation and tropospheric water vapor content. As a consequence, cloud cover has also shown an increase, and extratropical precipitation in the Northern Hemisphere has increased 5 to 10 percent since 1900.

Other climate-forcing agents (e.g., anthropogenic-induced greenhouse gas emissions) can alter the Earth's radiation balance and may also explain the upward temperature trend. For instance, tropospheric ozone (O_3), a greenhouse gas and surface pollutant, has increased by nearly 35 percent since the preindustrial era.

Tsunamis

TSUNAMIS (SOMETIMES CALLED seismic sea waves) are large sea waves that are created by underwater earthquakes, volcanic eruptions, or even nonseismic events such as landslides and meteorite impacts. Tsunamis are also known as tidal waves, even though this is a misnomer because the waves have nothing to do with tides. The word *tsunami* is a Japanese word meaning "harbor wave." Tsunamis are not easily seen on the open water, as they have extremely long wavelengths on the order of tens of kilometers. The speed of the wave is directly related to the depth of the water; therefore, as the water depth decreases, the tsunami moves slower. As the waves propagate toward the coast, the speed will decrease, but the amplitude or the height of the waves can achieve extraordinary levels. Tsunamis lose energy as they approach the coast, but they still have incredible amounts of energy, as they often cause beach erosion and undermine trees and other types of coastal vegetation. The fast-moving water is capable of flooding several hundreds of meters inland, well above normal flood levels, and destroying buildings and other structures. Tsunamis can extend to heights well above sea level, in extreme cases sometimes as high as 30 m. or 100 ft.

Volcanic activity and earthquakes are the prime causes of tsunamis. When the seafloor starts to buckle, the overlying water will begin to displace. As the seafloor rises and sinks, the displaced water will form waves because of the effects of gravity. Most of the major earthquakes occur at plate boundaries.

There are three different types of plate boundaries. A divergent boundary takes place where two plates move away from each other. At this type of boundary, volcanoes will form, out of which molten material will flow. Also, weaker, shallow-focus earthquakes can occur along these boundaries. Divergent boundaries are very common in the midocean such as at the Mid-Atlantic Ridge, the East Pacific Ridge, the Mid-Indian Ridge, and the Southeast-Indian Ridge. Convergent boundaries occur where two plates moving in opposite directions collide. One plate will be denser and will subduct underneath the other. These subduction zones are a very common location for earthquake activity. There are three different types of convergent boundaries: oceanic-continental convergence, oceanic-oceanic convergence,

The third and largest wave of the tsunami of December 26, 2004, invades the promenade on Ao Nang Beach, Thailand. Waves were reported as high as 30 m. or 100 ft., and it was the deadliest in recorded history, with an approximate 230,000 lives lost,

and continental-continental convergence. At an oceanic-continental convergent boundary, the oceanic crust is denser and will subduct underneath the continental crust. Volcanoes will form along the continental boundary, whereas deep trenches will form off the coast. Shallow-focus earthquakes often form along these subduction zones, such as along the west coast of South America. At an oceanic-oceanic convergent boundary, two ocean plates collide, forming a volcanic island arc on the ocean floor. Examples of this type of boundary include the Aleutian Islands, the Mariana Islands, and Japan. At a continental-continental convergent boundary, two continental plates collide, typically forming huge mountain ranges such as the Himalayas or the Alps. Under this type of convergence, volcanic activity is rare, but earthquake activity is very common. The final type of boundary is called a transform boundary, where two plates slide past each other. Transform boundaries occur along vertical fractures called faults, which are noted for great magnitudes of earthquake activity. Most faults are found near midoceanic ridges, but they can also extend through continents, as evidenced by the San Andreas Fault in California.

Tsunamis can be formed by anything that displaces a large volume of water from its equilibrium state. When earthquakes or volcanoes generate tsunamis, water is displaced as a result of the uplift or subsidence of the seafloor and water column. Sometimes submarine landslides, which are common with large earthquakes as well as volcanic collapses, can displace great volumes of water. However, these types of disturbances disturb the water from above, rather than from below. Tsunamis derived from these types of mechanisms usually do not last long and have minimal impacts on the coastlines.

The most recent deadly tsunami was the Asian tsunami that occurred after the 2004 Indian Ocean earthquake on December 26 of that year. The epicenter, which is the location at the Earth's surface directly above the focus of the earthquake, took place off the coast of Sumatra, Indonesia. The magnitude of this earthquake has been estimated to be between 9.1 and 9.3 on the Richter scale (the scale devised to estimate the amount of energy released in an earthquake). This made it the fourth most powerful recorded earthquake since 1900. The earthquake lasted almost 10 minutes and was the second most powerful ever recorded on a seismograph (an instrument that measures the seismic waves from an earthquake). Waves were reported as high as 30 m. or 100 ft., and it was the deadliest in recorded history, with an approximate 230,000 lives lost, mostly in the countries of Indonesia, India, Sri Lanka, and Thailand. Before this, the 1782 Pacific Ocean tsunami was the deadliest in recorded history, with an estimated 40,000 casualties in the South China Sea. Other powerful tsunamis include the 1883 tsunami following the eruption of Krakatoa, a volcanic island in Indonesia, and the 1908 tsunami that occurred in the Mediterranean Sea near Messina, Italy.

There has been speculation about possible effects of global warming after the 2004 tsunami, with proponents suggesting that the increase in average temperature allows the atmosphere and the oceans to gather energy, which may cause more earthquake activity. Critics, however, claim that if this were the case, there would be more of a correlation between El Niño and tsunamis, as El Niño warms the ocean over an active region with many plate boundaries. Therefore, links to global warming and tsunamis are unsubstantiated because it is difficult to associate what is happening at the surface of the ocean with the depth at which the focus of the earthquakes takes place.

Tunisia

LOCATED IN NORTH Africa between Algeria and Libya, the Republic of Tunisia has a land area of 63,170 sq. mi. (163,610 sq. km.), with a population of 10,327,000 (2006 est.) and a population density of 161 people per sq. mi. (62 people per sq. km.). In spite of its having an arid climate, 19 percent of the land in Tunisia is arable, with 13 percent under permanent cultivation. There is also an additional 20 percent used as meadows or pasture, mainly for the raising of sheep, goats, and cattle. Only 4 percent of the country is forested.

Tunisia has its own supplies of crude oil and natural gas, and as a result, 99 percent of the country's electricity generation comes from the use of fossil fuels, with 1 percent coming from hydropower. In terms of its per capita rate of carbon dioxide emissions, they have risen from 1.6 metric tons per person in 1990 to 2.29 metric tons in 2004. Some 65 percent of Tunisia's carbon dioxide emissions come from liquid fuels, with 23 percent coming from gaseous fuels and 10 percent from the manufacture of cement. Heavy use of air conditioning, especially in the economically important tourist sector, results in electricity production making up 39 percent of the country's carbon dioxide emissions, with 25 percent coming from transportation, 24 percent from manufacturing and construction, and 11 percent from residential use.

The effect of global warming and climate change on Tunisia has seen the alienation of some arable land, with the rising temperature affecting the level of crop production. It has also led to gradual shortages of water in some inland parts of the country and in the increasing use of desalination, which in turn leads to increases in the amount of electricity that needs to be generated. The Tunisian government of Zine El Abidine Ben Ali took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992. It accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on January 22, 2003, with it entering into force on February 16, 2005.

Turkey

LOCATED MAINLY IN Asia, but with a small part of its land considered to be in Europe, the Republic of Turkey has a land area of 302,535 sq. mi. (779,452 sq. km.), with a population of 74,877,000 (2006 est.) and a population density of 240 people per sq. mi. (93 people per sq. km.). Istanbul, the former capital and the largest city, has a population density of 13,256 people per sq. mi. (5,137 per sq. km.). The present capital, Ankara, has a population of 3,641,900, with a population density of 13,328 per sq. mi. (1,424 per sq. km.). Some 32 percent of the land area of Turkey is arable, with 4 percent under permanent cultivation, and an additional 16 percent is used as meadows or pasture. Some 26 percent of the country remains forested, and there is only a small timber industry. In terms of its per capita rate of carbon dioxide emissions, it was 2.6 metric tons per person in 1990, rising to 3.14 metric tons per person by 2004.

Electricity generation in Turkey comes largely from fossil fuels (74.1 percent), with 25 percent being from hydropower. The use of hydropower has not been without controversy. Although it has generated much hydroelectricity, there have been environmental problems with the Illisu Dam in southeastern Turkey, as well as with some other projects. The production of electricity is responsible for 38 percent of Turkey's carbon dioxide emissions, with 8 percent coming from other energy industries, 25 percent being from manufacturing, 20 percent from transportation, and 13 percent from residential use. Heavy use of coal means that 44 percent of the emissions are the result of the use of solid fuels, with 37 percent being from liquid fuels, 10 percent from gaseous fuels, and 9 percent from the manufacture of cement.

Turkey has suffered some effects of global warming and climate change, with a rise in the average temperature in the country resulting in the snowmelt on some of the previously snow-covered peaks in the east of the country. More important, it has also led to the alienation of agricultural land throughout the country, with the need for water for irrigation and drinking leading to water shortages in some rural areas. There have also been problems in the agriculturally poor eastern part of Turkey, where there is already low productivity in farms and high levels of poverty.

The Turkish government took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992. It has not expressed an opinion on the Kyoto Protocol to the UN Framework Convention on Climate Change.

Turkmenistan

LOCATED IN CENTRAL Asia, Turkmenistan is a country primarily made of desert. It lies between 35 degrees 08 minutes and 42 degrees 48 minutes N and between 52 degrees 27 minutes and 66 degrees 41 minutes E, north of the Kopet-Dag mountains, between the Caspian Sea to the west and the Amu-Darya River to the east. Turkmenistan covers 188,455 sq. mi. (488,096 sq. km.) and had a population of 5,097,028 in 2007.

Despite its extensive oil and gas resources, Turkmenistan remains a poor, predominantly rural country, with the majority of the population relying on intensive agriculture in irrigated oases, and it is extremely vulnerable to climate change.

Turkmenistan has a distinctive continental climate, with an average annual air temperature ranging from 54–62 degrees F (12–17 degrees C) in the north to 59–64 degrees F (15–18 degrees C) in the southeast and to the absolute maximum temperature of 118–122 degrees F (48–50 degrees C) in the Central and South-East Kara-Kum. The highest amount of annual rainfall is observed in the mountains (up to 398 mm. in Koyne-Kesir), as is the least rainfall (less than 95 mm. above the Kara-Bogaz-Gol Bay). Up to 80 percent of Turkmenistan's land consists of desert. Meteorological data reveal an increase of annual and winter temperatures in Turkmenistan dating from the beginning of the past century. Since 1931, the mean annual temperature has increased by 1 degree F (0.6 degrees C) in the northern part of the country and by 0.7 degrees F (0.4 degrees C)in the south.

At the same time the number of days with temperatures higher than 104 degrees F (40 degrees C) has increased since 1983. Climate Models predict temperature increases in Turkmenistan of 5–7 degrees F (3–4 degrees C) by the middle of the 21st century. Precipitation projections are highly uncertain, but given the existing aridity and high interannular and interseasonal variability of Turkmenistan's climate, even a slight temperature increase is likely to exacerbate the existing water stress in the region.

Turkmenistan signed and ratified the UN Framework Convention on Climate Change in 1995. In January 1999, Turkmenistan ratified the Kyoto Protocol and published the Initial Communication on Climate Change. Because Turkmenistan is covered under the Kyoto Protocol's Clean Development Mechanism, it can trade carbon credits with other countries that fall under the Joint Implementation Mechanism.

The major sources of carbon emissions in Turkmenistan include oil and gas extraction, petroleum refining, and the chemical industry, as well as motor transport concentrated mainly in Ashgabat, Turkmenbashi, Balkanabat, Mary, Turkmenabat, and Dashoguz.

Turkmenistan has taken some steps to reduce carbon emissions, such as a massive tree planting project throughout the country (Green Belt Project), modernization of Turkmenbashi and Seyidi refineries to conform to modern ecological standards, and relocation of the cement factories away from inhabited areas.

However, the nation's widespread poverty, recent decline in the educational system, misuse of hydrocarbon revenues, and high economic dependence on cotton production and exports leave Turkmenistan particularly vulnerable to high climatic variability, desertification, and droughts.

Tuvalu

TUVALU HAS BEEN independent since 1978, joining the United Nations in 2000. The resident population has been estimated to be about 10,000 people in 2007, living on nine small, low-lying atoll islands. The total land area is only 9.4 sq. mi. (24.4 sq. km.); when the Exclusive Economic Zone is included, the total national area of Tuvalu is 289,576 sq. mi. (750,000 sq. km.). Tuvalu does not have substantial natural resources—the coral atoll soil is of poor quality, alkaline, shallow, and with low water-holding quality. Added to these environmental challenges are a lack of rainfall, lack of natural resources, the occurrence of cyclones, and the threat of sea-level rise. About 44 percent of the population lives on urban Funafuti, and the internal migration rate is expanding. The overcrowded urban situation has meant that having a sufficient freshwater supply is difficult.

As a small and fragmented Pacific Island nation, Tuvalu is increasingly vulnerable to cyclones, flooding, and sea-level rise, accompanied by environmental threats, such as land loss and coastal erosion, soil salinization, and intrusion of saltwater into the atolls' freshwater lenses and groundwater. Two incidences of flooding have been noted as being particularly severe for the urban island of Funafuti—one in 1977 and another one in 1993. Other climatic effects include coral bleaching in reef systems. Tuvalu's vulnerability, however, is also because of its impoverished economic situation, with large employment rates in the public sector, aid dependency, and a lack of natural resources for export; fragmentation and isolation of the islands; and a lack of capacity to support its population, which makes sea-level rise a problematic development issue. Current estimations of average sea-level rise in the South Pacific are 0.7 mm. per year. However, in relation to sea-level rise, the land of Funafuti island is sinking, which problem is accelerated by tectonic movement. As a consequence, and including indications of tide-gauge data, the sea-level rise in the Funafuti area has been estimated by scientists to be 2 + 1 mm. per year.

ENVIRONMENTAL REFUGEES

Tuvalu entered international negotiations on climate change in 2002, when Koloa Talake, the prime minister at the time, suggested pursuing legal actions against greenhouse gas emissions leading to global warming and the consequences of sea-level rise for Tuval, on the international level. The National Summit on Sustainable Development in Tuvalu in 2004 emphasized the need to promote awareness and strategies for adaptations on the national level. Migration as a final solution will be difficult for Tuvaluans and is also culturally contested. Existing migration schemes for Tuvalu are small.

Different from many other Pacific nations, Tuvalu, similarly to Kiribati, does not have the privilege of free access to the Pacific Rim countries. Current access allows 75 Tuvaluans to migrate each year to Australia and New Zealand. The strong relationship of Tuvaluans to their land, however, makes migration a last resort. Recent publications have suggested that Tuvalu and Tuvaluans are being publicly victimized when they are represented as potential places of disaster and as environmental refugees, respectively.

Tyndall, John (1820–93)

JOHN TYNDALL WAS born in Leighlinbridge, County Carlow, in Ireland on August 2, 1820. After working as a surveyor and a mathematics teacher, he attended the University of Marburg in Germany, where he received his Ph.D. In 1854, he became a professor of natural philosophy at the Royal Institution in London (a scientific research center founded in 1799). In 1867, he was made superintendent of the institution, taking over from Michael Faraday.

Tyndall's most well-known scientific studies included the nature of sound, light, and radiant heat and observations on the structure and movement of glaciers. Glaciers had become a scientific area of interest during that time because in the 1830s, Louis Agassiz (considered the father of glaciology) had discovered that a large portion of Europe and North America had once been covered with ice.

Tyndall developed an interest in meteorology as a result of his love for mountain climbing. He studied alpine glaciers and took meteorological

John Tyndall was a 19th-century physicist. He is renowned for his studies in the absorption of heat by atmospheric gases.

measurements on Mont Blanc in the Alps. Using a spectrophotometer he designed, Tyndall studied the absorption of infrared light (at the time called radiant heat) by atmospheric gases. Infrared light is felt as heat and has wavelengths of approximately 0.7 to 1.0 μm. Visible light for comparison has wavelengths of approximately 0.4 to 0.7 μm.

Some of the invisible gases (oxygen, nitrogen, and hydrogen) were transparent to radiant heat, whereas water vapor and carbonic acid (now known as carbon dioxide) absorbed and reemitted infrared light, thereby warming the atmosphere close to the earth. From these experiments, Tyndall realized that water vapor, carbon dioxide, and ozone—even in small quantities—were the best absorbers of heat radiation, and he later speculated on how changes in these gases could correlate to climate change.

GREENHOUSE GASES

Among the various atmospheric gases in the troposphere, Tyndall discovered the importance of water vapor and carbon dioxide as greenhouse gases that trap heat on the surface of the earth. Without these atmospheric gases to trap heat, the heat would rapidly radiate back into space, and the Earth would be much colder. During cold nights, there is an enhanced chance of fog or dew in the mornings because the moisture in the air (water vapor) condenses into droplet as the air cools. In deserts—hot and dry climates—there is a lack of water vapor in the air, and the sand radiates heat easily into space. Changes in the atmospheric levels of gases produce changes in the climate as well.

In the 1860s, Tyndall began to suggest that slight changes in the atmospheric composition could bring about climatic variations. Tyndall was the first scientist to explain the Ice Ages as being caused by greenhouse effect. In particular, he noted that variations in water vapor resulted in a change in the climate and realized the importance of the greenhouse effect in maintaining ecosystems necessary for life. He thought changes in the composition of the atmosphere may have produced all changes in the climate.

Using the laws of thermodynamics, Tyndall proposed that changes in carbon dioxide cause an initial change in temperature, and when the humidity changes accordingly, the change in humidity leads to a second change in the temperature.

During the Victorian era, he was the contemporary and friend of other important scientists. In addition to his scientific research, he promoted scientific education of the public with scientific demonstrations and advocated using hands-on laboratory experimentation to teach science. In 1874, Tyndall used his address before the British Association for the Advancement of Science to proclaim rational thought and skepticism as the aim and superiority of science.

In the 1870s, he made a lecture tour of the United States and included his lab demonstrations. Over the course of his professional life, he was the recipient of numerous scientific awards and recognition. In addition to his dynamic public speeches using laboratory experimentation, he published a wide range of papers, treatises, and books. Digital versions of John Tyndall's books can be found at http://books.google.com and include *Lectures on Light Delivered in the United States in 1872–1873*, first published in 1873; *Hours of Exercise in the Alps*, first published in 1871; and *The Glaciers of the Alps*, first published in 1861.

John Tyndall died on December 4, 1893, from an overdose of chloral hydrate. At the inquest, his wife testified she mistakenly gave him chloral hydrate instead of his normal medication, leading to his death.

TYNDALL EFFECT

The Tyndall effect, a scientific principle on the dispersion of light beams through colloidal suspensions or emulsions, was named for him. The importance of his research continues, as his work continues to shape scientific research on climate change.

The Tyndall Centre, with headquarters at the School of Environmental Sciences at the University of East Anglia, founded in 2000, is named after John Tyndall, in honor of his being one of the first scientists to recognize the Earth's natural greenhouse effect and observing, identifying, and proposing the climate effects of the radiative properties of atmospheric gases. The mission of the Tyndall Centre is to research and educate policymakers on climate change, to develop and apply research methods for climate change, and to promote international dialogue on managing future climate change.

In support of this goal, research at the Tyndall Centre includes action to provide information through data collection and interpretation and modeling to assess possible scenarios of the effect of human and natural causes on climate change and to disseminate this information by encouraging international discussion and policymaking. By using empirical research, the Tyndall Centre proposes protection of coastline ecosystems, city-scale emissions testing, and accountability for contributions to climate change. The Tyndall Centre focuses on this objective, with a strategy to investigate and identify behavior modification and education opportunities to promote sustainable approaches to limiting human-induced climate change.

Uganda

UGANDA IS SITUATED in the interlacustrine highlands of central Africa; these highlands are generally characterized by a high plateau that is associated with the Great Rift Valley that dominates Uganda. The plateau generally lies between 3,280 to 6,562 ft. (1,000–2,000 m.). One characteristic feature of the Great Rift Valley is the development of numerous lakes; these include Tanganyika and Kivu, while in the Albertine Rift region in the north, the lakes include George, Edward, and Albert. Uplift along the shoulders of the Western Rift Valley resulted in the reversal of the previously west-flowing rivers and the creation of the basin now occupied by Lake Victoria. The Nile River, which forms the eastern boundary of the interlacustrine highlands, is the major outlet of Lake Victoria, flowing northward from Lake Victoria. Farther to the west, Uganda is dominated by the Ruwenzori mountain range—the infamous mountains of the moon—that straddle the border with the Democratic Republic of Congo.

The climate of Uganda varies from humid through seasonally arid conditions. Precipitation is dependent largely on the Intertropical Convergence Zone (ITCZ); the movement of the ITCZ follows the position of maximum surface heating associated with the overhead position of the sun. Climate is further modified by topography and by the proximity of the large lakes. The distribution of vegetation is mainly dependent on altitude, levels of precipitation, and human activities. Because of human pressure, cultivated and grazed land occupies much of Uganda. Much of the interlacustrine highlands lie within a phytogeographical zone known as the Lake Victoria Regional Mosaic, where five distinct floras meet; namely, the Afromontane, Guineo-Congolian, Somalia-Masai, Sudanian, and Zambazian Regional Centers of Endemism. Above 6,562 ft. (2,000 m.) there are three distinct vegetation belts; namely, Afroalpine, Ericaceous, and Montane forest belts. The Afroalpine Belt occurs mainly above 11,810 ft. (3,600 m.) in the high mountains of the region, which include Mount Elgon, the Virunga volcanic mountains, and the Rwenzori.

Environmental histories of Uganda have been reconstructed via a long history of palaeoecological research from the numerous lakes and swamps. Recent interest in other proxy records, such as archaeology, historical linguistics, oral traditions, and meteorological data have provided a detailed understanding of the environmental history of Uganda and the associations between environmental and human histories in the region. Under the cool and dry climate conditions of the last glacial maximum, vegetation from higher altitudes extended to lower elevations. From around 15,000 years before present (yr. BP), as global climates warmed, montane forest types retreated back to mountainous areas, reaching the minimal extent around 6,000 yr. BP under the warm and wet conditions of the mid-Holocene.

The climate history from 5,000 yr. BP to the present is more complex, as ecosystems have been increasingly influenced by human activity. A period of relatively drier climate between 5,000 and 2,000 yr. BP is marked by relatively low lake water levels. Vegetation also reflected this climate change, experiencing a marked transition to drier forest types from about 3,500 yr. BP. Uganda experienced a return to relatively moist environmental conditions after about 2,000 yr. BP; during this same period, areas around Lake Victoria experienced a decrease in evergreen forest, with it being replaced by semideciduous forest. The introduction of agriculture to Uganda is commonly associated with Bantu-speaking people, who are reported to have spread throughout much of central Africa after about 3,000 yr. BP.

Ukraine

UKRAINE IS A republic in east Europe, part of the former Soviet Union. Its capital and largest city is Kiev (50 degrees 27 minutes N, 30 degrees 30 minutes E, population of 2.6 million in 2007, estimation by the Department of Ukrainian State Statistics). The total area of Ukraine is 233,090 sq. mi. (or 603,700 sq. km., the 44th country in size and second in Europe after European Russia). The total population is around 46.6 billion (in 2007, estimation by the Department of Ukrainian State Statistics). The word Ukraine originally meant "near the border" (of Russia and Poland).

The country has a mostly temperate continental climate, though a more Mediterranean climate is found on the southern Crimean coast. Precipitation is disproportionately distributed, being highest in the west and north (up to 31–39 in., or 800–1,000 mm. per year) and lesser in the east and southeast (around 16–18 in., or 400–450 mm. per year). Winters vary from cool along the Black Sea to cold farther inland. Summers are warm across the greater part of the country but are generally hot in the south. The average temperature in January is 18–19 degrees F (minus 7 to minus 8 degrees C) in the northern Ukraine, while it is 37–39 degrees F (3–4 degrees C) in the southern Crimea. The absolute January minimum/maximum temperature minus 43 degrees F to 67 degrees F (minus 42 degrees C to 19.5 degrees C) was observed in the northeast/Crimea. January precipitations vary from 1–2.5 in. (35–65 mm.) per month. The average temperature in July is around 64–75 degrees F (18–24 degrees C). The absolute July maximum/minimum temperature 106/36 degrees F (41.0/2.4 degrees C) was observed in the northeast. July precipitations vary from 1–7 in. (30–185 mm.) per month.

The linear temperature trend varies from around 1.8–3.6 degrees F (1–2 degrees C) per 100 years for the northern Ukraine in winter/spring to 30 degrees F (minus 1 degree C) per 100 years for the southern Ukraine in summer/fall. The linear trend of precipitation varies from around 4 in. (100 mm.) a year per 100 years for drier regions to minus 4 in. (100 mm.) a year per 100 years for wetter regions. So, the continental climate of Ukraine is becoming more mild. The interannular climate variability of Ukraine (especially its northern part) is under the strong control of the North Atlantic Oscillation.

The Ukrainian landscape consists mostly of fertile plains, or steppes, and plateaus, crossed by rivers such as the Dnieper, Seversky Donets, Dniester, and Southern Buh as they flow south into the Black Sea and the smaller Sea of Azov. To the southwest, the delta of the Danube forms the nation's border with Romania. The Danube is the largest European river, which rises in the Alpine region. Its average discharge from 1947–2001 was about 6,350 cu. m. per second. The maximum/minimum discharge (9,180/4,420 cu. m. per second) is observed in May/October. There is a positive linear trend of mean annual Danube discharge, which is about 200 cu. m. per second per 50 years. The country's only mountains are the Carpathian Mountains in the west, of which the highest is Mount Hoverla at 6,762 ft. (2,061 m.), and those in the Crimean peninsula in the extreme south, along the Black Sea coast.

The Black Sea is the southern border of Ukraine and is the largest natural reservoir of sulfate dioxide in any sea in the world. As a result of cyclonic general circulation in the Black Sea, the upper boundary of the sulfate dioxide zone is situated at a typical depth of about 262–328 ft. (80–100 m.) in the internal parts of the sea, and it deepens to up to 492–590 ft. (150–180 m.) along the shelf slope. The intensity of the principal element of the Black Sea general circulation (the so-called Rim current) varies from one decade to another as a result of quasi-periodic low-frequency changes of external forcing (such as wind stress, fresh/heat balance, and Mediterranean water inflow). The upper boundary of the sulfate dioxide zone moves up and down because of such quasi-periodical variability. There is also small negative trend of depth of sulfate dioxide zone (around minus 10 m. per 50 years), which points to its shoaling in the internal part of the sea in recent decades. This is the result of Rim current intensification caused by stronger external forcing.

The Black Sea, bordering the south of the Ukraine, is the largest natural reservoir of sulfate dioxide.

UN Conference on Trade and Development/Earth Council Institute: Carbon Market Program

THE UNITED NATIONS Conference on Trade and Development (UNCTAD)/Earth Council Carbon Market Program (CMP) started in 1991 as the UNCTAD Emissions Trading Project and has opened the way for a collaboration between governments and the private sector in the development of a global carbon market. The program aims to reduce greenhouse gas emissions and is targeted primarily to economies in transition and third world countries. An emission trading system aims to control pollution by providing economic incentives for the reduction of polluting emissions. A central authority establishes a limit on the amount of a pollutant that can be emitted. Companies or other groups that release polluting emissions have to hold an equivalent number of credits or allowances, which represent the right to emit a specific amount. The total amount of credits cannot exceed the limit, so that total emissions cannot go beyond that level. Groups that need to increase their emissions must buy credits from those who pollute less. The transfer of allowances is described as a trade, although the buyer is actually being fined for polluting, while the seller is being compensated for their reduction of the emissions.

The starting point of the program is the recognition that future economies will be carbon constrained. UNCTAD and the Earth Council conceive their function as preparing developing countries for the likely changes in relative prices and relative production costs that the introduction of climate policies and measures will cause. They are also trying to facilitate a smoother transition to a postunregulated carbon economy.

The CMP aims to reduce the effect of climate change by contributing to the development of an integrated global emissions trading system in which all participant countries accept the principle of common but differentiated responsibilities. The United Nations Secretariat issued a major report on the subject in May 1992, as a contribution to the work of the Earth Summit held in Rio de Janeiro in June 1992. Since then, UNCTAD and the Earth Council have stimulated and encouraged research and capacity building in the area of greenhouse gas emissions trading. As one of their primary activities, UNCTAD and the Earth Council have lent their support to interested governments, corporations, and nongovernmental organizations for the development of a multilateral market for trading in greenhouse gas emission allowance and certified emission reduction credits, in accordance with the Kyoto Protocol and the decisions of the Conference of the Parties. The program also includes an annual Carbon Market Policy Forum, which brings together buyers, sellers, and market makers from the public and private sectors in both developed and developing countries.

A significant element of CMP is its work with economies in transition in developing their capacity to implement the Kyoto Protocol. CMP has devised a wide range of capacity-building activities and materials to assist accession countries, which form the Central Group 11 (CG11), in their development of national Kyoto strategies. CMP also has developed stocktaking reports of the current situation in relation to emissions trading and the Kyoto Protocol in accession countries. In addition, it has discussed a policy framework that identifies the various policy options and practical steps that CG11 countries may take, as well as the identification of specific capacity-building needs. In addition, UNCTAD and Earth Council have launched the Carbon Market E-learning Centre (CMEC), which contains modules related to emissions trading. The CMEC supplies learning opportunities for global audiences on the use of emissions trading as an economic resource to implement the UN Framework Conventions on Climate Change and the Kyoto Protocol. The center offers online courses and, more important, virtual workshops. These help other institutions to develop their own courses through the e-learning facilities of the CMEC.

UNCTAD and Earth Council Institute support the efforts of developing and transitional countries to participate effectively in the emerging trade and investments in allowances and credits for carbon emissions. As part of the CMP, UNCTAD and Earth Council Institute have also encouraged investments from the private sector for the Clean Development Mechanism (CDM) of the Kyoto Protocol, particularly in Least Developed Countries. The program has supported the creation of public-private bodies for the implementation of the CDM and has attempted to develop the CDM through capacity building, starting from the needs of local communities. The CMP has lent its support particularly to Brazil, as well as to African countries such as Tanzania, Uganda, Mozambique, Zambia, and Malawi.

United Arab Emirates

LOCATED IN THE Persian Gulf, the United Arab Emirates (U.A.E., formerly the Trucial States) has a land area of 32,278 sq. mi. (83,600 sq. km.), with a population of 4,380,000 (2006 est.) and a population density of 139 people per sq. mi. (64 people per sq. km.). Its economy is heavily dependent on petroleum and natural gas, with the country enjoying a very high standard of living. With little natural freshwater and regular sand and dust storms, the U.A.E. has little arable land, with most of the food in the country being imported.

With a dry desert climate and great wealth, widespread use of private automobiles and air conditioning has resulted in heavy use of electricity, all of which comes from fossil fuels. This has resulted in the country having the third highest rate of per capita carbon dioxide emissions in the world—29.3 metric tons in 1990, falling to 16.9 metric tons in 1996, and then rising steadily to 37.8 metric tons per person by 2004. Some 67 percent of the carbon dioxide emissions have come from gaseous fuels, with 27 percent from liquid fuels, and 3 percent from gas flaring. In terms of the sector generating the carbon dioxide emissions, 43 percent comes from electricity production, 45 percent from manufacturing and construction, and 8 percent from transportation.

An effect of global warming and climate change in the U.A.E. has been the raising of the average temperature in the country, making the establishment of arable land even harder. It has also forced the country to invest heavily in desalination plants to provide the country with enough freshwater. There has been large-scale use of water to transform Dubai, and some environmentalists have been critical of the use of water for the maintenance of gardens and golf courses in the country. The rise in the temperature of the water in the Persian Gulf has also led to the bleaching of coral reefs and further depletion of fish stock.

The U.A.E. government took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992. The government accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on January 26, 2005, with it entering into force on April 26, 2005.

United Kingdom

THE UNITED KINGDOM of Great Britain and Northern Ireland has a land area of 94,526 sq. mi. (244,100 sq. km.), with a population of 60,587,300 (July 2006) and a population density of 637 people per sq. mi. (246 people per sq. km.). London, the capital and the 16th largest city in the world, has a population density of 11,927 per sq. mi. (4,597 per sq. km.). Some 25 percent of the land of the United Kingdom is devoted to agriculture, with a further 46 percent used for meadow or pasture, and 10 percent of the land being forested.

Traditionally, most of the electricity generation in the United Kingdom has come from coal, which has been mined in parts of Scotland, Yorkshire, Nottinghamshire, and South Wales. The continued use of coal, and also of oil, Britain having made use of the North Sea oil fields since the 1970s, has meant that 73.2 percent of Britain's electricity generation was, in 2001, still coming from fossil fuels—coal, oil, and natural gas—with 23 percent coming from nuclear fuel and only 1.5 percent from hydropower. Although recent governments have tried to use nuclear power more extensively, this move has been widely opposed by many people, who are concerned about the safety of nuclear power, with political pressure over the location of the various nuclear power stations.

The United Kingdom ranks 37th in terms of its carbon dioxide emissions per capita, with 10.0 metric tons in 1990, falling steadily to 9.2 metric tons by 1998, and then rising to 9.79 metric tons by 2004. A third of all carbon dioxide emissions in the country are from the generation of electricity, with 27 percent from transportation, through heavy use of private automobiles, and large traffic jams and tailbacks in London and many other major cities, some 17 percent generated for residential use, and 15 percent from manufacturing and construction. In terms of the source of these emissions, 27 percent is from solid fuels, with 36 percent from liquid fuels and 35 percent from gaseous fuels, and 1 percent from gas flaring.

There have been many effects on Britain of global warming and climate change. Because statistics have been collected there since the 18th century, it has been easier to study the changes. The number of cold days has steadily decreased, with an average of 4 days per year above 68 degrees F (20 degrees C) for most of the period since 1772, but 26 days above 68 degrees F (20 degrees C) in 1995. Indeed, October 2001 was the warmest October in central England, with four of the five warmest years in the previous three and a half centuries being in the 1990s and early 2000s. One study has shown that oak trees have experienced earlier leafing as the climate gets warmer.

As well as rises in temperature, there have also been widespread floods, with that in October and November 2000 resulting in the flooding of some 10,000 houses at a cost of about $1.5 billion. This was the worst flooding in Britain since those in March to June of 1947, with the melting of a six-week snowpack, although some war damage to locks on canals leading into the River Thames made the floods worse than normal. Since then, there had been floods in 1968, 1993, and 1998, with those in 2000 following the wettest autumn since records were first collected in the late 1660s. Although floods have not been unknown in Britain—and the River Thames flooded again in 2003 and 2006—in June and July 2007 there were much more serious floods. These caused damage estimated at $3 billion, with Northern Ireland experiencing floods on June 12 and East Yorkshire and the Midlands being hit three days later.

Over the next five weeks, large parts of Berkshire, Gloucestershire, Oxfordshire, and South Wales were also inundated, with rainfall in June 2007 being twice the June average. Indeed, some areas of the country received the average monthly precipitation in one day. The worry has been that the floods, which took place twice a century on average, are now taking place every three to five years. The flooding would be much worse without the construction of the Thames Barrier in the 1970s, which has prevented any serious floods from happening in London since those in January 1928, March 1947, and 1968.

During the 1990s, a detailed survey of plant species in the country showed that the date of the first flowering of 385 British plant species had advanced by an average of 4.5 days when compared with the previous four decades. Flowering is particularly sensitive to the temperature in the month before the plant flowers, indicating that plants have become sensitive to the changes in temperature, with those that flower in spring being the most responsive. In terms of fauna, British birds have steadily expanded their ranges northward, with more birds that had previously only been found in the south of the country being spotted in northern England and Scotland. Over the last 25 years, some birds have expanded the northern margins of their ranges by about 12 mi. (19 km.). Another study of birds has shown that between the years 1971 and 1995, some 32 percent of the 65 species in the study have started laying eggs earlier—on average 8.8 days earlier—each year. In addition, frogs, toads, and newts have started spawning

Floods causing an estimated $3 billion in damages hit the United Kingdom in 2007, including this flooding in Sheffield.

between 9 and 10 days earlier than had been the case 20 years earlier.

The British government of John Major took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992. The next government, that of Tony Blair, signed the Kyoto Protocol to the UN Framework Convention on Climate Change on April 29, 1998, ratifying it on May 31, 2002, with it entering into force on February 16, 2005.

The United Kingdom Climate Strategy introduced in 1994 had the objective of keeping greenhouse gas emissions of carbon dioxide, methane, and nitrous oxide at 1990 rates—carbon dioxide by incentives to business and home users to conserve energy; methane by reducing landfill through a landfill levy and a greater regulatory environment, as well as limiting methane emissions from coal production; and nitrous oxide through technological innovations in the manufacture of nylon. The introduction of three-way catalytic converters was planned to reduce carbon monoxide, especially from car exhausts, by up to 50 percent, and the reorganization of large power stations was expected to reduce nitrogen oxides by 35 percent.

In November 2000, the United Kingdom's Climate Change Policy, which was formulated following the United Nations Conference on Environment and Development, was formally launched. The United Kingdom was, in 2004, the eighth largest producer of carbon emissions, with the country being responsible for about 2.3 percent of the world's total coming from fossil fuels. The plan drawn up by the Blair government was not just to cut the emissions back to 12.5 percent less than the 1990 rate during the period from 2008 until 2012, as agreed by the Kyoto Protocol, but also to reduce them to 20 percent lower than the 1990 rate by 2010. The methods used by the British government to reduce carbon emissions largely hinged on encouraging business to improve its use of energy, to cut back on emissions from cars by providing better public transport, to promote energy efficiency in homes, and to get agriculture to reduce emissions.

As worry about the effects of global warming and climate change received much publicity in the British press, the Campaign against Climate Change was founded in 2001 to oppose the rejection of the Kyoto Protocol by U.S. president George W. Bush. Although it had small beginnings, on December 3, 2005, it did organize a large rally in London, and another took place on November 4, 2005. By this time, there were also a number of other pressure groups, including Stop Climate Chaos. Formed as a coalition of a number of other groups, including the Campaign against Climate Change, in September 2005, Stop Climate Chaos was also organizing protests. This was to lead to the I Count Campaign to try to get governments around the world to introduce measures to prevent world temperatures from rising more than 3.6 degrees F (2 degrees C).

On June 21, 2006, royal assent was given to a parliamentary bill that became the Climate Change and Sustainable Energy Act 2006, which, introduced to the British Parliament by Mark Lazarowicz, a Scottish Labour member of parliament, encourages microgeneration installations to reduce the use of large power stations and, as a result, reduce carbon dioxide emissions and fuel poverty, whereby some poor people had been unable to afford to heat their residences. The impetus from this led to the drafting of the Climate Change Bill, which was published on March 13, 2007, based heavily on the measures suggested in the I Count campaign. It aimed to reduce the United Kingdom's carbon emissions for 2050 to 60 percent of the level for 1990, with an intermediate target range of 26 to 32 percent by 2020. The bill was initially criticized for failing to include international aviation and shipping but quickly gained cross-party support, although it has not been passed into law. The British government has also been very keen on establishing a system of having a greenhouse gas allowance trading regime, although plans for this are still being drawn up.

United Nations

GLOBAL CLIMATE CHANGE is one of the most pressing issues of the 21st century. Because of the use of coal, oil, and gas for energy and the loss and degradation of forests, our planet is warming faster than at any time in the last several thousand years. We have already experienced warming temperatures, changing rainfall patterns, and sea-level rise. These disruptive forces have severe effects on economies, environment, and society of humankind. Nonetheless, the climate challenge may at the same time be viewed as an enormous opportunity for a significant economic change. It is quite evident that the United Nations (UN), by implementing a number of notable conventions and treaties, assumes a key role to play in a wide range of activities concerned with understanding, mitigating, and adapting to climate change. In a nutshell, the past few decades have seen a growing recognition of the importance of involvement of the UN with the complex scientific and technical issues related to global warming, climate change, and sustainable development.

Although it is rightly perceived that it is just a kind of global challenge the UN is uniquely positioned to address, it is also recognized that this is not a challenge for this world body alone. To handle the dilemma, it requires a truly concerted global effort—an initiative that draws together national governments, private sector, and civil society in one sustained push for change. This policy-relevant piece concludes by asserting the following forward-looking reflections that the UN, with its sensitivity and imagination, will be able to more successfully convey the urgency of the situation and send the following message to all of us: we should unite at any cost to save our beloved planet.

THE UN CONVENTIONS ON CLIMATE CHANGE

Regardless of the fact that the international scientists have drawn attention to the threats posed by global warming in the 1960s and 1970s, it took some years before the global community responded. In 1988, an Intergovernmental Panel on Climate Change (IPCC), an authoritative UN network of 2000 scientists, was created by the UN Environment Programme (UNEP) and the World Meteorological Organization. In 1990, this group presented a first assessment report that reflected the views of 400 scientists. The report indicated that global warming was real and urged that something be done about it. The findings of the panel prompted governments to create an international treaty, the UN Framework Convention on Climate Change (UNFCCC). By the standards of international agreements, the negotiation of the convention was rapid. It was ready for signature at the UN Conference on Environment and Development, more popularly known as the Earth Summit, held in Rio de Janeiro in 1992.

More comprehensively, the Convention on Climate Change, which entered into effect on March 21, 1994, sets an overall framework for intergovernmental efforts to tackle the challenge posed by climate change. It recognizes that the climate system is a shared resource, the stability of which can be affected by industrial and other emissions of carbon dioxide and other greenhouse gases (GHGs). Under this convention, which enjoys near universal membership, with 191 countries having ratified it, governments gather and share information on GHG emissions, national policies, and best practices; launch national strategies for addressing GHG emissions and adapting to expected effects, including the provision of financial and technological support to developing countries; and cooperate in preparing for adaptation to the effects of climate change. Notwithstanding, the recent UNFCCC report underscores the principal changes to patterns of investment and financial flows required to tackle climate change in the next quarter century. A major accomplishment of the convention, which is general and flexible in character, is that it admits that there is a problem.

A number of nations have recently approved an addition to the UNFCCC, the Kyoto Protocol, a second, more far-reaching international treaty on climate change that entered into force on February 16, 2005. The Kyoto Protocol has more powerful and legally binding measures that call for industrialized countries to collectively reduce emissions to 5 percent below 1990 levels between 2008 and 2012. In fact, these trends have been projected to accelerate over the recent years, including the Conference of the Parties of the UNFCCC, held in Bali (Indonesia) in December 2007, although the Vienna Climate Change Talks 2007 were attended by nearly 1,000 representatives from over 150 governments, business and industry, environmental organizations, journalists, and research institutions.

THE UN RESPONSE TO CLIMATE CHANGE ACTION

In 2007, climate change has indeed become one of the highly prioritized concerns for the UN, because there is now an overall understanding that the phenomenon will seriously affect the way the world operates in toady's challenging era of globalization, from healthcare and water issues to economic activity, humanitarian assistance, and the peace-building and security aspects. The UN has already demonstrated a long-standing commitment and responsibility toward resolving the cardinal environmental hazards encompassing reducing GHG emissions to limit future climate change and improving the capacity of the world's biodiversity and poorest communities to adapt to its inevitable effects. This universal organization has played a pivotal role in generating the scientific consensus, elevating the issue to the cover pages of the global media, and placing it on the in-tray of heads of state and government, as well as the chief executive officers of businesses and industries.

The UN, through the UNFCCC, helps to accelerate the take-up of clean and renewable energies to counter the climate change challenge. To be more specific, the Clean Development Mechanism (CDM) of the Kyoto Protocol permits developed countries to offset some of their emissions through clean and renewable energy projects and certain forestry schemes in developing countries. The CDM funds flowing from north to south will reach up to US$100 billion over the coming years. The high-technology industries and job opportunities are emerging in both developed and developing nations. China and India are currently homes to two of the biggest wind turbine and power companies. The foreign direct investment in renewable energy, driven in part by the UN-brokered climate treaties, is anticipated to top US$80 billion in 2007. The UN system is further endeavoring to nourish this process. For instance, the UNEP, in partnership with the UN Foundation and Asian Development Bank, piloted a project that has brought solar power to 100,000 people in India.

This sort of progress actually echoes the Millennium Development Goals adopted by the UN, as they relate to such areas as poverty alleviation, public health, basic education, and so on. Furthermore, the UN assists in harnessing the power of the carbon markets and evaluates the potential for forests to cope with challenge emanated from the climate change. The UN's Food and Agriculture Organization, for example, estimates that 13 million hectares of the world's forests are lost annually and that deforestation accounts for approximately 20 percent of the global GHG emissions.

The issue of climate change, along with such steps as the UN Global Compact, assists the restoration of nexus between the UN and other segments of society making up business and industry. Although an intriguing feature of recent months is a call by the private sector for international regulation across the globe, businesses appear eager to do their part if the ground rules are clear and comprehensive. In addition, many other welcoming initiatives are already being undertaken. The European Union, for instance, has agreed to a 20 percent emission reduction target, which will rise to 30 percent if other countries follow suit. The Group of Eight Summit in Germany has also affirmed the ongoing UN climate change process. It is demanding that governments and the UN deliver an international agreement to address this issue. Developing countries are also acting at the same time. In Brazil, efforts to counter deforestation in the Amazon have shown positive results, whereas China has recommitted itself to reduce its energy intensity by 20 percent.

In addition, the prime minister of India has recently ordered a review of his nation's GHG emissions.

The UN is looking at its own backyard as well. The Capital Master Plan for the refurbishment of the UN headquarters in New York is assessing how to factor green measures into the project, looking to make the structure a striking example of an ecofriendly building. This is part of a wider evaluation of how UN operations, from building to procurement of goods and services, can respond to the sustainability challenge. It is redundant to say that the UN World Tourism Organization (UNWTO) has developed an information-gathering Web resource consisting of data, studies, policy papers, videos, and other materials, as part of its effort to combat climate change. Although the tourism sector is expected to mitigate and adapt in the face of global warming and to explore and put in place more climate-friendly and climate-proof alternatives, the UNWTO service is a contribution to fostering the knowledge base and search for solutions to meet the climate challenge.

Finally, the UN is the only forum in which an agreement striving to reduce GHG emissions beyond 2012 could practically be brokered among the 190-plus countries with diverse outlooks and economies, but of a common atmosphere. Despite the fact that the warming of the Earth's atmosphere has by this time adversely affected fragile ecosystems and the livelihoods of poor people, this protest at the same time offers manifold alluring prospects for all of its member states.

FUTURE DIRECTIONS

The most recent findings of the IPCC have emphasized that the science on climate change is very clear. The panel report, issued in May 2007, has also unequivocally confirmed the warming of the climate system and linked it directly to human activities. The IPCC has outlined the likely effects of climate change in the near future if the international community fails to act. Although this grave threat is now beginning to receive the high attention it merits, it brings up an underpinning question about how the UN itself will meet this ultimatum, carrying serious implications for our planet and our future generations.

UN Secretary-General Ban Ki-moon, who has identified climate change as one of his top priorities since his

A moment of silence was observed for the victims of the Algiers bombing during the United Nations Climate Change Conference in Bali, Indonesia, December 3–14, 2007. The gathering brought together representatives of over 180 countries.

very first days in office, intends to take a leadership role in supporting efforts by the international community to address the problem by bringing world leaders together and ensuring that all parts of the UN system will contribute to the solution. The UN, as a global forum with broader participation, is best suited to forging a common approach to responding to climate change. Observing the imminence and severity of the problems posed by the accelerating changes in the global climate, the secretary-general has warned that we cannot go on this way for long, and that we cannot continue with business as usual. He also urged us to take joint action on a global scale to address climate change. It is true that there are numerous policy and technological options available to face this impending crisis, but we should have the political will to seize them.

Both developed and developing countries have to be able to reassess the big picture of what is required by identifying the key building blocks for an effective response to climate change. There is a consensus that the response needs to be global, with the involvement of all countries, and that it needs to give equal weight to adaptation and mitigation. The industrialized nations can do much more to reduce GHG emissions and encourage energy efficiency, and they can also support clean development in fast-growing economies and adaptation measures in countries facing the greatest hardships from climate change. In contrast, the developing countries need to be more engaged in addressing climate change while safeguarding their socioeconomic growth and poverty eradication. As for the UN as a whole, it should help the developing economies to finance and deploy energy efficient technologies and incorporate adaptation into the UNFCCC and related environmental organizations.

As an expert scientific panel has recently reported to the UN, to head off the worst of climate change, the governments must pour tens of billions of dollars more than they are into clean-energy research and enforce sharp rollbacks in fossil-fuel emissions. The UN itself must better prepare to help tens of millions of environmental refugees, and authorities everywhere should discourage new building on land less than 1 m. (39 in.) above sea level. The construction of climate-resilient cities may also be championed. The climate-resilient cities are identified as cities that produce low per capita emissions and that can manage weather-related events. Moreover, a climate-resilient city has a reliable supply of potable water, given that water will likely become scarcer as weather patterns change.

The UN is an intergovernmental organization, but it collects its strength and inspiration from the support of civil society worldwide. In fact, there are a number of wonderful illustrations of cohesive ties binding the UN to global civil society. Although these relationships date back to the earliest days of this global forum, they have truly come of age just recently. In spite of the truth that this has been possible because of a deliberate and sustained outreach effort on both parts, it also reflects the substantially expanded role of civil society organizations on the world stage. That is why today's UN relies on its partnership with the nongovernmental organization (NGO) community in virtually everything it does. Some research findings show that the nonstate actor can contribute effectively and efficiently, if it fosters awareness in developing inventive initiatives at the grassroots level, which inspire people to work toward a solution. Thus, one area in which the cooperative partnership between the UN and civil society is increasingly essential relates to the global challenge posed by climate change. Conceding that the NGOs have historically been at the forefront of the struggle to draw attention to the environment, and to push for action to protect it, they may be stimulated to shoulder their redoubled responsibility toward building grassroots support for a breakthrough, as well as common ground for fighting climate change.

Climate change is not just an environmental issue but one that has serious socioeconomic implications as well. Because this advanced issue requires the attention of many sectors such as finance, energy, transport, agriculture, and health, climate change should firmly be positioned in the broader sustainable development agenda. Climate change impinges on all countries, because its aftermaths know no boundaries. Hence, this issue must be addressed in the context of the international development agenda. To be more concrete, the actions on climate change must be integrated into development efforts and scientific research led by various parts of the UN family. This may include work to address investment flows and finance schemes relevant to the development of an effective and appropriate international response to climate change and increased support for adaptation and for involving industry leaders to encourage support from the private sector. In other words, multilateral and bilateral donors, regional development banks, and international investment flows into the developing countries ought to reflect adaptation in their investment decisions.

It is expected that the Bali summit, by building a climate of trust among all governments in that spirit, will determine future action on mitigation, adaptation, the global carbon market, and financing responses to climate change for the period after the expiry of the 166-member Kyoto Protocol, the current global framework for reducing GHG emissions, in 2012.

CONCLUSION

Combating climate change presents a remarkable opportunity to break with the past and to look anew at the way we operate, the way we do business, and the path we use to relate to each other, now and in the future. Nevertheless, as climate change is a global problem, it needs a long-term global solution. The UN's ultimate goal is to make a comprehensive agreement under the UNFCCC process. Such an agreement must tackle climate change on all fronts, including climate adaptation, disaster mitigation, clean technologies, global deforestation, and resource mobilization. The UN should be at the center of brokering a fair, equitable, and decisive climate change regime for the new millennium. Toward confronting the climate change challenge, the UN needs an international collaborative stride made by governments, the private sector, and civil society. If this comprehensive organization succeeds, it will not only change the world but will save humanity. The UN must lead the world to a universal consensus discussion and enroot a strategic policy guideline to be realized over the coming years; the faster we get at it, the easier it is going to be to adapt.

United Nations Development Programme (UNDP)

THE UNITED NATIONS Development Programme (UNDP) is the United Nations' (UN's) global development network that assists developing countries in managing and funding sustainable environmentally sensitive global and national development and, as such, is the world's largest multilateral development source. The UNDP was created (1965–71) by merging the Expanded Programme of Technical Assistance with the UN Special Fund. The UNDP currently works in 166 countries, with the UNDP Resident Representative in each generally serving as the resident coordinator of the UN development activities. The UNDP is an executive board within the UN General Assembly. The UNDP administrator is the third-ranking position in the UN, following the secretary-general and deputy secretary-general. Headquartered in New York City, the UNDP is funded entirely by voluntary contributions from member nations. The UNDP annually publishes local, regional, national, and global Human Development Reports. The UNDP concentrates on five development challenges: democratic governance, poverty reduction, crisis prevention and recovery, energy and environment, and HIV/AIDS.

UNDP GOALS AND INITIATIVES

The umbrella goal of the UNDP is to cut world poverty in half by 2015; that goal is supported by seeking to achieve in the same year eight subsidiary Millennium Development Goals (MDGs), so named because they were derived from the September 2000 UN Millennium Summit. The MDGs are to eradicate extreme poverty and hunger; achieve universal primary education; promote gender equality and empower women; reduce child mortality; improve maternal health; combat HIV/AIDS, malaria, and other diseases; ensure environmental sustainability; and develop the Global Partnership for Development endorsed at the March 2002 International Conference on Financing for Development in Monterrey, Mexico, and reaffirmed in August 2002 at the Johannesburg World Summit on Sustainable Development.

The goal of achieving environmental sustainability is rooted in the idea that developing and impoverished countries are those countries that are most damaged by environmental degradation and by the use of expensive polluting energy sources. The UNDP's goal of ensuring environmental sustainability concentrates on effective water governance, access to sustainable energy services, sustainable land management targeting desertification and land degradation, the conservation and sustainable use of biodiversity, and national/sectoral policies controlling emissions of ozone-depleting substances (ODSs) and persistent organic pollutant (POP) emissions. The UNDP seeks to accomplish these objectives by linking its developing country client states with environmentally sensitive development projects that produce long-term jobs. The UNDP also helps these same countries develop and adopt policies that encourage and sustain these projects and assists in developing other governmental policies and action plans that might positively affect environmental sustainability. The UNDP also helps these countries develop the capacity to manage their environment, energy resource use, and sustainability while reducing poverty, sustaining their advancing development, and integrating the local communities and women into this management.

The UNDP promotes the effective use of the client state's water resources by developing policies and programs integrating the sustainable use of marine, coastal, and freshwater resources; adequate and accessible clean water sources; and the sanitation services necessary to sustain and improve these water resources. The UNDP supports these integrated water resources management programs by initiating and then requiring transboundary waters management within a water governance framework uniting local, national, and regional governmental entities.

The UNDP promotes access to sustainable clean energy services by supporting sustainable and integrated transboundary energy resource development and energy use targeted at reducing the poverty in the client state. The UNDP promotes the use of energy technologies that are climate change neutral or abating. The UNDP facilitates these programs by providing access to funding sources that include, but are not limited to, the Kyoto Protocol's Clean Development Mechanism and the Global Environment Facility (GEF) program. All of the funding sources accessible through the UNDP support projects that mitigate climate change and support indigenous sustainable livelihoods.

The UNDP promotes sustainable land management, contending that land degradation and desertification are two of the major causes of rural poverty in developing countries. The UNDP concentrates on educating and helping its client states and their composite communities maintain the integrity of the indigenous land-based ecosystems by developing or revising land governance policies that protect the land, sustain livelihoods, and mitigate or adapt to climate change. The UNDP also supports the creation of infrastructure projects that prevent or retard land degradation and desertification. These projects are funded for the most part by integrated multistakeholder relationships symbiotically uniting local, national, regional, and global entities.

The UNDP promotes conservation and sustainable biodiversity by helping client states and their composite communities maintain and develop the capacity to manage their indigenous biodiversity and ecosystems. This process not only seeks to sustain the indigenous biodiversity and ecosystems but also seeks to manage them so as to provide more food, fuel, sustainable livelihoods, and medicines in addition to better security and shelter. This process sometimes entails the development of clean water systems, improved disease control, and better preparedness for and reduced vulnerability to natural disasters. The UNDP helps these countries develop and then manage their agriculture, fisheries, forests, and other resources in a pro-poor approach oriented to developing marketable self-sustaining biotechnology.

The UNDP's Montreal Protocol and GEF programs are designed to support the reduction and elimination of ODSs and POP emissions on the national and sectoral levels while maintaining the economic competitiveness of the client states through alternative technologies and increasing indigenous capacity.

United Nations Environment Programme (UNEP)

THE UN ENVIRONMENT Programme (UNEP) coordinates all United Nations (UN) global and regional environmental activities, assists developing countries in implementing environmentally sound policies, encourages sustainable development through sound environmental practices, reviews the status of the global environment, seeks consensus in environmental policy, and alerts the global community and governments of new and emerging threats to the biosphere. The UNEP officially divides its responsibilities into seven divisions: Early Warning and Assessment; Environmental Policy Implementation; Technology, Industry, and Economics; Regional Cooperation; Environmental Law and Conventions; Global Environment Facility Coordination; and Communications and Public Information.

The UNEP grew out of the June 1972 UN Conference on the Human Environment, but its mandates and objectives are derived from UN General Assembly resolution 2997 (27) (December 15, 1972), as amended at the UN's 1992 Conference on Environment and Development, the 1997 Nairobi Declaration on the Role and Mandate of UNEP, and the Malmö Ministerial Declaration of May 31, 2000. The UNEP is headquartered in Gigiri, Nairobi, Kenya, and has six regional offices and a number of country offices all under the governance of UNEP's Governing Council. Fifty-eight member states allocated according to geographical regions and serving three-year terms make up the council. The council has the primary responsibility for the developing UN policies and programs on environmental issues. The council attempts to mediate differences and promote cooperation between UN member states. The UNEP secretariat employs 890 global staff members and is funded by UN member states. The UNEP's executive director, as of June 2006, was Achim Steiner. Steiner was preceded in the position by Dr. Klaus Töpfer, who followed Dr. Mostafa Kamal Tolba, who held the position from 1975 to 1992.

GOALS AND ACTIVITIES OF UNEP

UNEP activities span the spectrum of global environmental issues concerning the atmospheric, marine, and terrestrial ecosystems. The UNEP develops international and regional meetings on environmental issues, promotes a synergy of science and policy on environmental issues, funds and implements development projects related to the environment, works with environmental nongovernmental organizations (NGOs), and is responsible for coordinating and implementing responses to climate change, especially when those changes relate to undeveloped countries with little funding. The UNEP cosponsors and coorganizes regional workshops on the common problems of climate change and possible response strategies in Africa, Latin America, the Caribbean, the Asian-Pacific Basin, and the former Soviet Union.

UNEP also sponsors the development of member state solar loan programs and plays a pivotal role in restoring the Shatt al Arab marshlands that were virtually destroyed by Iraq's Saddam Hussein when the Marsh Arabs sided with Iran in the Iran-Iraq War. The UNEP estimated in 2001 that the marshes were reduced to no more than 386 sq. mi. (1,000 sq. km.). Restoration of the marshlands began in 2003, following the end of organized Iraqi military resistance to the 2003 Anglo-American invasion of Iraq to oust Hussein, and by 2007, the marsh was restored to approximately 50 percent of the area it made up before the Iran-Iraq War. In a similar vein, the UNEP helped/helps create guidelines and treaties relating to transboundary air and water pollution and international trade in harmful chemicals.

The UNEP plays an integral role in creating criteria and indicators for assessing ecological and economic vulnerabilities to climate change and developing regional responses and adaptation. The UNEP is creating a handbook on economical agricultural adaptive strategies to climate change and has published a handbook on climate change communications. The UNEP also plans and implements the Climate Change Outreach Programme, promoting climate change awareness at the national level and assisting governments in developing adaptive response strategies. Its Assessment of Impacts of and Adaptation to Climate Change in Multiple Regions and Sectors project, funded by the Global Environment Facility, seeks to create the scientific and technical capacity in over 45 mostly African countries to respond to climate change.

The discovery of a hole in the ozone layer of the atmosphere in 1985, coupled with the earlier detection of the warming of the Earth (1980), gave impetus to the idea that one of the causes is human-induced climate change (anthropogenic climate change) from man-made, ozone-depleting gases. The United Nations and the World Meteorological Organization (WMO) responded by creating in 1988 the Intergovernmental Panel on Climate Change (IPCC) and tasking it with studying the hypothesized phenomenon on a comprehensive, objective, open, and transparent basis. The IPCC determined that the Earth had warmed over the last 150-year period and that that warming was in part caused by human activity. The executive summary of the report concluded that most of the observed global warming experienced in the last 50 years is a result of the increase in greenhouse gas concentrations. The IPCC and former U.S. vice president Al Gore were jointly awarded the Nobel Peace Prize on October 12, 2007, for their work on global warming.

The UNEP and the WMO provide the joint secretariat support to IPCC. The IPCC does not engage in research. Its assessments are based on peer-reviewed and published scientific/technical literature under guidelines set forth in the Principles Governing IPCC Work. The IPCC has three Working Groups and a Task Force. Working Group I assesses the scientific aspects of the climate system and climate change. Working Group II assesses the vulnerability of socio-economic and natural systems to climate change, negative and positive consequences of climate change, and adaptive strategies. Working Group III assesses options for limiting greenhouse gas emissions and ways of mitigating climate change. The Task Force on National Greenhouse Gas Inventories is responsible for the IPCC National Greenhouse Gas Inventories Programme and developed the methodology for calculating national greenhouse gas inventories.

After the IPCCs Fourth Assessment Report was issued in February 2007, 46 nations, led by France, signed the Paris Call for Action seeking the replacement of the UNEP with a new and more powerful United Nations Environment Organization. The top four greenhouse gas emitters, the United States, China, Russia, and India, did not sign.

United States of America

THE UNITED STATES of America is the world's largest industrialized country and emitter of carbon dioxide. It is therefore widely regarded as the most significant contributor to global warming and climate change. U.S. climate change policies have never remained consistent, as they have tended to shift in accordance with the presidential administration in office. The current administration, led by George W. Bush, has come under particular scrutiny from the media, the scientific community, the general public, and other countries for its climate change policies.

The focus on climate change in the United States became particularly acute in the late 1980s and evolved out of concern about the growing damage to the ozone layer. For two decades, that problem had occupied the attention of scientists and policymakers. In the early 1970s, scientific researchers at the University of California in Irvine established clear evidence that chlorofluorocarbons (CFCs)—chemical compounds made up of fluorine, chlorine, and carbon—were damaging the ozone layer, the thin protective layer above the Earth's atmosphere. The increased solar radiation entering the atmosphere as a result of this damage had the potential to cause health problems such as skin cancers and cataracts. At the time, CFCs were widely used as refrigerants, cleaning solvents, and the basis for aerosol products.

In October 1976, the U.S. Environmental Protection Agency (EPA) prohibited companies from manufacturing CFC-based products unless they were essential and threatened to cancel the product registration of companies that failed to comply. The following year, the agency ordered a gradual phase-out of CFCs from household products such as deodorants, hairsprays, and cleaners. In 1985, the United Nations Environment Programme (UNEP) created a framework convention for the protection of the ozone layer. It encouraged governments to adopt relevant measures to that end, devised a Conference of the Parties composed of governments that had ratified the convention, and appointed a UN secretariat to monitor and frame the actions of the Conference of the Parties. The creation of the framework convention paved the way for international negotiations over the regulation of CFCs. These negotiations, although initially hindered by energy interests in both the European Union (EU) and the United States, ultimately led to the Montreal Protocol of 1988, a worldwide treaty that mandated a staged reduction in the production and consumption of fully halogenated CFCs. The treaty was more lenient toward developing countries, as it gave them a 10-year grace period for the phase-out of CFCs and promised them technological assistance from industrialized nations in return for switching to CFC alternatives. The United States ratified the Montreal Protocol on April 21, 1988, and brought it into effect at the beginning of the following year.

During the next 18 months, the signatories of the Montreal Protocol realized that the original draft of the protocol did not go far enough in controlling CFC emissions. At the second Conference of the Parties in June 1990, delegates placed further restrictions on the production and use of CFCs and further reduced the acceptable level for CFCs in the atmosphere. The fourth Conference of the Parties, which took place two years later, led to further changes. For example, the United States had to limit its production of ozone-depleting substances in accordance with its own Clean Air Act. Over time, the Montreal Protocol virtually eliminated CFC emissions and significantly reduced the threat to the ozone layer. Ultimately, it was the model on which future environmental regulations were based.

INTERNATIONAL FOCUS ON CLIMATE CHANGE

At the same time as ozone depletion was occupying the attention of international policymakers, the issue of planetary climate change was also gaining ascendancy on the world stage. As a phenomenon, climate change was by no means new, having been identified by scientists in the late 1950s. However, in the 1980s, it became the focus of widespread public and political attention. In the summer of 1988, the United States experienced its hottest and driest summer since records began. Fire destroyed millions of acres of forest in western regions of the country, and in the south, barges and small boats became stranded as the Mississippi River began to recede. The Midwest experienced prolonged periods of drought, and across the country crop yields declined severely. On June 23, the temperature in Washington, D.C., reached a record 101 degrees F (38 degrees C).

In response to the extreme weather conditions, Senator Timothy Wirth (D-CO) convened a U.S. Senate hearing on the issue of climate change. Paul Revere, a scientist for NASA, confirmed at the hearing that extra carbon was building in the atmosphere and heating the Earth. His colleague James E. Hansen similarly asserted that the planet was experiencing its highest temperatures of the 20th century. Both men used the phrase "the greenhouse effect" to describe global warming. They also claimed that global warming was occurring as a result of human activity, especially the combustion of fossil fuels such as coal and oil.

Just days after the Senate hearing ended, politicians, officials, and scientists gathered in Toronto, Canada, for an environmental conference. The delegates proposed a 20 percent reduction in global carbon dioxide emissions by 2005, although they based this proposal less on firm economic and scientific analysis than on a desire to show their commitment to solving the climate change problem. Later that year, in December, the UNEP and the World Meteorological Organization jointly created the Intergovernmental Panel on Climate Change (IPCC), an organization designed to bring together climate information from around the world.

THE DIVISIVE ISSUE OF GLOBAL WARMING

At a 1989 summit meeting of the world's seven largest industrial democracies, it was apparent that the EU and United States were becoming increasingly divided over global warming. West European countries thought that the evidence about climate change was irrefutable, whereas George H.W. Bush, the American president, argued that the matter required further research. A number of factors accounted for the disparity between the two sides, particularly the fact that the United States was experiencing higher and faster population growth than Europe, and thus would be more adversely affected by limitations on carbon emissions and fuel consumption. In 1990, the IPCC released its first report, which reflected the general consensus of scientists that global warming was a serious issue.

The 1992 UN Conference on Environment and Development, at Rio de Janeiro in Brazil, represented the first step toward international regulation of climate change. Attended by governments from around the world, the conference resulted in a treaty called the Framework Convention on Climate Change (FCCC), which sought to limit greenhouse gases at a level that would not interfere with the planet's natural climate system. It also established a new Conference of the Parties, a forum in which nations would meet and establish environmental standards. The United States, still under the leadership of George H.W. Bush, promptly ratified and implemented the treaty, as did the majority of governments at the conference. Industrialized countries also used the conference as an opportunity to adopt a program called Agenda 21, which promised development assistance to developing countries on the condition they took steps to adopt more environmentally sound policies.

In January 1993, recently elected U.S. president William J. Clinton assumed control of the White House. The vice president in the new administration, Albert Gore, had published a book the previous year called *Earth in the Balance*, which he hoped would alert the general public to the fragility of the natural environment. On Earth Day in April of that year, Clinton, in adherence with the stipulations laid down in the FCCC, publicly announced that he aimed to reduce carbon dioxide emissions to their 1990 level by the year 2000. He also called for a tax on energy consumption, although strong opposition from the Democratic-controlled Congress thwarted this proposal.

The IPCC released its second report in 1996. The report stated that human activities were having a clear effect on climate change. Although some scientists were still skeptical about the findings, the majority agreed that global warming had become a major problem. In light of the evidence presented in the report, Conference of the Parties delegates sought further preventative measures. At the Second Conference of the Parties in Geneva that year, Timothy Wirth, now undersecretary for global affairs in the Clinton Administration, announced that the United States was willing to limit its greenhouse gas emissions if other countries were prepared to do the same. Delegates at the conference began to draw up a protocol for the framework convention that they could sign at the next Conference of the Parties, scheduled for Kyoto, Japan, in 1997. The most important aspect of the draft protocol was its proposal to reduce carbon emissions to a set level between 2008 and 2012.

As part of his ongoing efforts to underline his commitment to solving the global climate crisis, Clinton gave a speech at a special meeting of the UN in New York in June 1997. He proposed the development of new technology, the introduction of strategies such as emissions trading, and the adoption of measures that would protect the environment without impeding economic growth. He followed up this speech by holding a press conference with Gore at the White House the following month. At the conference, he reiterated his government's commitment to tacking climate change. The U.S. Senate, which had come under Republican control in the midterm elections, was becoming increasingly uneasy at Clinton's rhetoric, and in late July it adopted a resolution that warned the president to exercise caution at the forthcoming Kyoto conference. Known as the Byrd-Hagel Resolution, after its two main sponsors, the resolution advised Clinton not to accept terms that would jeopardize the American economy or place less responsibility for climate change on developing nations. Although opposition in Congress was mounting, Clinton stated at a meeting of the National Geographic Society in October that he supported reducing U.S. emissions to their 1990 level between 2008 and 2012. He neglected to explain, however, that the plan might have negative economic consequences for the United States.

INTERNATIONAL RESPONSES

The third Conference of the Parties took place in Kyoto, Japan, in November 1997 and was attended by 10,000 government officials from across the globe, as well as scores of lobbyists, observers, and media representatives. During the proceedings, the United States reiterated Clinton's plan to reduce carbon dioxide emissions to their 1990 level during the first commitment period, between 2008 and 2012. Most of the European countries felt that this measure was inadequate, and they demanded more substantial action. The dissension between Europe and America thwarted an agreement over emissions policy, and only a last-minute trip to Japan by Gore resulted in a compromise between the two sides. Gore said that the United States would reduce its carbon dioxide emissions to 7 percent below the 1990 level during the first commitment period, scheduled for 2008 to 2012, and the Europeans agreed to cut their emissions to 8 percent below the 1990 level during the same time frame. Overall, the Kyoto text only committed the 38 industrialized countries in attendance at the conference to reducing their emissions. It placed no obligation on developing nations, who argued that a binding emissions treaty would hinder their path to full industrialization.

The treaty, although open for signatures at the end of the conference, was by no means complete. A number of issues remained unresolved, including emissions trading and carbon dioxide sinks. Emissions trading, a policy strongly favored by the United States, would allow countries that had improved on their emissions targets to sell the difference to countries at risk of not meeting their targets. Many European countries were unfamiliar with this policy and were reluctant to adhere to it without full knowledge of its consequences. Australia, Japan, and the United States also advocated that carbon dioxide sinks—reservoirs such as forests and oceans that absorb carbon and prevent it from escaping into the atmosphere—should be included as part of countries' emissions targets. Clinton signed the treaty in 1998 but did not present it to the Senate for ratification.

The sixth Conference of the Parties opened at The Hague in the Netherlands in late November 2000. It was somewhat overshadowed by events in the United States, where the result of the November 7 presidential election was still in dispute because of ongoing recounts in the state of Florida. The key purpose of the conference was to establish the regulations for the implementation of the Kyoto Protocol. For the previous three years, dissension and conflicting interests had prevented the protocol from coming into force. The Umbrella Group—a federation composed of the United States, Australia, Canada, and Japan and supported by energy companies and oil-rich countries such as Kuwait—argued that carbon sinks should be allowed to count as part of countries' reduction targets. The Umbrella Group also hoped to include a provision for emissions trading in the Kyoto regulations.

In its *Third Assessment Report*, published at the beginning of 2001, the IPCC further emphasized the role of humans in the climate change process. Discrediting the idea that global warming stemmed from natural phenomena such as volcanic activity and changes in the sun's radiation, the IPCC argued that the combustion of fossil fuels such as coal, oil, and natural gas was the only reasonable cause of climate change. Moreover, it attributed global warming to an average temperature increase of just 1 degree over the previous century and warned that if fossil fuel consumption continued without restraint, the planet would experience an additional 3 degrees to 10 degrees of warming by the year 2100. The panel was confident, though, that there was still enough time to halt the process of climate change.

U.S. WITHDRAWL FROM THE KYOTO PROTOCOL

The same month the IPCC report was published, George W. Bush entered the White House, and he moved quickly to limit his country's responsibility for reducing carbon dioxide emissions. On March 28, he announced that he was going to withdraw the United States from the Kyoto Protocol. He justified his decision by arguing that the protocol would have a harmful effect on the American economy and that it unfairly placed most of the burden for reducing carbon dioxide emissions on industrialized nations. Dick Cheney, the vice president in the Bush Administration, openly repudiated the protocol. As an alternative, Bush proposed an extensive program of scientific research and technological innovation. To that end, he instructed the National Academy of Sciences (NAS) to carry out an extensive study on the impact of the greenhouse effect. Bush's actions prompted outrage among the signatories of the Kyoto Protocol. Many of the EU member countries said that the United States had no right to reject the validity of the protocol.

The NAS released its findings in May 2001. The report reiterated that climate change was a very real phenomenon, caused predominantly by human actions.

The Intergovernmental Panel on Climate Change warned that if fossil fuel consumption continued without restraint, the planet would experience an additional 3 to 10 degrees of warming by the year 2100.

It concurred that there had been an average temperature increase of 1 degree F during the 20th century, and estimated that temperatures would increase between 2.5–10 degrees F (1.4–5.5 degrees C) during the 21st century. It further predicted that sea levels could rise as much as 3 ft. (1 m.) by 2100, resulting in adverse social consequences such as homelessness, starvation, and growing numbers of environmental refugees. Even in light of clear evidence about the harmful consequences of carbon emissions, the Bush Administration continued to circumvent the issue of climate change.

A NEW U.S. PLAN

The same month as the NAS published its report, Vice President Dick Cheney's energy task force announced a national plan to develop new sources of energy. Cheney publicly announced that the plan would secure America's energy needs for the long-term future, but the plan did not place any emphasis on conserving energy or making energy consumption more efficient. An environmental group later discovered that representatives from the energy industry had exerted a large degree of influence over the task force. A few weeks later, Bush revealed his plans for a U.S. Climate Change Initiative, which would support climate change research and manage the distribution of funding for such research.

An American delegation was present at the seventh Conference of the Parties in Bonn in July 2001, despite the United States' repudiation of the Kyoto treaty. Paula Dobriansky, the head of the delegation, agreed that it would not participate in any discussions pertaining to the treaty. However, the United States still made its presence felt at the conference. Dobriansky announced to a bemused audience that Bush was committed to halting the process of climate change and then went on to reiterate the administration's opposition to the Kyoto Protocol. She said that the United States would only stop other countries from adhering to the protocol if such actions harmed the country's interests. The conference was also notable for the fact that the EU finally consented to the idea of carbon sinks, agreeing to let countries include sinks as part of their carbon reductions. The EU also agreed that there should be no limit on emissions trading. Both provisions were included in the Bonn Agreement, which also stipulated that countries would be responsible for additional emission reductions in the second commitment period if they missed their initial targets.

In 2002, Bush announced that he aimed for an 18 percent reduction in the intensity of greenhouse gas emissions by 2012. He proposed to achieve this through measures such as consumer information campaigns, new mandatory regulations, and partnerships with energy firms. He argued that his plan demonstrated his government's commitment to meet the terms of the United Nations Framework Convention on Climate Change. However, many scientists and politicians pointed out that Bush's plan only sought to reduce the intensity, and not the quantity, of greenhouse gas emissions. The scientific community predicted that if the United States continued to follow the same plan in the coming decades, it could potentially cause greenhouse gas emissions to increase 30 percent above their 1990 level by the year 2030. In addition to that plan, the Bush Administration and the energy industry established a new energy project called FutureGen in 2003. The purpose of the project was to build an advanced facility for generating power through the gasification of coal and the sequestering of carbon emissions. The facility, which is currently under construction, is scheduled to open in 2012.

Although Bush began to acknowledge in 2003 that climate change stemmed from human actions, his initiatives did not extend much beyond those that were already in force. He was reelected in 2004, and by the following year the United States was still heavily reliant on coal-burning power plants for its energy. In 2005, coal-generated energy represented 32 percent of all the energy generated across the country. Around 23 percent of the nation's energy came from natural gas, 18 percent from natural gas and petroleum, and 10 percent from nuclear generation. According to figures compiled by the UN Statistics Division, the United States had the highest level of carbon dioxide emissions in the world in 2004. It emitted the equivalent of 7 billion tons of carbon dioxide, by far the highest rate of any country in the world, and the same amount of greenhouse gases as 2.6 billion people living in 151 developing nations. China, the world's fastest-growing economy, was in second place, having emitted the equivalent of just over 4 billion tons of carbon dioxide. However, the difference in carbon emissions between the two countries was far greater when broken down to an average figure for each member of the population. American emissions amounted to an average of 23.92 tons of emissions per person, whereas China's emissions only averaged out to 3.36 tons of emissions for every member of the population.

Many prominent American environmental groups continued to campaign vigorously for the United States to join the Kyoto Protocol but were hindered by a powerful industrial lobby. However, more than half of the states in the union had started their own initiatives to reduce greenhouse gas emissions. In California in 2003, then-governor Gray Davis stipulated that car manufacturers had to reduce the emissions level of all vehicles sold in the state. The California Air Resources Board established new emissions standards for cars that came into effect at the end of 2005. Davis's successor, Arnold Schwarzenegger, also took a firm stance on the environment.

Despite the Bush Administration's claims that the United States cannot adhere to the Kyoto Protocol, scientific evidence has proven that more restrictive policies on carbon emissions will not have a detrimental effect on American economic growth. During the energy crisis of 1973 to 1986, the country actually improved its energy efficiency: its economy grew by 35 percent, and its energy output remained at a consistent level. Robert Ayers, an ecological pioneer, estimates that 19 of every 20 units of energy in the United States are wasted and advocates capturing those wasted units to cut America's energy consumption.

In recent years, there have been clear indicators about how global warming has been affecting the United States. Eighteen of the warmest years on record occurred between 1980 and 2006; 2005 was officially the hottest year ever recorded. Ten of the 12 strongest hurricanes on record occurred in 2005. Many of those hurricanes had a direct effect on the United States, particularly Hurricane Katrina, which devastated the city of New Orleans and parts of Louisiana and killed hundreds of people. In Montana, the number of glaciers at Glacier National Park is rapidly falling. In 1910, the park had 150 glaciers, and that number is now less than 30.

Evidence about how climate change will affect the United States in the future has been growing. Peer-reviewed data show that the country could lose up to 14,000 sq. mi. (36,260 sq. km.) of territory as a result of global warming. The NAS predicts a 3-ft. (1 m.) rise in sea levels by 2100, and the Environmental Protection Agency estimates that the acreage available for cultivation in Maryland and Pennsylvania could drop as much as 43 percent in the coming decades. Scientists estimate that Glacier National Park's glaciers will have disappeared by 2030. They are also predicting a major reduction in winter snowpack in the Pacific Northwest and Rocky Mountain regions, which would not only harm the economy of those regions by eradicating the conditions necessary for winter sports such as skiing and snowboarding but would also threaten the drinking water supplies, drawn from melting snow, of millions of people. Other possible consequences of global warming for America include higher levels of aridity in the Southwest and Great Plains, increased flooding along major river basins, more wildfires, and the spread of disease and illness. In the past few years, the effect of climate change has become a prominent issue in popular American culture. Both the fictional disaster movie *The Day After Tomorrow* and Gore's documentary *An Inconvenient Truth* graphically depict what will happen to the United States, and other parts of the world, if temperatures continue to rise unabated.

University Corporation for Atmospheric Research

THE UNIVERSITY CORPORATION for Atmospheric Research (UCAR) is a nonprofit institution that has a mission to "support, enhance, and extend the capabilities of the university community, nationally and internationally; understand the behavior of the atmosphere and related systems and the global environment; and foster the transfer of knowledge and technology for the betterment of life on Earth." It was founded in the year 1960 and is based in Boulder, Colorado. The UCAR research lab maintains an affiliated nature preserve.

UCAR collaborates with universities to manage the National Center for Atmospheric Research (NCAR) and the UCAR Office of Programs. The goal of these three organizations is "Understanding our changing Earth system, Educating about the atmosphere and related sciences, Supporting a global community of researchers, and Benefiting society through science and technology."

The establishment of UCAR began in the 1950s, when faculty representatives from 14 universities met to discuss the need for supporting the atmospheric sciences, as well as enhancing the study of these sciences. These faculty members realized the research potential in an institution that could foster collaborations and maintain personnel that one university on its own would not have the resources to do. Thus, the NCAR was founded with support from the U.S. National Science Foundation. UCAR was formally established in 1960 to manage NCAR and foster Earth systems science. Earth systems science investigates not only the atmosphere as an entity but also its relations with the Earth's oceans and lands, as well as with the sun.

The universities and institutions that work with UCAR are member universities, international affiliates, or academic affiliates. Member universities must be North American universities offering doctoral degrees in the atmospheric and related sciences. International affiliates are international universities that grant equivalent degrees, and academic affiliates are North American universities that award predoctoral degrees in similar fields. Some of the member universities include the University of Alaska, Columbia University, Drexel University, the University of Illinois at Urbana-Champaign, the University of Missouri, Old Dominion University, Saint Louis University, and the University of Wyoming. In addition, there are private-sector members who participate in UCAR by funding projects, assisting with technology, collaborating with UCAR research, or acting on UCAR governance boards.

NCAR researchers and technical staff frequently collaborate with the UN Intergovernmental Panel on Climate Change (IPCC) to write or review reports of the latter institution. On October 11, 2007, the Nobel Peace Prize was awarded to former U.S. vice president Al Gore and the IPCC for their work evidencing the human effect on global warming.

Earlier that year, the IPCC had published its fourth periodic assessment of climate change; these assessments began in the year 1991. Assessments take into account numerous pieces of climatological data, analyze past climate patterns, and predict future patterns for local and global environments.

UCAR also manages an Office of Education and Outreach (EO), which communicates with the public, and especially youths, about the necessity and intrigues of working in Earth systems science.

University Corporation for Atmospheric Research Joint Office for Science Support

THE JOINT OFFICE for Science Support (JOSS) of the University Corporation for Atmospheric Research (UCAR) is a group of professional and skilled technical and administrative specialists whose mission is to serve and support the scientific community. JOSS headquarters is located in Boulder, Colorado. The office receives funding from the National Science Foundation and the National Oceanic and Atmospheric Administration (NOAA), as well as from other U.S. agencies, private sources, and international organizations. Before 2005, JOSS was divided into two groups: the Field Operations and Data Management (FODM) group and the Program Support Operations (PSO) group. In 2005, the FODM staff moved to NCAR's Earth Observing Laboratory, and PSO/JOSS remained in UCAR UOP (Office of Programs) and retained the name JOSS. Many of the events sponsored by JOSS have to do with climate change and its effect on human existence. JOSS also collaborated closely with the Global Atmospheric Research Program (GARP) for its alpine (1979) and monsoon (1982) experiments in Switzerland and India, respectively.

JOSS collaborates with scientists and research managers to plan and conduct scientific programs in the most productive and cost-effective ways. JOSS supports planning efforts, research programs, field experiments, and data management activities worldwide. The office offers a wide range of services. It can be a consultant both for individual investigators and for research managers and funding agency officials planning extensive geophysical field experiments and monitoring projects.

JOSS also helps researchers to establish their own network of professional relationships with key people in other institutions and agencies, the U.S. Department of State, and other governments. JOSS aids researchers in planning and conducting meetings, workshops, and conferences. The office has an extensive breadth of knowledge and many years of experience in most regions of the world and advises others about research activities in the United States and elsewhere.

The office team organizes field trips through detailed budgeting, site surveys, and logistical and operational support. It takes care of establishing staff and operations centers for the field project and directs daily operations. JOSS supplies ground support for aircraft, ships, radar, and other observing platforms and systems and hires and trains local workers. On average, JOSS provides various support services for over 475 scientific events and more than 2,500 travelers every year. Supported meeting size has ranged from 12 to 1,200 participants. These international and domestic meetings are relevant to scientists and governmental agencies because they are the initial planning stages of future research or the sharing of information and opinions within the scientific community and government. JOSS-supported meetings have also provided a wide range of topics related to climate change.

For example, JOSS supported a large meeting of Native Americans from across the United States. Representatives from various tribes came together to share their opinions about how climate affects their own lives and how they are adapting their old ways into the modern world with regard to climate issues. JOSS has also supported several large, politically significant meetings in Washington, D.C., designed to help atmospheric scientists share their knowledge, research findings, and predictions with agencies that have the power to influence government decisions.

From 1995 to 2001, JOSS took an active part in the Indian Ocean Experiment (INDOEX). The experiment started from the assumption that regional consequences of global warming depend critically on the potentially large cooling effect of another pollutant, known as aerosols. These aerosols scatter sunlight back to space and cause a regional cooling effect, thus causing uncertainty in predicting future climate. The Indian Ocean Experiment attempted to address the complex influence of aerosol cooling on global warming by collecting in situ data on the regional cooling effect of sulfate and other aerosols.

The project's goal was to study natural and anthropogenic climate forcing by aerosols and feedbacks on regional and global climate. International Global Change Research Program considered this issue to be of critical importance. INDOEX measured long-range transport of air pollution from south and southeast Asia toward the Indian Ocean during the dry monsoon season from January to March 1999. Surprisingly high pollution levels were observed over the entire northern Indian Ocean toward the Intertropical Convergence Zone at about 6 degrees S.

Agricultural burning and especially biofuel use were shown to enhance carbon monoxide concentrations. Fossil fuel combustion and biomass burning caused a high aerosol loading. The growing pollution in the region gave rise to extensive air quality degradation, which, the experiment pointed out, had local, regional, and global implications, including a reduction of the oxidizing power of the atmosphere. JOSS was also involved in GARP experiments, as well as in the establishment of the international research institute on El Niño and its consequences.

JOSS provides administrative, travel, and logistical support for several institutions that operate in the field of climate change and global warming, such as the Intergovernmental Panel on Climate Change, the International Research Institute for Climate and Society, the Office of the U.S. Global Change Research Program, the NOAA Climate Program Office, and the Inter-American Institute for Global Climate Change Studies. It also produces Reports to the Nation on Our Changing Planet, a series of general interest monographs that provide science-based information on issues regarding climate and global change for the general public.

University of Illinois at Urbana-Champaign

University of Alaska

THE UNIVERSITY OF Alaska system has three main campuses (University of Alaska Fairbanks (UAF), University of Alaska Anchorage, and University of Southeast) and 15 satellite campuses. However, beyond individual researchers at various campuses, all four global warming or climate change research centers, institutes, and groups are found at the UAF campus. The four centers are the Alaska Climate Research Center (ACRC), the International Arctic Research Center (IARC), Center for Global Change and Arctic System Research, and the Alaska Center for Climate Assessment and Policy (ACCAP).

Under the direction of the Geophysical Institute, the ACRC conducts secondary data gathering, storage, and report analysis. The ACRC is funded by the State of Alaska under Title 14, Chapter 40, Section 085. The IARC is a joint venture between Japan and the United States. It is an international focused research center that includes 20 research groups and over 60 international scientists. The IARC mission is to determine whether climate change is manmade or natural, what the data points are needed to make this determination, and what the possible effects of climate change are.

In 2007, a national and international controversy sprang out of the IARC when Director Syun-Ichi Akasofu claimed the 2005 peer-review Internatioal Panel on Climate Change (IPCC) report was methodologically flawed. Dr. Akasofu claimed the IPCC did not have an anthropogenic (natural) greenhouse gases control to account for their assertion of a 0.6 degrees man-made climate change over the past 100 years. Professor Akasofu also claimed that CO_2 and other greenhouse gases are not responsible for climate change the researchers would have included anthropogenic greenhouse gases. In a public response to criticism from the academic community, Akasofu noted that, "Since I am not a climatologist, all the data presented in my note are found in papers and books published in the past; that is why I do not want to publish my note as a paper in a professional journal." Although not a climatologist, Akasofu learned speculation on climatology has widely circulated among antiglobal warming groups.

The Center for Global Change and Arctic System Research was founded in 1990 with the goal of fostering interdisciplinary Arctic and sub-Arctic research in Arctic biology, atmospheric chemistry, climatology, engineering, geophysics, hydrology, natural resources management, social sciences, and marine sciences to better understand global change in the Arctic. There are two subgroups and a 1,042-page Arctic research study by the Center for Global Change and Arctic System Research affiliates. One subgroup is the Globe Learning and Observations to Benefit the Environment (GLOBE), founded in 1997. GLOBE is an international group that develops hands-on environmental science curriculum for K–12 students, teachers, and scientists. Another subgroup, founded in 1994, is the University of Alaska-National Oceanic and Atmospheric Administration (UA-NOAA) Cooperative Institute for Arctic Research (CIFAR). CIFAR is one of 13 national university-based NOAA institutes.

It focuses on atmospheric and climate research/modeling. The UA-NOAA studies focus on arctic haze, marine science, fisheries, and sea ice research. The last subgroup is a research study called the Arctic Climate Impact Assessment (ACIA). The ACIA report was prepared for the Fourth Arctic Council Meeting in Reykjavik, Iceland, in November 2004. Some of the findings from the report note that over the past 50 years, the mean surface air temperature has increased 3.6–5.4 degrees F (2–3 degrees C) and late summer ice decreased by 15–20 percent over the past 30 years; in addition, between 1961 and 1998, North American glaciers lost 108 cu. mi. of ice.

The ACCAP was founded in 2006. The ACCAP mission is to determine the biophysical and socioeconomic effect of climate change within Alaska and to improve regional, local, and Alaskan ability to create policies that address the changing climate. The ACCAP works in affiliation with NOAA-Regional Integrated Sciences and Assessments, Institute of Northern Engineering, International Arctic Research Center, the Institute for Socioeconomic Research at the University of Alaska Anchorage, and the Alaska Climate Research Center.

Andrew Hund
University of Alaska, Anchorage

University of Arizona

THE UNIVERSITY OF Arizona (UA or U of A) is a land-grant and space-grant public institution of higher education and research located in Tucson. The University of Arizona was the first university in the state of Arizona, founded in 1885, when Arizona was still a territory. UA includes Arizona's only allopathic medical school. In 2006, total enrollment was 36,805 students. UA embraces its threefold mission of excellence in teaching, research, and public service. Now in its second century of service to the state, UA has become one of the nation's top 20 public research institutions.

The UA graduate school offers several programs of study in atmospheric and environmental science. The Department of Atmospheric Sciences offers programs leading to the master of science and doctoral degrees. Research is conducted through the Institute of Atmospheric Physics in areas such as climate and global change, land-atmosphere interaction, convective processes, atmospheric dynamics, radiative transfer, remote sensing, atmospheric aerosols, atmospheric chemistry, cloud and precipitation physics, lightning, atmospheric electricity, weather forecasting, and numerical weather prediction. The Department of Soil, Water, and Environmental Science (SWES) offers graduate work leading to M.S. and Ph.D. degrees in soil, water, and environmental science. Two tracks are offered, environmental science and soil and water science. In addition to the major, each Ph.D. student must complete a minor, which can be intra- or interdepartmental. Many, if not most, SWES graduate students enroll in several non-SWES courses as part of their program. This reflects the multidisciplinary characteristics of the SWES program in general, and also that a minor is required for all Ph.D. students.

The most frequently studied outside courses are in chemistry, chemical and environmental engineering, hydrology and water resources, and microbiology. With an M.S. or Ph.D. in environmental science, students will be prepared for careers in business and industry, governmental agencies, educational institutions, and private consulting firms. Many Ph.D. students obtain faculty positions at colleges and universities. The Environmental Studies Laboratory was created in 1999 to provide facilities and equipment for the research of past, present, and future environmental variability and change. Current research encompasses paleoclimate studies across the globe, wildfire studies in southwestern North America, and relationships between climate and society across multiple spatial and temporal scales. The laboratory is just one of several complementary investigative groups of environmental and earth system sciences in the Department of Geosciences and at UA. The laboratory is involved in a number of efforts aimed at improving the quality of and participation in K–12 education.

Research carried out by staff and students at the Environmental Studies Laboratory and their forerunners at the University of Colorado and Columbia University has centered around two broad themes. The oldest concentrates on paleoenvironmental science and its application toward understanding the full range of environmental variability, with a focus on climate and ecology. More recently, the laboratory has worked on improving connections between environmental sciences and society, with the specific goal of increasing the scientific basis of environmental decision making. Both themes involve a conscious effort to work across broad temporal scales and over spatial scales that extend from local to global. By working on projects in many key systems around the world, the hope is to craft a better understanding of the global system.

Fernando Herrera
University of California, San Diego

University of Birmingham

THE UNIVERSITY OF Birmingham is an English university in the city of Birmingham. Founded in 1900 as a successor to Mason Science College, with origins dating back to the 1825 Birmingham Medical School, the University of Birmingham was arguably the first so-called red brick university. It currently has over 18,000 undergraduate and over 11,000 postgraduate students. The University of Birmingham has an international reputation for excellence in research and teaching in environmental science, engineering, and policy. There are currently around 150 academic staff actively investigating scientific, technical, and socioeconomic aspects across a broad range of environmental disciplines, including the management of freshwater resources, environmental restoration, sustainable use of natural materials, pollution control, waste management, management of natural hazards, and human health.

The Center for Environmental Research and Training plays a key role in providing a focus for the university's environmental expertise. It acts as a gateway for external organizations, enabling this expertise to be made more widely accessible, and provides a mechanism for the promotion and management of interdisciplinary research within the university. The Institute for Energy Research and Policy, founded in 2005, focuses on research into the economics of energy policy, energy efficiency, wind power, and hydrogen-based energy systems. The Centre for Environmental Research and Training and the School of Geography Earth and Environmental Sciences are internationally recognized in many areas of climate change research. The center seeks to enhance the university's international reputation for environmental research and teaching by advancing partnerships with institutions overseas, such as in Poland, Malaysia, Thailand, and the West Indies.

In October 2006, as part of an ongoing series of initiatives to reduce greenhouse gas emissions from university activities, a new climate change website was launched. The website's purpose was to provide advice and information on the solutions that the university as a whole can provide to the challenge of climate change. In addition, extra effort has been made to implement more energy-efficient practices.

The University of Birmingham is also one of a select group of universities that are committed to carbon management with the Carbon Trust to actively cut their carbon emissions and so minimize the long-term effects of climate change. The Carbon Trust has designed a university-focused program, which will provide technical and change management support to help the sector realize carbon emissions savings. The primary focus of the work is to reduce emissions under the control of the university, such as academic, accommodation, and leisure buildings and vehicle fleets. Practical support will be given in areas such as identifying carbon-saving opportunities, developing an emissions reduction implementation plan, providing analysis software, and offering workshop support for staff and senior management training.

Fernando Herrera
University of California, San Diego

University of California, Berkeley

THE UNIVERSITY OF California, Berkeley, is the premier public research university in the United States, with 97 percent of its academic programs being among the top 10 in the country. Commonly referred to as UC Berkeley, Berkeley, and Cal, the university's academic excellence is sustained by a $2.46 billion endowment. Berkeley was founded in 1868 and is the oldest of the 10 University of California campuses. During the 1930s, the leadership of university president Robert Sproul helped Berkeley to establish itself as a leading research university, and by 1942 the American Council on Education ranked Berkeley second only to Harvard in the number of distinguished academic departments. A reorganization of the University of California system in 1952 resulted in the naming of Clark Kerr as the first chancellor for the Berkeley campus. Since then, there have been nine other chancellors; the current chancellor is Robert Birgeneau, who has filled this role since 2004.

Berkeley is a comprehensive university offering over 7,000 courses in 130-plus academic departments organized into 14 colleges and schools, offering nearly 300 degree programs. The university awards over 5,500 bachelor's degrees, 2,000 master's degrees, 900 doctorates, and 200 law degrees each year. With 33,558 students and 1,950 faculty, the student-faculty ratio is 17 to 1—among the lowest of any major university. Berkeley is the most selective school in the UC system and is one of the most selective universities in the country. For the 2006–07 academic year, 4,157 freshmen matriculated at Berkeley, from an applicant pool of just under 41,750 applicants. Graduate admissions vary by department, although in 2006 the university's doctoral programs admitted 1,058 students from a pool of 14,263 applicants.

Collectively, Berkeley's 32 libraries tie with University of Illinois for the fourth largest academic library system in the United States, surpassed only by the U.S. Library of Congress, Harvard, and Yale. In 2003, the Association of Research Libraries ranked Berkeley as the top public university library in North America and third among all universities. As of 2006, Berkeley's library system contains over 10 million volumes and maintains over 70,000 serial titles.

The scholarly achievements and excellence of the faculty and alumni have helped to build and maintain

Berkeley's excellent reputation. Berkeley scientists invented the cyclotron, discovered the antiproton, isolated the polio virus, created the Unix computer operating system, and discovered numerous transuranic elements including seaborgium, plutonium, berkelium, lawrencium, and californium. During World War II, Ernest Orlando Lawrence's Radiation Laboratory at Berkeley contracted with the U.S. Army to develop the atomic bomb, and Berkeley physics professor J. Robert Oppenheimer was named scientific head of the Manhattan Project in 1942. Berkeley faculty have a no less distinguished record in fields outside the physical sciences: they include 221 American Academy of Arts and Sciences Fellows, 83 Fulbright Scholars, 28 MacArthur Fellowships, 384 Guggenheim Fellows, 87 members of the National Academy of Engineering, 132 members of the National Academy of Sciences, 3 Pulitzer Prize winners, and 92 Sloan Fellows. Berkeley counts 61 Nobel laureates among its faculty, researchers, and alumni—the sixth most of any university in the world; 20 have served on its faculty.

Berkeley's reputation for student activism was forged in the 1960s. With the end of World War II and the subsequent rise of student activism, the California Board of Regents succumbed to pressure from the student government and ended compulsory military training at Berkeley in 1962. Then, in 1964, an impromptu response by students to the university's ban on campus political activity led to the beginning of the Free Speech Movement and, ultimately, the freedom of expression by students. This movement grew during the protests against U.S. involvement in the Vietnam War during the 1960s and early 1970s. Today Berkeley has over 700 established student groups, nearly 100 of which are political. There is also a strong sense of public service among Berkeley graduates. For example, Berkeley sends the most students to the U.S. Peace Corps of any university in the nation.

As part of its academic excellence, Berkeley is also a leader in environmental research. There are over 100 individual undergraduate and graduate programs at Berkeley that focus on the environment, in addition to dozens of top research centers. The university is also active in research concerning global warming and climate change, with several centers involved in research and advocacy on these and related issues. For example, the University of California Climate Change Center was established in 2003 by the California Energy Commission to undertake a broad program of scientific and economic research on climate change in California. The center has sites at both the Berkeley and San Diego campuses of UC. The Berkeley center, based at the Goldman School of Public Policy, focuses on economic and policy analysis, whereas the site in San Diego (at the Scripps Institute of Oceanography) focuses on physical climate modeling. Several other departments on the Berkeley campus are involved in the work of the center including the Department of Agricultural and Resource Economics, the Department of City and Regional Planning, the Department of Civil and Environmental Engineering, the Graduate Group in Energy and Resources (ERG), and the Environmental Energy Technologies Division of the Lawrence Berkeley National Laboratory.

The ERG is an interdisciplinary academic unit of the Berkeley campus that was created in 1973 to develop, transmit, and apply critical knowledge to enable a future in which human material needs and a healthy environment are mutually and sustainably satisfied. ERG conducts programs that include graduate teaching and research on issues of energy, resources, development, human and biological diversity, environmental justice, governance, global climate change, and new approaches to thinking about economics and consumption. The University of California Energy Institute (UCEI) is a multicampus research unit of the University of California system begun in 1980, whose mission has been to foster research and educate students and policymakers on energy issues. The Center for Global Metropolitan Studies (GMS) is a campus initiative to foster interdisciplinary collaboration to investigate and address problems and opportunities posed by global metropolitan growth and change through research. The Berkeley Institute of the Environment (BIE) was established in 2005 and brings together and helps enhance diverse campus programs and research units by making research tools and understanding accessible across disciplinary lines to address complex environmental problems, while fostering collaboration and thinking about critical environmental problems. The Institute of Transportation Studies (ITS) is one of the world's leading centers for transportation research, education, and scholarship. Research areas include transportation sustainability, future urban transit systems, and environmental effects. The UC Berkeley Transportation Sustainability Research Center (TSRC) was formed in 2006 to combine the research forces of the five aforementioned centers, institutes, and groups (ERG, UCEI, GMS, BIE, and ITS). The TSRC is a multicampus unit that supports research, education, and outreach.

Other campus activities related to global warming include the research and advocacy work of the College of Engineering. For example, on August 2, 2007, the college released a blueprint for fighting global warming by reducing the amount of carbon emitted when transportation fuels are used in California. This low-carbon fuel standard is designed to stimulate improvements in transportation fuel technologies and is expected to become the foundation for similar initiatives in other states, as well as nationally and internationally.

There is also a Chancellor's Advisory Committee on Sustainability that promotes environmental management and sustainable development on the Berkeley campus. The mission of the committee is to engage the campus in an ongoing dialogue about reaching environmental sustainability and to integrate environmental sustainability with existing campus programs in education, research, operations, and public service. The committee is charged with advising the chancellor on matters pertaining to the environment and sustainability as it directly relates to the university.

Berkeley's tradition of student political action has also merged with global climatic change issues. For example, in March 2007, students organized the California Campus Climate Challenge Summit to learn about global warming, climate change, and methods for influencing policy change via student activism. Such activities also highlight the social justice aspects of issues concerning global warming and the desire by some to create an environmental and social movement to help raise awareness about this issue. Also, Berkeley alumna Sissel Waage has just coedited a book to address issues of climate change and global warming. The book features a wide array of authors ranging from activists to scholars to students, who each discuss what the average person can do to turn their private concerns into public action.

University of Cambridge

THE UNIVERSITY OF Cambridge (Cambridge University), located in Cambridge, England, is the second-oldest university in the English-speaking world and has a reputation as one of the world's most prestigious universities. The university grew out of an association of scholars in the city of Cambridge that was formed in 1209 by scholars leaving Oxford after a dispute with the townsfolk there. The universities of Oxford and Cambridge are often jointly referred to as Oxbridge. In addition to their cultural and practical associations as a historic part of English society, the two universities also have a long history of rivalry with each other. The University of Cambridge currently has 31 colleges, of which three admit only women (New Hall, Newnham, and Lucy Cavendish). The remaining 28 are mixed, with Magdalene being the last all-male college to begin admitting women, in 1988. Two colleges admit only postgraduates (Clare Hall and Darwin), and four more admit mainly mature students or graduate students (Hughes Hall, Lucy Cavendish, St. Edmund's, and Wolfson).

The other 25 colleges admit mainly undergraduate students but also allow postgraduates following courses of study or research. Although various colleges are traditionally strong in a particular subject, for example, Churchill has a formalized bias toward the sciences and engineering, the colleges all admit students from just about the whole range of subjects, although some colleges do not take students for a handful of subjects such as architecture or history of art. It is noteworthy that costs to students (accommodation and food prices) vary considerably from college to college. This may be of increasing significance to potential applicants as government grants decline in the next few years.

The Department of Land Economy offers a three-year honors undergraduate degree program, as well as postgraduate studies in environmental policy. The main focus of the program is land and environmental protection. Up to 40 students are admitted each year. The University of Cambridge offers a variety of taught courses relating to the environment, whether as part of an undergraduate degree course or a postgraduate course. Climate change research at the University of Cambridge ranges from long-term climate modeling using geological data to in situ measurements of the present composition of the Earth's atmosphere, at all scales from global climate models to study of the dynamic chemical processes controlling the present state of the atmosphere. Significant expertise in atmospheric sciences and earth sciences provides a strong foundation for research into limiting the effects of human activity on the Earth's climate, mitigating the effects of climate change, assessing the effects of climate change on human health, and designing economic policies and technologies for climate change mitigation.

The Cambridge Environmental Initiative was launched in December 2004. The primary mission of this initiative is to facilitate and support interdisciplinary environmental research within the University of Cambridge, promote the university's external profile in environmental research, and encourage new environmental research initiatives within the university.

The Cambridge Center for Climate Change Mitigation Research is an interdisciplinary research center, focusing on climate change mitigation at the local and global levels. The main objective of this collaboration is to foresee strategies, policies, and processes to mitigate human-induced climate change, which are effective, efficient, and equitable, including understanding and modeling transitions to low-carbon energy-environment-economy systems. The center houses global, European, and U.K. research teams adopting a common set of conventions and protocols that are networked with multidisciplinary teams working in different countries.

In March 2007, former U.S. vice president Al Gore delivered a climate change training program to 200 of the United Kingdom's top leaders from business, government, media, education, and civil society. The program brought together leaders committed to communicating and taking action on climate change across the United Kingdom and internationally. The program, hosted by the University of Cambridge, was designed to help trainees understand the issues and think critically about solutions and actions required to address climate change issues.

Fernando Herrera
University of California, San Diego

University of Colorado

THE UNIVERSITY OF Colorado at Boulder (CU) is the flagship university of the University of Colorado system. CU has produced a number of astronauts, Nobel laureates, Pulitzer Prize winners, and other notable individuals in their fields.

The Department of Atmospheric and Oceanic Sciences (ATOC) is an interdisciplinary program that provides an educational and research environment to examine the dynamic, physical, and chemical processes that occur in the atmosphere and the ocean. A major theme is the establishment of a physical basis for understanding, observing, and modeling climate and global change. At the undergraduate level, approximately 2,000 students are pursuing baccalaureate degrees in environmental studies, environmental biology, environmental engineering, environmental law, geological sciences, geography, environmental policy, and other subjects. Several hundred graduate students are also pursuing advanced degrees involving research on environmental topics at CU.

ATOC is coordinated with the environmental program at the University of Colorado. Interdisciplinary education and research opportunities exist with the hydrology program and the environmental policy program. Interdisciplinary research opportunities also exist with the Cooperative Institute for Environmental Studies, the Institute for Arctic and

Alpine Research, the Center for Complexity, and the Laboratory for Atmospheric and Space Physics. Graduate students, research staff, and faculty work together on a wide range of research projects. ATOC has extensive computer facilities and laboratories in remote sensing, chemistry, and hydrodynamics. The presence of leading laboratories in the environmental sciences in Boulder, including the National Center for Atmospheric Research and the National Oceanic and Atmospheric Administration Environmental Research Laboratories, provides additional opportunities for a rich educational experience.

Climate research at the University of Colorado is driven by the goals and broad objectives that have been articulated by the World Climate Research Program and the U.S. Global Change Research Program, which are to develop the fundamental scientific understanding of the climate system and climate processes that is needed to determine to which extent climate can be predicted, as well as the extent of man's influence on climate. The program encompasses studies of the global atmosphere, oceans, sea and land ice, and the land surface, as well as their coupling. To achieve these goals, climate research at the University of Colorado plans to design and implement observational and diagnostic research activities that will lead to a quantitative understanding of significant climate processes, including the transport and storage of heat by the ocean; the exchange of heat, moisture, and momentum between atmosphere, ocean, and sea ice; and the interaction among cloudiness, radiation, the land surface, and the global hydrological cycle. Research in global and regional models capable of simulating the present climate and, to the extent possible, of predicting climate variations on a wide range of space and timescales are also being actively pursued.

CU is known internationally for its interdisciplinary research on a variety of global change issues. Working closely with Boulder-based federal research laboratories, CU research centers such as the Cooperative Institute for Research in the Environmental Sciences, the Institute for Arctic and Alpine Research, and the Laboratory for Atmospheric and Space Physics have successfully brought together a variety of academic

The University of Colorado at Boulder was founded in 1876 at the base of the Rocky Mountains. The natural beauty of the area draws many students interested in pursuing degrees in environmental studies and policies.

disciplines to work on global change issues, which cross traditional disciplinary and departmental lines. On the policy side, the Natural Resources Law Center and the Environmental Policy Program have brought together lawyers, economists, historians, and political scientists to study global change and other environmental issues. Unique interdisciplinary education programs in climate change are being developed at the University of Colorado through a partnership of the Department of Atmospheric and Oceanic Sciences and the Environmental Studies Program, overcoming the disciplinary and departmental barriers that exist in many university programs.

The program at the University of Colorado proves a unique combination of disciplinary depth and inter- and multidisciplinary breadth necessary for students who plan to work in this area. Current research topics include El Niño and tropical climate variability, polar climate; polar regional climate modeling, World Data Center for Glaciology, Institute for Arctic and Alpine Research, Program in Arctic Regional Climate Assessment, sea ice remote sensing, sea ice modeling, land/atmosphere interactions, land surface model, boreal forest dynamics model, Land-Atmosphere CO_2 exchange, paleoclimate, Past Global Change Group/Institute for Arctic and Alpine Research, impact of clouds and aerosols on climate, aerosol modeling research group home pages, and global climate modeling.

Fernando Herrera
University of California, San Diego

University of Delaware

THE UNIVERSITY OF Delaware (UD) is the largest university in Delaware. The main campus is located in Newark, with satellite campuses in Dover, Wilmington, Lewes, and Georgetown. Approximately 16,000 undergraduate and 3,000 graduate students attend this university annually. Although UD receives public funding for being a land-grant, sea-grant, space-grant, and urban-grant state-supported research institution, it is also privately chartered. The university's endowment is currently valued at about $1.2 billion. In 2007, UD was ranked 15th nationally in *Kiplinger's Personal Finance* magazine list of the 100 best public institutions of higher education. The University of Delaware was also ranked 15th best value for in-state students and 10th best value for out-of-state students. Seven academic colleges confer degrees at UD.

The College of Marine and Earth Studies is one of the seven colleges at UD. The undergraduate component of the college is currently housed within the Department of Geological Sciences, where students can major in earth science education or geology. Geology majors can undertake concentrations in paleobiology or coastal and marine geoscience. Students may also major in environmental science, collaboration between the Departments of Geological Sciences, Geography, and Biological Sciences. Environmental science majors can select several concentrations including the geological environment or the marine environment. There are also marine studies courses that are open to undergraduate students. These range from introductory classes for nonscience majors to advanced programs for science and engineering majors. The college offers graduate programs (master's and doctoral degrees) in geology, oceanography, and marine studies. The College of Marine and Earth Studies brings the latest advances in technology to bear on ocean, Earth, and atmospheric research, as well as on teaching.

Graduate study in climatology involves exposure to a wide range of research methods that can be used to help solve climate-related environmental problems. Faculty and graduate student research interests span the range of climatology and include climatic modeling, synoptic climatology, atmospheric dynamics, climate dynamics, physical climatology, water-budget climatology, paleoclimatology, climatic geomorphology, glaciology, global climate change, human effects on climate, and climatic influences on society, particularly on human health and socioeconomic activity.

Climatology courses offered at UD include Geography 612: Physical Climatology, Geography 620:

Atmospheric Physics, Geography 623: Atmospheric Dynamics, Geography 651: Microclimatology, Geography 652: Seminar in Climatology, Geography 653: Synoptic Climatology, Geography 655: Water Budget in Environmental Analysis, Geography 657: Climate Dynamics, Geography 681: Remote Sensing of Environment, Marine Studies 809: The Ocean and Climate Variation, and Geography 855: Climatological Research.

University of California, San Diego

University of East Anglia

THE UNIVERSITY OF East Anglia (UEA) is a leading campus university located in Norwich, England. It was founded as part of the British government's New Universities Program in the 1960s. The university is a member of the 1994 group of leading research-intensive universities. Academically, it is one of the most successful universities founded in the 1960s, consistently ranking among Britain's top higher-education institutions. It was 19th in the Sunday Times University League Table 2006, and joint first for student satisfaction among mainstream English universities in the 2006 National Student Survey. Furthermore, the university was ranked 57th in Europe and one of the top 200 universities in the world in the 2006 World University Rankings undertaken by the Shanghai Jiao Tong University.

The School of Environmental Sciences is one of the longest-established, largest, and most fully developed Schools of Environmental Sciences in Europe. The School of Environmental Sciences offers undergraduate and graduate degree programs with an emphasis in a number of studies. The school is also engaged in research in a number of areas from atmospheric sciences to marine sciences. The school has been ranked high in research and teaching.

The Climatic Research Unit (CRU) is widely recognized as one of the world's leading institutions concerned with the study of natural and anthropogenic climate change.The unit consists of a staff of around 30 research scientists and students and has developed a number of the data sets widely used in climate research, including the global temperature record used to monitor the state of the climate system, as well as statistical software packages and climate models. The aim of the Climatic Research Unit is to improve scientific understanding in three areas: past climate history and its effect on humanity, course and causes of climate change during the present century, and prospects for the future.

The Climatic Research Unit is part of the School of Environmental Sciences, with close links to other research groups within the department, such as the Centre for Social and Economic Research on the Global Environment. The unit undertakes collaborative research with institutes throughout the world on a diverse range of topics and is coordinating or contributing to a number of networking activities. The CRU participates in both pure and applied research, sponsored almost entirely by external contracts and grants from academic funding councils, government departments, intergovernmental agencies, charitable foundations, nongovernmental organizations, commerce, and industry. Alongside its research activities, the unit has an educational role through its contribution to formal teaching with the School of Environmental Sciences (most notably, the M.Sc. in climate change) and various forms of in-service training, including postgraduate education. It is regarded as an authoritative source of information on both the science and policy aspects of climate change by the media and maintains a high public profile. The unit staff have published many peer-reviewed articles as well as editing various scientific journals, newsletters, and bulletins.

University of California, San Diego

University of Florida

ORIGINALLY FOUNDED IN 1853 as the East Florida Seminary, the institution later renamed the University of Florida (UF) moved to its current location in Gainesville in 1906. The largest and oldest university in the state, UF resides on 2,000 acres and provides educational opportunities for over 46,000 students. As the flagship institution of higher learning in the state, UF has acted as a steward in addressing global warming and climate change issues through its sustainability initiatives.

In 1994, UF president Charles Young signed the Talloires Declaration in an effort to convey support for actions to reduce environmental degradation and the depletion of natural resources. Three years later, members of the UF community initiated a grassroots campaign called Greening UF to engender a sense of environmental stewardship on campus. During 2000, the need for an administrative presence to develop sustainability initiatives was realized in the creation of an Office of Sustainability, housed within the College of Design, Construction, and Planning. In 2001, UF took another step along the path to greater campus sustainability by mandating that Leadership in Energy and Environmental Design (LEED) criteria be followed on all new building and renovation endeavors. UF's own Rinker Hall became the first building in the state of Florida to earn LEED Gold certification in 2004 and the newly renovated Library West achieved Gold status in 2007.

The call for a campus-wide Office of Sustainability was made by the Student Senate in 2004, and in fall 2005, a national search was initiated for a director of a centralized Office of Sustainability. The search for a director of the Office of Sustainability concluded in 2006 with the hiring of Dedee DeLongpré, a former development director for schools in California and program administrator for Fauna and Flora International. UF galvanized support for statewide sustainable action by hosting the inaugural Florida Campus and Community Sustainability Conference in October 2006.

Though UF began supporting major environmental initiatives over a decade ago, much of the university's recent push to enhance its stewardship has taken place during the tenure of President Bernie Machen (2004–present). In 2005, UF became the first university to be recognized as a Certified Audubon Cooperative Society. Speaking of this accomplishment and of sustainability during National Campus Sustainability Day on October 25, 2005, President Machen described the challenges and opportunities that the university has faced. President Machen espoused a full-spectrum approach to increasing sustainability by addressing the university's effect on the environment through green building, decreasing energy dependence, and reducing waste disposal to zero by 2015.

A year later, at the Florida Campus and Community Sustainability Conference, President Machen took on a much more direct tone regarding the issue of climate change, which he declared to be an urgent problem. In his speech, he described how UF would tailor its sustainability goals for 2007 specifically to decrease the university's emissions to combat climate change. President Machen outlined the progress made toward this end and also described new programs that UF would implement. As an academic institution, UF has already made strides to integrate sustainability into the classroom, as evidenced by the over 100 courses, 10 programs, and over 20 research entities relating to sustainability that are offered by the university.

In terms of engaging climate change from a supply chain perspective, President Machen talked of UF's effort to reduce emissions by buying locally produced food for use in dorm cafeterias and by implementing a sustainable purchasing policy. President Machen also detailed the university's energy-reduction strategy, which involves using power produced by renewable sources, turning down heat and lights in many campus buildings during vacation breaks, and purchasing more fuel-efficient fleet vehicles. Following the announcement of these environmental actions, President Machen reinforced UF's dedication to addressing climate change by being the first to sign the American College and University Presidents Climate Commitment at the end of 2006.

Through its multifaceted sustainability initiatives and commitment to emissions and energy reductions at all levels, UF has emerged as an environmental steward in the state of Florida and among universities across the United States. With the aid of strong administrative backing and the support of an environmentally conscious student body and faculty, UF provides a prime example of how a large educational institution can foster widespread social responsibility while minimizing its own negative effect on the environment.

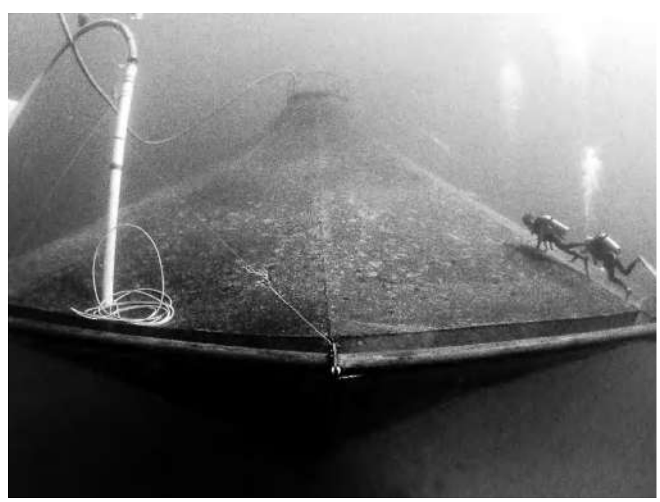
University of Hawaii

THE UNIVERSITY OF Hawaii, also known as UH, is a public, coeducational college and university system that confers associate, bachelor's, master's, doctoral, and postdoctoral degrees through three university campuses, seven community college campuses, an employment training center, three university centers, four education centers, and various other research facilities distributed across six islands throughout the state of Hawaii. All schools of the UH system are accredited by the Western Association of Schools and Colleges. UH at Manoa is the flagship institution of the system. It is well respected for its programs in Hawaiian/Pacific studies, astronomy, east asian languages and literature, asian studies, second language studies, linguistics, ethnomusicology, medicine, and law. UH education centers are located in more remote areas of the state, supporting rural communities via distance education.

A total of 616 programs are offered throughout the UH system, with 123 devoted to bachelor's degrees, 92 to master's degrees, 53 to doctoral degrees, three to first professional degrees, four to postbaccalaureate degrees, 115 to associate's degrees, and various other certifications. The Department of Oceanography offers a bachelor's degree program in global environmental science. This program emphasizes the study of Earth and Earth's physical, chemical, biological, and human systems. Students learn to investigate natural as well as economic, policy, and social systems and their response to and interaction with the Earth system.

The School of Ocean and Earth Science and Technology (SOEST) was established by the Board of Regents of UH in 1988 in recognition of the need to realign and further strengthen the excellent education and research resources available within the university. SOEST brings together four academic departments, three research institutes, several federal cooperative programs, and support facilities of the highest quality in the nation to meet challenges in the ocean, Earth, and planetary sciences and technologies.

The Hawaii Natural Energy Institute (HNEI), located on the campus of UH, is a one of the many research institutes housed by the SOEST. HNEI has become an acknowledged international leader in the energy field and has broadened its expertise to encompass the development of technologies that will enable us to tap our oceans for energy, food, minerals, and other resources. The institute's responsibilities include conducting and supporting basic research, managing research facilities and laboratories, demonstrating the applications of its work, and investigating the social, environmental, and financial effect of energy- and marine-related activities. Researchers at HNEI have a long history of investigating technology solutions, such as renewable energy systems and carbon sequestration, to reduce greenhouse gas emissions. Since 1989, HNEI has been a major participant in an international effort to study the feasibility of sequestering carbon dioxide in the deep ocean. Laboratory studies conducted in a novel large deep ocean



Divers clean the outside of SeaStation 3000, an open-ocean aquaculture project operated by the University of Hawaii.

simulator designed and built by HNEI have provided extensive data on the breakup of liquid carbon dioxide jets and fundamental information on carbon dioxide hydrate formation. HNEI cooperates in these endeavors with faculty from UH; federal, state, and local governments; private industry; public utilities; foreign governments; community groups; and universities and research institutes throughout the world.

The International Pacific Research Center is a climate research center housed by SOEST. This center was founded to gain greater understanding of nature and the causes of climate variation in the Asia-Pacific region, to determine whether such variations are predictable and to discover how global climate change affects the region.

SEE ALSO: Hawaii; National Science Foundation; Pacific Ocean.

Fernando Herrera
University of California, San Diego

University of Illinois

THE UNIVERSITY OF Illinois is a system of public universities. It consists of three campuses: Urbana-Champaign, Chicago, and Springfield. The governing body of the three campuses is the board of trustees. The campus at Urbana-Champaign is known as the U of I and UIUC, whereas the Chicago campus is known as UIC, and the Springfield campus UIS. The largest university in the Chicago area, UIC has 25,000 students, 15 colleges, including the nation's largest medical school, and annual research expenditures exceeding $290 million. Playing a critical role in Illinois healthcare, UIC operates the state's major public medical center and serves as the principal educator of Illinois' physicians, dentists, pharmacists, nurses, and other healthcare professionals.

The modern UIC was formed in 1982 by the consolidation of two University of Illinois campuses: the Medical Center campus, which dates back to the 19th century, and the comprehensive Chicago Circle campus, which in 1965 replaced the two-year undergraduate Navy Pier campus designated to educate returning veterans. UIC's student body is recognized as one of the nation's most diverse, and the students reflect the global character of Chicago.

The School of Earth, Society, and Environment brings the resources of the Departments of Atmospheric Science, Geology, and Geography at the University of Illinois together to study Earth systems. The school awards bachelor of science degrees in atmospheric science, geography, and geology, as well as in the interdisciplinary major Earth Systems, Environment, and Society (ESES). The school also actively pursues advanced research and programs of graduate studies. At the Department of Atmospheric Sciences, students can pursue master of science (M.S.), and doctor of philosophy (Ph.D.) degrees. The University of Illinois is deeply involved in climate research at many levels, both within the department and in interdisciplinary research across the campus.

Faculty and students in the department carry out a number of research projects directed toward understanding climate variability and climate change. Students work with professors to conduct research to help explain the interactions between climate and the biosphere, ocean, and human activities, as humans alter the cycles of greenhouse gases such as carbon and methane. Students use global climate models to make projections of future changes under various plausible economic scenarios and simulate important geophysical processes, such as the past, present, and possible future behavior of the Atlantic thermohaline circulation.

Students also conduct research on how energy, water, and carbon are transported between the land surface and the atmosphere in systems ranging from agroecosystems to rainforests. Quantifying and understanding the causes of climate change is one of the greatest challenges of our time. The ESES major is an academic, liberal arts, and sciences degree. Students interested in a getting a more applied degree might be interested in the College of Agricultural, Consumer, and Environmental Sciences Natural Resources and Environmental Sciences (NRES) program, which offers a wide range of NRES and horticulture courses, from plant propagation to wildlife ecology.

Courses offered by UIC in the area of climate change include: ATMS 447: Climate Change Assessment, ATMS 448: Climate and Climate Change, ATMS 300: Weather Processes, ATMS 401: Atmospheric Physics, ATMS 402: Principles of Atmospheric Dynamics, ATMS 403: Weather Forecasting, ATMS 449: Biogeochemical Cycles and Global Change, ATMS 491: Topics in Atmospheric Sciences, GEOG 415: Physical Climatology, and IB 440: Plants and Global Change.

University of California, San Diego

University of Kentucky

THE UNIVERSITY OF Kentucky, also referred to as UK, is a public, coeducational university located in Lexington. Founded in 1865, the university is the largest in the commonwealth by enrollment, with 27,209 students. The university as a whole has been ranked the 19th-best public research university based on the scholarly activity of faculty. The university features 16 colleges, a graduate school, 93 undergraduate programs, 99 master's degrees, 66 programs in Ph.D.s and other doctoral degrees, and four professional programs.

The Department of Earth and Environmental Sciences at UK offers B.S., B.A., M.S., and Ph.D. degrees in geology, a minor in geology, and administers a topical major (B.S.) in environmental sciences. The department currently includes 10 regular faculty members, one lecturer, and 14 other faculty members who hold adjunct appointments. Approximately 40 graduate students and 35 undergraduates are enrolled annually. The study of environmental issues such as groundwater quality, waste disposal associated with the extraction of Earth resources, and climate change require understanding and application of several disciplines, including the fields of geology, chemistry, biology, agronomy, hydrology, and engineering. An environmental scientist must have a diverse background in all the natural sciences to develop creative solutions to environmental problems. The topical major in environmental sciences is intended to provide the breadth of scientific training needed to develop such solutions. At the same time, it provides flexibility for the student and adviser to build a curriculum tailored to the student's specific interests.

Courses with environmental applications offered at UK include: GEO 251: Weather and Climate, GLY 585: Hydrogeology, NRC 301: Resource Management and Conservation, NRC 359: Global Positioning Systems, NRC450G: Biogeochemistry, NRC 555 GIS: and Landscape Analysis, and PLS 366: Fundamentals of Soil Science.

Research within the Department of Earth and Environmental Sciences is funded by grants and contracts from the National Science Foundation, the Department of Energy, the PRF, and other federal, state, and industrial sources. Areas of graduate research include tectonics, hydrogeology, sedimentary geology, geochemistry, petrology, geophysics, and coal geology.

University of Leeds

THE UNIVERSITY OF Leeds is a major teaching and research university in Leeds, West Yorkshire. Leeds is a leading research institution and one of the largest in the United Kingdom with over 32,000 full-time students. Established in 1904, it is one of the six original civic universities, and in 2006 it was ranked second for the number of applications received. Leeds is now among the top 10 universities for research in the United Kingdom and is internationally acknowledged as a center of excellence in a wide range of academic and professional disciplines. Many of its research initiatives cross traditional subject boundaries, and Leeds currently promotes projects through 58 interdisciplinary centers and seven research schools. The university recognizes the importance of the environment and has established policies and programs to tackle environmental issues at a local and global level. Business in the Environment has ranked the University of Leeds as the top university in the region for environmental management and performance. The university also won the 2006 Green Gown Award for Waste Management and the 2007 Award for Continuous Improvement.

The School of Earth and Environment was formed in 2004 from the merger of the previous schools of Earth Sciences and of Environment. The school currently has over 60 academic staff, 35 support staff, and over 50 postdoctoral research fellows and associates. It is one of the largest schools in the United Kingdom that focuses on a multidisciplinary approach to understanding environment: the school studies the Earth from its core to its atmosphere and examines the social and economic dimensions of sustainability. The school offers both three-year BSc and four-year undergraduate degrees in geological, geophysical, and environmental sciences. The school also offers graduate degrees in Earth, atmospheric sciences, and sustainability research. The University of Leeds has recognized Earth and environmental systems science as one of its 12 gold research peaks of excellence. The school also has extensive ongoing research projects and collaborates with members of other departments and institutes such as mathematics and applied physical sciences and engineering, the Earth and Biosphere Institute, and the Earth, Energy, and the Environment Institute. This research grouping receives the second-highest research income nationally from the Natural Environment Research Council through competitive grant proposals.

The Earth and Biosphere Institute is a group of internationally recognized scientists with interests in the effects of biotic and environmental changes on a spectrum of time and space scales, from short term to geological, and from nanoscale to global. Research initiatives are ongoing within the University of Leeds and with groups from outside the university. The Earth, Energy, and Environment Institute is a multidisciplinary institute housed at the University of Leeds. The purpose of the institute is to provide integrated research solutions, knowledge transfer, and training in this energy-related area on all levels, from the regional to the global.

University of California, San Diego

University of Maine

THE UNIVERSITY OF Maine, established in 1865, is the flagship university of the University of Maine system. It is located in Orono, just outside Bangor, one of Maine's largest cities. Also known as UMaine, the university has an enrollment of over 11,000 students, making it the largest university in the state. The college was the fourth to be established in Maine, after Bowdoin, Bates, and Colby. Originally intended as an agricultural college, it also places a large emphasis on engineering and the sciences. The University of Maine is a major research institute composed of six separate and distinct colleges offering 184 areas of study. The Department of Earth Sciences offers graduate degree programs focusing on climate change in conjunction with the Climate Change Institute.

The Climate Change Institute (formerly the Institute for Quaternary and Climate Studies) is an interdisciplinary research unit organized to conduct research and graduate education focused on the variability of the Earth's climate, ecosystems, and other environmental systems and on the interaction between humans and the natural world. Institute investigations cover the Quaternary period, a time of numerous glacial/interglacial cycles and abrupt changes in climate, ranging in time from the present to nearly 2 million years ago. Research activities include field, laboratory, and modeling studies that focus on the timing, causes, and mechanisms of natural and anthropogenically forced climate change and on the effects of past climate changes on the physical, biological, chemical, social, and economic conditions of the Earth. Institute research is supported by grants from a variety of sources including the National Science Foundation, the National Oceanic and Atmospheric Administration, NASA, and endowments from the Bingham Trust and the Dan and Betty Churchill Exploration Fund.

The Climate Change Institute offers an M.S. degree program with potential for a continuing Ph.D. program through Earth Sciences or an independent degree through the graduate school. Students in the program investigate human and global change, past, present, and future. This program involves in-depth documenting of past and present and predicting future environmental changes and human cultures through the primary disciplines of climatology, archaeology, glaciology, glacial geology, ecology, history, marine geology, and modeling. Over 40 faculty and staff of the institute provide multidisciplinary strength in the fields of climatology, archaeology, glaciology, glacial geology, geochemistry, ecology, history, remote sensing, and marine geology.

The institute's internationally recognized researchers have contributed to the scientific literature in multiple areas of study including understanding controls on the climate system, identifying and exploring abrupt behavior in the climate system, detecting and documenting human-source pollution in the atmosphere, exploring changes over time in the behavior of major atmospheric circulation systems such as El Niño/Southern Oscillation and the North Atlantic Oscillation, studying climate-induced changes in the distribution and abundance of plants and animals, detecting and documenting changes in civilization resulting from climate change, and identifying changes in the extent of ice sheets and mountain glaciers and their effect on the environment.

Fernando Herrera
University of California, San Diego

University of Maryland

THE UNIVERSITY OF Maryland in College Park was founded in 1856 as the Maryland Agricultural College and renamed in 1920 as the University of Maryland. The College Park main campus operates within a group of state-supported institutions of higher education in Maryland. The system's research and service components include the University of Maryland Biotechnology Institute in College Park and the Center for Environmental and Estuarine Studies, with laboratories at Horn Point, Solomons, and Frostburg.

The meteorology/oceanography program is a graduate department program with an expanded scope of activity to include the dynamic system of atmosphere in relation to oceans, land, and life. Though the department does not offer an undergraduate major, they do offer an undergraduate minor in meteorology and oceanography. Advantages to the university programs include proximity to nearby federal agencies such as NASA and the National Centers for Environmental Prediction, as well as the department's partnerships with NASA and the National Oceanic and Atmospheric Administration (NOAA), allowing for close collaboration. Graduate students in the department may have the opportunity to conduct research through these partnerships. An example of these partnerships is the Joint Global Change Research Institute—a university-based collaboration between the University of Maryland and the U.S. Department of Energy's Pacific Northwest National Laboratory or the Earth System Science Interdisciplinary Center, a joint center between the university's departments of meteorology, geology, and geography and the Earth Sciences Directorate at the NASA Goddard Space Flight Center.

The meteorology department conducts research in a broad range of areas, including atmospheric chemistry, climate studies, glaciology, numerical weather prediction, and remote sensing, with a range of activities including fieldwork, remote sensing, and numerical modeling from pole to pole and from the troposphere to the mesosphere. Current funded climate research in particular focuses on global change (including Earth system modeling and analysis and modeling of climate hesitative to greenhouse gas concentrations), atmospheric and oceanic reanalyses, hydroclimate studies, ocean-atmosphere interaction, monsoons, extratropical interannual variability, clouds and radiation, and NWP methods in climate modeling.

Founded as a joint collaboration between the Departments of Atmospheric and Oceanic Science and Geology and Geography at the University of Maryland and the Earth Sciences Directorate at the NASA/Goddard Space Flight Center, ESSIC (the Earth System Science Interdisciplinary Center) is based at the university. ESSIC's focus is to study and understand the dynamics of human activities on atmosphere, ocean, land, and biosphere components of the Earth. ESSIC also administers the Cooperative Institute for Climate Studies, sponsored by the NOAA National Satellite, Data, and Information Services and the NOAA National Centers for Environmental Prediction.

ESSIC's research centers on climate variability and change, atmospheric composition and processes, the global carbon cycle (including terrestrial and marine ecosystems/land use/cover change), and the global water cycle. ESSIC combines primary research of within-system observations with remote sensing and predictive models to forecast global changes and potential regional impact.

The University of Maryland Enterprise Campus, or M Square, is a 124-acre research park adjacent to the University of Maryland/College Park Metro Station. NOAA's National Center for Weather and Climate Prediction is one of the anchor tenants of M Square to take advantage of proximity to the University of Maryland—a leading center for climate research and numeric weather forecasting, which is developing major new partnerships with federal agencies in the areas of earth science, remote imaging, climate change, and energy research.

In addition to academics, the Center for Integrative Environmental Research (CIER) is based at the university. CIER is dedicated to creating a comprehensive understanding of the complex environmental challenges facing society and to developing valuable tools to inform policy and investment decision making. To support resilient flourishing natural and human systems, a truly integrative approach is needed. These multidisciplinary processes combine insights from the physical, engineering, natural, social, and health sciences and stimulate active dialogue across the science-society divide. CIER researchers and graduate students collaborate at global, national, regional, and local scales to explore issues with and across two major sustainability challenges: society's use of material and energy and urban environmental change.

The University of Maryland is setting an example for public and private sectors, as the president of the university joined other college presidents and chancellors around the country in taking a community leadership role and modeling ways to minimize global warming emissions and integrate sustainability into the curriculum and university environment, via membership in the Leadership Circle of the American College and University Presidents Climate Commitment.

SEE ALSO: Education; Maryland; National Oceanic and Atmospheric Administration (NOAA).

Independent Scholar

University of Miami

THE UNIVERSITY OF Miami, founded in 1925, is a private, coeducational teaching and research institution noted for its extensive study-abroad programs, marine science institute, and medical center. The university confers bachelor's, master's, doctoral, and professional degrees in a broad range of academic disciplines including the arts and sciences and marine science. The main campus is in Coral Gables, Florida, and the Rosenstiel School of Marine and Atmospheric Science (RSMAS) is located on Virginia Key on Biscayne Bay.

The university's undergraduate programs related to climate change include ecosystem science and policy and geological sciences. Ecosystem science and policy covers a range of environmental issues from various perspectives. The geological sciences program is taught in the College of Arts and Sciences; the major includes themes of Earth origins, environmental preservation, global dynamics, and internal and surface processes. A special aspect of the geological sciences program is an option for a five-year B.S./M.S.

program coordinated with RSMAS to complete the graduate portion of the education.

The Rosenstiel School was established in 1940 on the Coral Gables campus and moved to Virginia Key on Biscayne Bay in 1957 after outgrowing its initial location. RSMAS is now a 16-building complex and home to a museum with a collection of approximately 400,000 invertebrate specimens, the National Institute of Environmental Health Sciences Marine and Freshwater Biomedical Sciences Center, NSF/NIEHS Oceans and Human Health Center, and the Division of Marine and Atmospheric Chemistry. Research facilities include advanced technology computing and laboratories with precision instruments (mass spectrometer, X-ray spectrograph, gas chromatograph, and a scanning electron microscope).

RSMAS's Division of Marine and Atmospheric Chemistry is a graduate program offering master's and doctoral degrees in chemical processes of the atmosphere and chemical processes of the ocean and hydrology. Fieldwork plays a major role, and the department's small size ensures student access to faculty, staff, and research opportunities.

The teaching/research facilities include chemical laboratory instrumentation, a laboratory onboard a cruise ship for collecting marine and atmospheric data, a 90-ft. research catamaran, and a simulation wind and wave tank for observation of specific air/sea interactions. RSMAS's library holds an extensive marine science collection.

Research opportunities are diverse as a result of having a faculty with a wide range of expertise and research interests. Faculty members from the six divisions at RSMAS (Applied Marine Physics, Marine and Atmospheric Chemistry, Marine Affairs and Policy, Marine Biology and Fisheries, Marine Geology and Geophysics, and Meteorology and Physical Oceanography) are working on research related to changing climate impact. A sampling of climate-related studies include the Southeast Climate Consortium (using advanced forecasting tools for agriculture, forestry, and water resources management in the southeastern United States), water resource management in the drought-prone state of Ceara in northeast Brazil (human response to climate change), and climate and fisheries (how changes in sea-level pressure, sea surface temperature patterns, and global mean temperature affect fish stocks).

The Cooperative Institute for Marine and Atmospheric Studies (CIMAS) is a research institute of the University of Miami located in the RSMAS. CIMAS serves as a mechanism to bring together the research resources of the university with those of the National Oceanic and Atmospheric Administration (NOAA) to perform research for understanding the Earth's oceans and atmosphere within the context of NOAA's mission.

The scientific activities in CIMAS are organized under broad research themes. The themes are topics of climate variability, fisheries dynamics, regional coastal ecosystem processes, human interactions with the coastal environment, air-sea interactions and exchanges, and integrated ocean observations; their scientific objectives are guided by NOAA's Strategic Plan and its specific goals in the context of the research activities and expertise resident in the university and the local Miami laboratories of NOAA.

The University of Miami is setting an example for public and private sectors, as when the president of the university joined other college presidents and chancellors around the country in taking a community leadership role and modeling ways to minimize global warming emissions and integrate sustainability into the curriculum and university environment, via membership in the American College and University Presidents Climate Commitment.

University of Michigan

THE UNIVERSITY OF Michigan (also known as Michigan, or UM) was established in 1817 and today is one of the premier research universities in the United States. The university has a strong reputation in all academic fields, with more than 70 percent of

Michigan's 200 major programs, departments, and schools ranking in the top 10 nationally. The university has one of the largest annual research expenditures of any university in the United States (nearly $800 million in 2006), and the university's endowment was valued at $5.65 billion also in 2006, making it the ninth-largest endowment in the United States and the third largest among public universities. The university has over 6,200 faculty members, 73 of whom are members of the National Academy and 400 of whom hold an endowed chair in their discipline. The university consistently leads the nation in the number of Fulbright Scholars and has matriculated 25 Rhodes Scholars, while having produced seven Nobel Prize winners.

The Michigan library system comprises 19 libraries with 24 collections, totaling 8.13 million volumes, with 177,000 volumes being added each year. The campus libraries include the Gerald R. Ford Presidential Library. Over 40,000 students attend UM, including 25,555 undergraduate and 14,470 graduate students in 600 academic programs. Students come from all 50 states and more than 100 countries. One quarter of all undergraduates are members of ethnic minority groups. The university also has a strong social conscience. It was on the steps of the Michigan Student Union on October 14, 1960, that President John F. Kennedy proposed the concept of the Peace Corps. Lyndon B. Johnson's speech outlining his Great Society program also occurred at Michigan.

Over 300 Michigan faculty members are engaged in research on environmental issues. Likewise, there are a number of institutes and centers at the university that are actively engaged in research concerning global warming and climatic change, as well as related issues such as sustainability and alternative energy. For example, the UM Climate Change Consortium is an initiative of the School of Engineering that runs an electronic forum about climate change. The School of Engineering is also renowned for its Solar Car Team, which placed first in the American Solar Challenge four times and third in the World Solar Challenge three times. The University of Michigan Transportation Research Institute provides leadership in interdisciplinary transportation-related research and also has experts conducting research on energy efficiency and emissions. The Frederick A. and Barbara M. Erb Institute for Global Sustainable Enterprises is affiliated with the School of Business and fosters global sustainable enterprise through interdisciplinary research and education initiatives. Even the operations of the university itself strive to be environmentally sensitive, with UM Waste Management Services encouraging recycling on campus. The university operates a 13,000-acre (53 sq. km.) biological station in the northern Lower Peninsula of Michigan—one of only 47 biosphere reserves in the United States.

The university also houses the Michigan Memorial Phoenix Energy Institute, which focuses on identifying and using secure, affordable, and sustainable energy sources. The institute uses public policy, economics, business, and social sciences to lay the foundation for successful implementation of scientific and technological achievements. Created in 1947 as a memorial to UM grads who gave their lives in World War II, the institute originally sought to explore peaceful ways to use atomic energy for the benefit of humankind. Then in 2004 the regents of the university broadened the charter of the Phoenix Project beyond atomic energy to encompass interdisciplinary research on and education about the development of energy policies that promote world peace, responsible use of the environment, and economic prosperity.

The UM Center for Sustainable Systems is located within the School of Natural Resources and Environment (SNRE) and focuses on the identification of systems-based approaches to sustainability through creative and effective teaching and research. SNRE also hosted in 2007 a national summit on climate change as part of the Clinton Global Initiative. The purpose of the summit was to bring together global leaders and key stakeholders to examine what is known about the composite regional effect of climate change and what management and policy options can help regions deal with changes in average conditions, as well as with extreme events.

Michael J. Simsik
U.S. Peace Corps

University of Nebraska

THE UNIVERSITY OF Nebraska in Lincoln, Nebraska (UNL), founded in 1869, is part of the state-supported University of Nebraska system. The discipline of ecology began at the University of Nebraska, and the campuses are botanical gardens and arboreta. The university confers bachelor's, master's, doctoral, and professional degrees in a variety of academic and professional disciplines, including agricultural sciences, animal sciences, health sciences, atmospheric sciences, earth and space sciences (which includes the former departments of geology and geophysics), and environmental sciences. Research facilities include the Cedar Point Biological Station, the Center for Great Plains Studies, and the Engineering Research Centers.

Within the university, the College of Agricultural Sciences and Natural Resources encompasses 27 programs of study and two preprofessional programs ranging from animal science, fisheries and wildlife, and agribusiness to professional golf course management. The areas related to climate change and the environment include Environmental Restoration Science, environmental studies, natural resource and environmental economics, and applied climate sciences.

Environmental restoration science is the study of soil (for producing crops and supporting groundwater purification and the conversion of waste material). The program combines classroom work with out-of-class experiences (internships and fieldwork), with an emphasis on soil in an environmental context. In addition to frequent opportunities for faculty and staff contact, students may be involved in the Soil and Water Resources Club, Agronomy Club, Soil Judging Team, or the Lincoln Chapter of the Soil and Water Conservation Society.

Environmental studies provides interdisciplinary study encompassing a variety of academic departments in the College of Agricultural Sciences and Natural Resources and the College of Arts and Sciences to study environmental and social sciences, global issues, and environmental protection. In addition to academic work across academic disciplines, the Environmental Resource Center provides access to environmental information, internship opportunities, and a study area. Students may be involved in a variety of environmentally related student groups such as Ecology Now, the Soil and Water Resources Club, and the Wildlife Club.

Natural Resource and Environmental Economics brings together natural sciences with economics, law, and other social sciences with a focus on assessing public policies regulating the use of natural resources and environmental amenities.

The Applied Climate Sciences (ACS) program (formerly called the Department of Agricultural Meteorology) is a graduate program bringing together a variety of academic disciplines for academic study and applied research on climate effects and variability; drought monitoring, mitigation, and planning; environmental biophysics; global climate change; High Plains climate; micrometeorology; and severe weather, among others.

Within the program are the bio-atmospheric interactions specialization (to understand interactions between the atmosphere and the biosphere) and the agricultural meteorology specialization (to understand bioatmospheric interaction and agriculture).

The facilities include laboratory, office, and classroom facilities to support research, teaching, and outreach regarding natural resources; the Agro-Meteorology Laboratory at the University of Nebraska Agricultural Research and Development Center near Mead; measuring stations for the National Atmospheric Deposition Program and the U.S. Department of Agriculture Ultraviolet B Monitoring Network; the High Plains Climate Center and its Automated Weather Data Network; and the National Drought Mitigation Center.

A sampling of research opportunities related to climate in the ACS programs includes climate variations, climate modeling, micrometeorology, remote sensing, and climate effects.

UNL's School of Natural Resources hosts the Great Plains Regional Center of the National Institute for Global Environmental Change. The focus of the center's research is environmental change in the grasslands of Colorado, Iowa, Kansas, Minnesota, Missouri, Montana, Nebraska, North and South Dakota, and Wyoming. Because of the agricultural value of crops and livestock produced in this region, even minor climate changes could have a major effect on the nation and the world. The data collected are also valuable for reference with regard to global regions with semiarid grassland ecosystems similar to the Great Plains.

SEE ALSO: Climate Change, Effects; Education; Nebraska.

Lyn Michaud
Independent Scholar

University of New Hampshire

THE UNIVERSITY OF New Hampshire in Durham, New Hampshire, was founded in 1866 as the College of Agriculture and Mechanic Arts. The school became the University of New Hampshire (UNH) in 1923 and is the main campus of the state's university system. Academic programs cover a variety of disciplines such as the arts and sciences, humanities, business, engineering, education, and the health professions. Research facilities included Anadromous Fish and Aquatic Invertebrate Research Laboratory, Jackson Estuarine Laboratory, Coastal Marine Laboratory, Jere A. Chase Ocean Engineering Laboratory, and Shoals Marine Laboratory.

Courses, programs, and departments interconnect on the subject of climate. The Climate Change Research Center (CCRC) is dedicated to the study of the Earth's atmosphere. Set up for graduate-level instruction, the CCRC also provides information materials (interactive displays) to various organizations and provides support to K–12 teachers through lesson guides and teacher training. Several center faculty also have appointments to the Departments of Earth Science, Natural Resources, Chemistry, and Engineering and work with undergraduates in the Research & Discover internship and Undergraduate Research Opportunity Program.

CCRC research focuses on understanding the fundamental properties of the atmosphere and how they have been affected by human activities and will continue to be so in the future, with areas of interest including air quality and climate, airborne sciences, biosphere-atmosphere exchange, halogen chemistry, ice course and air-snow exchange, new england climate assessment, and organic aerosols.

Courses taught by CCRC faculty are specific to the research being conducted in the department: Introduction to Atmospheric Science (fundamental principles and dynamics of the earth's atmosphere), Global Atmospheric Chemistry (relationship between atmospheric chemistry, climate, and global change), Atmospheric Aerosol and Precipitation Chemistry (processes determining the chemical and physical characteristics of atmospheric aerosol particles and precipitation), Measurement Techniques in Atmospheric Chemistry (instrumental methods used in atmospheric chemistry and biogeochemical research), Earth System Science (components, interactions, and concepts for characterizing the Earth's integrated system), and Regional Air Quality (measurement programs to examine air quality in New England and other global regions).

Earth Sciences is a multidisciplinary department including geology, oceanography, hydrology, ocean mapping, and geochemical systems specialization. Students have the option of choosing among the different disciplines in creating a program specific to interest and, in addition, have many different research opportunities from local research to field work at sites including Antarctica, Greenland, the Pacific and Indian oceans, Mexico, China, the Himalayas, Indonesia, Pakistan, and the western United States. Research in earth sciences covers all the Earth system components and relies on connections with researchers and faculty in natural resources.

Natural Resources and Earth Systems Science is an interdepartmental graduate program offering only a doctoral degree in natural resources and environmental studies or Earth and environmental science. The program relies on interdisciplinary work to understand and manage the environment with many possible options for study including atmospheric science and ethical and policy issues.

The UNH/National Oceanic and Atmospheric Administration Cooperative Institute for Coastal and Estuarine Environmental Technology (CICEET) researches coastal resource management. Working with a network of colleagues throughout the United States, CICEET's focus is ecosystem health and coastal resiliency to find technology to address coastal challenge as well as providing usable information for people to have continued access to clean water and healthy coasts.

UNH hosted the Global Analysis, Integration, and Modeling International Project Office of the International Geosphere-Biosphere Program until termination of the program in 2004. The decade-long project researched existing models. The more-than-decade-long project provided the foundation for the Global Carbon Project and created the platform for new integrative modeling activities.

The UNH is setting an example for public and private sectors; the president of the university joined other college presidents and chancellors around the country in taking a community leadership role and modeling ways to minimize global warming emissions and integrate sustainability into the curriculum and university environment with membership in the American College and University Presidents Climate Commitment. Since 1997, the University Office of Sustainability—the oldest endowed sustainability program in U.S. higher education—has brought together all members of the university community in integrating sustainability throughout UNH (in curriculum, operations, and research and engagement).

Independent Scholar

University of Oklahoma

THE UNIVERSITY OF Oklahoma (OU), located in Norman, was founded in 1890. The university confers bachelor's, master's, doctoral, and professional degrees in a variety of academic and professional disciplines. The university is home to the College of Atmospheric and Geographic Sciences, containing the School of Meteorology and the Department of Geography.

The School of Meteorology will celebrate its fiftieth anniversary in 2010. The school is housed in the National Weather Center building, which also is home to 12 academic, research, and operational meteorology organizations. With over 320 undergraduate and 80 graduate students, OU has the largest meteorology program in the United States, and the department offers a Bachelor of Science in Meteorology degree or a Professional Meteorology master's degree. Undergraduate students also have the opportunity to participate in an international exchange program featuring the universities of Reading in England, Monash in Australia, and Hamburg in Germany.

The School of Meteorology performs shared research with the National Oceanic and Atmospheric Administration's National Severe Storms Laboratory and participates in a variety of national projects. In February 2008, the National Weather Center in Norman, Oklahoma, hosts the first U.S.–China Symposium on Meteorology: Mesoscale Meteorology and Data Assimilation.

The Department of Geography provides for the study of human interactions with climate, earth structures, and natural resources and the effect these interactions have on human culture. The department offers bachelor's, master's, and doctoral degrees. Faculty expertise includes cultural, historical, political, and economic geography; applied physical geography; and geographic information science. Research is conducted in climatology, natural resources, human effects on the planet, and cartography.

In addition to academics, the College of Atmospheric and Geographic Sciences hosts several research centers. The Center for the Analysis and Prediction of Storms includes the Center for Collaborative, Adaptive Sensing of the Atmosphere and the Linked Environments for Atmospheric Discovery. The mission of the center is the development of techniques to predict severe weather conditions using on-site and remote sensing systems.

The Cooperative Institute for Mesoscale Meteorological Studies was established in 1978 between OU and the National Oceanic and Atmospheric Administration. In addition to linking scientific expertise from academia, the center has collaborative relationships with all the National Oceanic and Atmospheric Administration units in Norman. Research programs include basic and convective mesoscale research, climate change monitoring and detection, and climatic effects. Additional research involves improving technology for the prediction of weather events.

Under legislative mandate, the Oklahoma Climatological Survey (OCS) was established in 1980 to collect, analyze, interpret, and provide information on climate and weather data to residents of Oklahoma. The OCS conducts research on climate change effects and provides data and support to the state climatologist.

Under joint administration by OU and Oklahoma State University, the Oklahoma Mesonet monitors weather and soil conditions at over 100 automated observing stations.

The Center for Spatial Analysis brings together various academic disciplines to study and apply geospatial science and technology.

Focused on strengthening the research of environmental scientists and facilitating relationships between the scientific community and the public, the Environmental Verification and Analysis Center participates in earth science work.

A network opportunity for teachers of geography, the Oklahoma Alliance for Geographical Education relies on affiliation with the National Geographic Society along with its associated state geographic alliances, as well as geography organizations from around the country.

The opportunity for Oklahomans to learn about and support NASA's mission research programs, including science and geography, along with other academic disciplines falls under the auspices of the Oklahoma NASA Space Grant Consortium. The consortium includes partnerships with Oklahoma universities, a science museum, a cooperative extension service, state and local governments, and other interested institutions.

Beyond academics and research, the president of the University of Oklahoma joined other college presidents and chancellors around the United States to take a community leadership role and to model ways to minimize global warming emissions and integrate sustainability within the curriculum and university operations and environment, with membership in the American College and University Presidents Climate Commitment.

Independent Scholar

University of Reading

THE UNIVERSITY OF Reading is located in Reading, England. With a foundation made by joining the School of Art begun in 1860 and the School of Science begun in 1870, Christ Church of Oxford established an extension college in 1892. Funding and expansion ensured success and led to the University of Reading being given a royal charter in 1926. The University of Reading has several educational centers conducting research in a variety of disciplines in the arts, humanities, sciences, and social sciences, including environmental sciences and meteorology.

The environmental science degree investigates the components of the Earth system, along with providing a scientific understanding of current and future environmental issues and their management. Within the major, students may choose a pathway in consultation with a course adviser. The pathway options include earth and atmosphere (interactions between the solid Earth, the Earth's surface, the oceans, and the atmosphere through geology, soil science, and meteorology), earth systems and environmental change (changes in rates, causes, and extents of change; the contribution of human activity; and how that activity can be managed appropriately), and habitat management.

The Department of Meteorology was founded in 1965, and offers a range of courses for both undergraduates and postgraduates. The teaching facilities include a lecture hall, laboratories for practical experimentation, and a meteorological enclosure for observations and experimentation. For teaching purposes and general access, current weather data and satellite pictures stream into the department.

Active research in regional weather systems, data assimilation, global atmospheric modeling, and global circulation and climate are ongoing. Established research and teaching links with the European Centre for Medium Range Weather Forecasts and the U.K. Meteorological Office provide additional learning opportunities and access to state-of-the-art equipment.

In addition to academics, the University of Reading is the home of the National Centre for Atmospheric Science (NCAS) Climate @ Reading Programme, the Environmental Systems Science Centre (ESSC), and the Data Assimilation Research Centre (DARC).

Based within the Department of Meteorology is the NCAS Climate @ Reading Programme. NCAS was called the Centre for Global Atmospheric Modeling from May 1990 until April 2006. NCAS Climate @ Reading provides scientific expertise, technical support, and training to address the following key challenges: increasing knowledge of climate variability and change on various timescales, using advanced computer technology for simulations; establishing the usefulness and accuracy of climate prediction models; and integrating various specialties for creating adaptability or mitigation of climate change.

NCAS Climate @ Reading is part of the Climate Programme charged with carrying out climate change research into how the climate will change by the end of the century, while taking into account natural variation and finding ways to predict climate change for the benefit of society. NCAS carries out this mission by integrating dynamics of the global climate system with earth system modeling, improved prediction, and ever-improving computer technology.

ESSC is a research center that is not involved in undergraduate teaching. It is funded as such by the Natural Environment Research Council (NERC). ESSC is one of the focal centers in the country for the study of remotely sensed data; the work involves coupling data with computer models of environmental processes. The wide range of interests of researchers parallels the research interests of NERC: meteorology, oceanography, geology, and hydrology. ESSC forms part of the School of Mathematics, Meteorology, and Physics.

Research interests are largely driven by the strategy of NERC, and so address problems relevant to issues within topics of global environmental change, hazard assessment and mitigation, natural resources, waste, and pollution. Research includes land surface processes, marine science, meteorology, and others.

DARC is funded under the NERC Earth Observation Centre of Excellence Initiative. The meteorology department holds the directorship and partners with Rutherford Appleton Laboratory and the universities of Cambridge, Edinburgh, and Oxford. The focus of DARC is theory development research and studying applications of data assimilation methods. This work involves the highly integrated combination of various Earth observation data sources with information available from sophisticated Earth system models and the European Space Agency Enlist satellite.

In addition to many collaborative partnerships worldwide, the University of Reading is one site of an international exchange program with the University of Oklahoma.

Lyn Michaud
Independent Scholar

University of St. Gallen (Switzerland)

THE UNIVERSITY OF St. Gallen, Graduate School of Business Administration, Economics, Law, and Social Sciences (HSG) is located in St. Gallen in northeastern Switzerland. The town of St. Gallen is a commercial center with roots in the early 7th century and a hermitage established by the Irish missionary Saint Gall. The hermitage became a Benedictine abbey and noted educational center in the 8th century.

On May 28, 1898, the Cantonal Parliament of the Canton of St. Gallen issued a resolution to establish a school for transport, commerce, and administration; this academy opened in 1899. The school continued under various names until being established as the University of St. Gallen. For the 2000/2001 educational year, the curriculum was revised to offer bachelor's and master's degrees.

HSG remains true to its original mission to provide an education easily translated into real life. Topics of study include business administration, economics, law, and social sciences leading to bachelor's, master's, and doctoral academic degrees. More programs are being offered in English, drawing many international students. In addition, executive education is offered by HSG to provide educational opportunities to people in business.

The Institute for Economy and the Environment (IWOe-HSG) was founded on October 1, 1992, at the University of St. Gallen to explore the global intersections of the natural world with the forces of economy and society. IWOe-HSG identifies potential problems and researches options to determine practical solutions. These issues cover a wide range of topics regarding renewable energy, financing renewable and sustainable options as well as addressing issues of concern like landscapes for the use and production of electricity from wind farms. To perform this work, the institute maintains a network with international businesses, other educational institutions, and research organizations.

In general, the institute analyzes conditions necessary for an environmentally sound market economy and corporate sustainability management. Furthermore, it imparts the findings to practical business situations to ensure that the work it does is relevant and has an effect on real-life situations. The foundation of the IWOe-HSG was supported by Oikos (the environmental student organization at the HSG) and the Oikos Foundation for Economy and Environment. IWOe-HSG is a nonprofit organization that receives support from the university and from private and nonprofit companies. At present, the institute's primary research projects include culture and sustainability, management systems for corporate sustainability, sustainability marketing and sustainable consumption, life cycle assessment, environmental finance and entrepreneurship, and renewable energy technologies.

In 1968, five students from the University of St. Gallen chose to make a difference by fostering dialogue between groups instead of joining the protests of many of their peers. They set up the International Students' Committee and formed a symposium designed to foster cross-generational dialogue in a neutral environment. Each year in May since 1970, the St. Gallen Symposium has been held at the university as a forum for international dialogue on the connections among business, politics, and society. Attendees include business professionals (corporate and entrepreneurial), policymakers, academic professionals, and students from the University of St. Gallen in Switzerland for integrative discussions on sustaining business and society in general. The topic for the symposium held in 2007 was "The Power of Natural Resources."

The International Students' Committee organizes the St. Gallen Symposium under the auspices of the St. Gallen Foundation for International Studies (which serves in an advisory and supervisory capacity). In addition to the students from St. Gallen an office (International Students' Committee Harvard) at Harvard University in the United States fosters international cooperation, with Harvard students supporting the St. Gallen member students. The team of students designs and plans the symposium from concept and content through to marketing and implementation. The team also determines key themes and interacts with a network of selected speakers from business, politics, and society, along with maintaining contacts with other leading international universities.

University of Utah

THE UNIVERSITY OF Utah, founded in 1850, is a public, coeducational institution located in Salt Lake City. The university confers bachelor's, master's, doctoral, and professional degrees in a variety of academic and professional disciplines. The university offers a focus on environmental science, and the university's College of Mines and Earth Sciences is home to the Departments of Meteorology and Geology and Geophysics.

The Department of Meteorology focuses on offering a background for meteorology and related environmental science careers with an understanding of system processes involving weather and climate. The program's emphasis on mountain weather and climate (as well as the complexities involved in forecasting weather on complex terrain) stems from Salt Lake's location on the western slope of the Wasatch Mountains (a range in the Rocky Mountains). Integrating math, physics, and chemistry and a broad range of academic opportunities with dynamic, physical, and synoptic meteorology prepares students for employment as meteorologists with the National Weather Service or for a broad range of careers with government and private employers in meteorology or environmental sciences.

The department's small size ensures student access to faculty, staff, and research opportunities. The faculty has diverse expertise and research interests in a broad range of observational, modeling, and theoretical studies. Current interests include tropical convection and hurricanes; boundary layer modeling; fire weather prediction and fire modeling; mountain meteorology; weather analysis and prediction; parameterization, remote sensing, and modeling of clouds; aerosol physics and

Water levels have been steadily decreasing in Lake Powell, which borders Utah and Arizona. The university's environmental program focuses on environmental policy and how human actions affect the natural dynamics.

air pollution; numerical modeling, data assimilation, and predictability; and climate change.

The department's teaching facilities on the main campus of the University of Utah include an audiovisual teaching laboratory also serving as a classroom, research equipment, and computing resource. A mountain meteorology laboratory is located about a mile away from the primary meteorology department.

Active research currently being done within the department by faculty members and funded by governmental and private organizations includes active research in clouds, aerosols, and climate; numerical weather prediction; mountain weather and climate; tropical convection and storms; and climate variability and change.

The Department of Geology and Geophysics offers both undergraduate and graduate degree programs. Undergraduates may declare majors in geoscience (with emphases in geology, geophysics, or environmental geoscience), geological engineering, or Earth science teaching. The four graduate programs are in geology, geophysics, geological engineering, and environmental engineering.

The Earth sciences overlap and integrate with a broadening range of disciplines. With a specific understanding of specialized processes and of fitting them into the broader system framework, students and researchers both gain a better understanding of earth science systems and the internal functional processes of geophysics, geobiology, and geochemistry. A sampling of projects and themes of special interest to those studying climate change includes environmental geology, paleoclimatology, geothermics, marine geology, and groundwater and surfacewater hydrology. Recent investigations of special note undertaken by University of Utah faculty, students, and collaborators were borehole thermal gradients as long-term records of earth surface paleotemperatures and global warming and Antarctic drill holes as recorders of Tertiary paleoclimate change.

The Environmental Studies Program at the University of Utah focuses on environmental policy and exists not as a single field of study but as a curriculum to provide an understanding of environmental systems and how human actions affect the natural dynamics. Students have the option of choosing from three different perspectives: biology and natural sciences, humanities and aesthetics, or human behavior/policy/decision making. In addition to academics, the University of Utah is home to the National Oceanic and Atmospheric Administration Cooperative Institute for Regional Prediction (CIRP). Established in 1996, and building on an applied research program started in 1991 for faculty and students to work in cooperation with local and regional forecasters, CIRP conducts research to improve regional forecasting and knowledge of western U.S. meteorology.

Benefits of this research to weather professionals, researchers, and the general public relate to improved access and quality of data related to weather prediction. Various programs within CIRP provide access to surface observations incorporated from numerous sources (surface stations around the United States), analyses of compiled data, specific information for the fire weather community, and extended forecasts. CIRP also provides workshops.

University of Washington

THE UNIVERSITY OF Washington, located in Seattle, was founded in 1851. The university confers bachelor's, master's, doctoral, and professional degrees in a variety of academic and professional disciplines including atmospheric sciences and Earth and space sciences (includes the former Departments of Geology and Geophysics) and environmental sciences.

Founded in 1947, the Department of Atmospheric Sciences focuses on teaching excellence incorporating a wide range of topics including weather forecasting, global warming, air quality, mountain weather, marine weather, El Niño, the ozone hole, ice ages, and the weather of Mars. Students who choose atmospheric science majors are prepared for a range of career options (weather forecasting, environmental meteorology, broadcast weather, and a broad range of careers with government and private employers in meteorology or environmental sciences).

The teaching facilities include a map room (for viewing weather data including radar and satellite imagery and forecast models) and an instruments laboratory (for learning about various types of observational instruments and computer interfacing by taking local observations).

The department's internship program encourages students to explore a variety of career paths while gaining valuable experience in addition to academic credit and possible stipends. The internships range from National Weather Service Forecast Offices to television stations, U.S. Forest Service, the Northwest Avalanche Center, the Pacific Marine Environmental Lab, and other laboratories and businesses. The faculty has diverse expertise and research interests, with research opportunities available to students.

The Department of Earth and Space Sciences integrates geology, math, physics, biology, and chemistry into a program to further the understanding of Earth structure, processes, and history and solar system structure, processes, and histories. The faculty areas of research are aimed toward predicting the future conditions of Earth, studying the geologic record, observing conditions, and modeling the present state. A sampling of projects of special interest to those studying climate changes includes glaciology, Quaternary research, climate, and paleoclimate.

The Program on the Environment offers interdisciplinary environmental education and is a focal point for information exchange on environmental education and research opportunities. The Earth Initiative encourages innovative partnerships to address environmental and natural resource challenges. By focusing on problem-specific environmental issues in the Pacific Northwest and beyond, the initiative brings together faculty, students, and community partners to create collaborative research, teaching, and scholarship.

The Program on the Environment, established in 1997, exists not as a separate department but as a collaborative network linking all university departments in providing environmental education. The programs provide education in natural sciences; social sciences; law, policy, and management; and ethics, values, and culture.

In addition to academics, the University of Washington is home to the Climate Impacts Group (CIG), which integrates climate science with public policy. With a focus on the U.S. Pacific Northwest, the group performs research on the consequences of climate change and provides information to policy makers on preserving regional resources vulnerable to climate changes.

By bringing together various disciplines to examine past climate and stressors, to analyze patterns of and predictable climate variations, as well as to determine past climate change effects, CIG extrapolates possible future responses to climate change in the Pacific Northwest's vulnerable areas.

CIG makes recommendations for approaches of human-induced changes on natural resources and overall climate effect. By developing close connections and maintaining networks with government, private, and North American tribal groups, as well as the agencies in charge of water, forests, fisheries, and coastal resources, the group ensures that their information is useful, informative, and transformational to the daily activities of appropriate resource management.

The University of Washington is setting an example for public and private sectors. The president of the university joined other college presidents and chancellors around the country in taking a community leadership role and modeling ways to minimize global warming emissions and integrate sustainability into the curriculum and university environment, with membership in the Leadership Circle of the American College and University Presidents Climate Commitment. By doing so, the university is building on past successes in developing plans for reducing energy consumption with the Environmental Stewardship Advisory Committee and Policy on Environmental Stewardship adopted in 2004, joining the UPASS program (bus pass) to reduce single-occupancy vehicle trips to campus, and acting as a founding partner of the Seattle Climate Partnership. In addition, the university has pledged to reduce greenhouse gas emissions by 2012 to 7 percent below the levels in 1990.

Upwelling, Coastal

COASTAL UPWELLING OCCURS when water along a coastline flows offshore and deeper water—usually relatively cool, rich in nutrients, and high in partial pressure of carbon dioxide—flows upward to fill its place. Upwelling areas are notable for their effect on carbon cycling, as upwelling not only brings dissolved inorganic carbon to the surface, where it is released into the atmosphere, but also stimulates phytoplankton blooms that further remove some of that carbon through photosynthesis; a small percentage of this bloom also sinks in the form of organic matter (organic carbon) to deep water and becomes buried in sediment, creating a long-term carbon sink. There is considerable interest among carbon-cycle scientists regarding the reciprocal interactions between upwelling systems and climate change. Although such upwelling can in principle occur along any coastline, marine or freshwater, some marine coastlines (e.g., Peru, the western United States, northwest Africa, and southwest Africa) are renowned for their annual upwelling events that are the source of major blooms of diatoms and dinoflagellates, which become the base for extensive marine food webs and coastal fishing industries.

In the past several decades, major research programs have developed around the influence of coastal upwelling ecosystems on ocean carbon cycling and atmospheric carbon dioxide, how natural climate change (such as glacial-interglacial cycles) has affected coastal upwelling and associated biological productivity over a range of timescales, and how human-induced climate change is affecting coastal upwelling rates and timing and the associated fisheries.

Carbon dioxide exchange between coastal surface water and the atmosphere varies considerably in time and space. Because the pattern is complicated and dynamic relative to the number of direct measurements, considerable uncertainty lingers regarding the net carbon flux through the system over the course of a year. In general, outgassing occurs near the coastline, where upwelled water outcrops at the surface. This water is often rich in carbon dioxide arising from the respiration of organisms ingesting organic matter that sank from the surface to deeper water (which may be the sea bottom along the continental shelf). As upwelled water moves from shore, phytoplankton bloom in response to dissolved nitrogen, phosphorus, and other nutrients and begin to use up some of the dissolved inorganic carbon, reducing the partial pressure of carbon dioxide.

Because this process occurs over a period of several weeks, the rate of uptake of dissolved inorganic carbon also changes through time, so that net outgassing will occur early in an upwelling event, gradually changing to net ingassing. Much of the phytoplankton is recycled in the surface layer, prolonging the bloom, but some of the nutrients and carbon escape the system through the fecal material of heterotrophs feeding on the phytoplankton. The nutrients of remineralized organic matter that sink may come to the surface in future years through upwelling, or the organic matter may sink below the depth of upwelled water into the deep sea or get buried in sediment. The latter two processes can take carbon out of the atmosphere for thousands or millions of years, respectively. Although these processes occur in other aquatic areas, enough of the global ocean carbon flux in a given year occurs through coastal upwelling zones to affect atmospheric carbon dioxide.

The strength and direction of surface winds that drive coastal upwelling vary over a broad spectrum of timescales. Changes in global heat retention through time affect the potential for temperature gradients that influence wind speed, and the distribution of land masses and topographic features such as mountains affect coastal shape, coastal currents, sea level and coastal profile, and atmospheric circulation patterns. Temperature and precipitation patterns and sealevel, among other variables, affect nutrient distribution in the oceans. All of these affect upwelling strength, biological productivity, carbon burial, and net effect on the global carbon cycle. Much research has been dedicated to understanding upwelling changes during glacial-interglacial cycles, tracking responses to changed wind speeds and to lowered sea level, and therefore steeper coastal profiles. Other research has examined how to predict occurrences of upwelling in, for example, the Mesozoic, under the assumption that upwelling is responsible for the accumulation of some petroleum deposits.

Both models and empirical observations of several coastal upwelling areas, such as off the coast of California and northwest Africa, suggest that atmospheric warming is leading to greater rates of upwelling. This increase is driven by a greater land-ocean temperature gradient and therefore greater wind speeds. This can lead both to greater outgassing of carbon dioxide (if not balanced by increased productivity) and loss of certain fish that cannot maintain their population position as a result of higher offshore current velocities.

Upwelling Equatorial

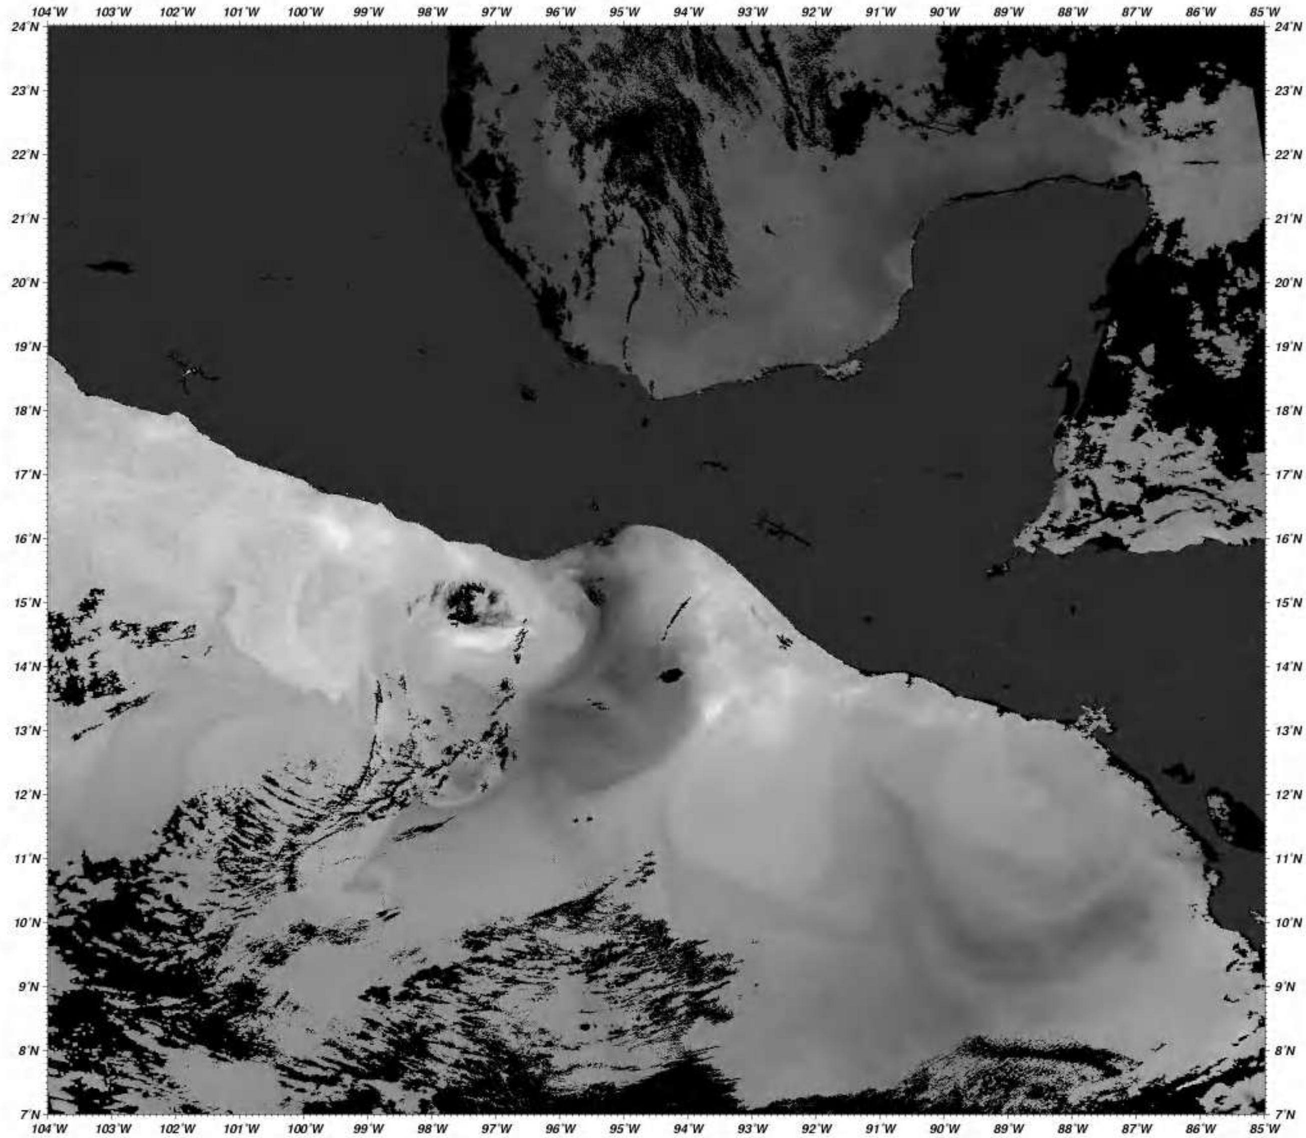
UPWELLING EQUATORIAL (UE) is upward water's motion in the upper layer of the Equatorial Ocean and occurs when a persistent easterly wind is blowing over the equatorial zone. Maximum upward velocity in the UE occurs just at the equator.

UE is a result of the permanent divergence of a westward surface south equatorial current in the narrow equator vicinity, forced by the southeast trade wind. Divergence of westward current at the equator is caused by the change of sign of the Coriolis force between the Northern and Southern hemispheres. As a consequence of divergence, the upper thermocline becomes shallower at the equator. Strong permanent equatorial divergence also causes an intense entrainment of more cold water from the thermocline into the upper mixed layer. This leads to cooling of the upper mixed layer. As a result, the sea surface temperature is about 1.8 degrees F (1 degree C) lower in the equator vicinity than in the interior Equatorial Ocean outside of it.

Pure UE occurs in the narrow vicinity of the equator, just within the divergent zone. Because of the slope of equatorial thermocline in a zonal direction (the thermocline is deeper in the western equatorial Atlantic and Pacific oceans than in the eastern) and the generation of coastal upwelling in the eastern Equatorial Oceans, UE manifestation, as relatively cold surface water, is more pronounced in the upper layer of the eastern Equatorial Oceans. Therefore, the cooler sea surface water looks like a long and thin equatorial tongue spreading from the eastern Equatorial Oceans. There is also quite high biological activity in this relatively cold tongue.

The thickness of the UE is restricted by the upper boundary of the equatorial undercurrent because the eastward current is accompanied by equatorial convergence and, hence, downward water's motion. That is why this thickness varies from about 328 to 656 ft. or 100 or 200 m. (in the western Equatorial Atlantic or Pacific Ocean, respectively) to 33 to 66 ft. or 10 to 20 m. (in the eastern Equatorial Atlantic and the Pacific Ocean).

UE is a quite persistent phenomenon in the Atlantic and Pacific oceans because the westward surface south equatorial current occurs there in the equator's vicinity almost throughout the entire year. However, UE intensity varies from season to season and from year to year. Seasonally, it is at a maximum in the Equatorial Atlantic and Pacific, when the south equatorial current intensifies, following the seasonal cycle of the southeast trade wind (with some delay that does not typically exceed a month); that is, in boreal late summer to early fall. Interannular variations of UE are mostly to the result of the El Niño/La Niña phenomena, especially in the Pacific Ocean. Just before El Niño developing (i.e., an anomalous warming of the upper layer in the Equatorial Pacific), the southeast trade wind dramatically weakens, and UE is over. In contrast, during La Niña (a cold episode in



Cold-water upwelling in the Gulf of Tehuantepec: This image of the Isthmus of Tehuantepec in Mexico shows sea surface temperatures observed by the Moderate Resolution Imaging Spectroradiometer (MODIS) on NASA's Aqua satellite.

the Equatorial Pacific Ocean), UE is strongly developed as a result of an anomalous intensification of the southeast trade wind and, hence, the south equatorial current. Interannular variability of the UE in the Equatorial Atlantic follows Pacific variability with some delay, which is typically not more than a few months. However, the magnitude of interannular UE variations in the Atlantic Ocean is not as large as in the Pacific Ocean. A seasonal cycle prevails in the Equatorial Atlantic, where the magnitude of the seasonal UE variations is two to three times bigger than the interannular ones.

In the Indian Ocean, UE (as a persistent phenomenon) occurs only in boreal winter, when the northeast monsoon has been developing. The UE is most pronounced in the western part of this basin. Seasonal UE variability is at maximum in the Indian Ocean. Interannular UE variability in the Indian Ocean is controlled by the Indo-Ocean Dipole, which is an inherent Indo-Ocean mode interrelated with the Pacific interannular variability (i.e., El Niño/La Niña phenomena), as can be seen in the recent results of Alexander Polonsky and coauthors and of Swadhin Behera and Toshio Yamagata.

Low-frequency (decade-to-decade) variability of the southeast trade wind or the northeast monsoon generates quasi-equilibrium UE variations. A more (or less) intense southeast trade wind and northeast monsoon leads to more (or less) intense UE.

Uruguay

URUGUAY IS LOCATED in southern South America, making a small wedge between Argentina and Brazil. Most of the country is covered by rolling grasslands, though it is crossed by several river systems and has a coastline on the Atlantic Ocean. Uruguay has no mountain ranges to buffer it from weather systems, making it susceptible to rapid weather changes. Droughts and periodic flooding are common. Climate change is expected to have some initial benefits for the livestock industry, but its long-term effects are unclear. Current climate models predict that Uruguay will see temperature increases of 2 degrees F (1.1 degrees C) by 2050 and 3.4 degrees F (1.9 degrees C) by 2100. Some models also indicate that there will be increased precipitation in both the summer and winter seasons, although there is some disagreement in these models.

Most of Uruguay is covered with evergreen grasslands perfect for the raising of cattle and sheep, which is a major part of the national economy. The grasslands may at first benefit from increased temperatures and higher atmospheric concentrations of CO_2, but it is not clear at which point the positive becomes a negative.

Sea-level rise is a concern along the Atlantic coastline. The capital city of Montevideo, home to about 45 percent of the population, sits on the coast, and much of the country's industrial infrastructure is concentrated around Montevideo Bay. A 1997 study predicted a rise in sea level of between 1.6–3.2 ft. (0.5–1.0 m.) by 2100. This would destroy much of the high-value real estate along the coast and severely damage the sewage and water purification systems of the city.

Uruguay has a population of just 3.5 million people. It has low population density, relatively high per capita income, and a well-developed economy. It is not a significant contributor to global carbon emissions; in fact, it is one of only a handful of countries that is carbon neutral, removing as much carbon from the atmosphere as it releases. In 1998, CO_2 emissions were about 1,800 metric tons per capita. Ninety-two percent of emissions come from liquid fuel use, and 8 percent from cement manufacture. Uruguay was one of the first countries to submit a greenhouse gas inventory to the United Nations Framework Convention on Climate Change, of which it is a signatory, and it has made regular reports on its progress.

Uruguay's government has moved aggressively to institute sustainable practices since the 1980s. In 1982, it instituted a law on soil management that has led to the sequestration of 1.8 million metric tons of carbon annually for the past 20 years; the Forest Protection Act of 1987 has increased the size of forest plantations from 200 to 6,500 sq. km. (77 to 2,510 sq. mi.), and the country has had a cumulative net carbon sequestration of 27.4 million metric tons.

U.S. Global Change Research Program

THE U.S. Global Change Research Program (USGCRP) supports research on the interactions of natural and human-induced changes in the global environment and their effects on society. The USGCRP began as a presidential initiative in 1989 and was codified by Congress in the Global Change Research Act of 1990, which mandates development of a coordinated interagency research program. Participants in the USGCRP include the Agency for International Development, Department of Agriculture, Department of Commerce, National Oceanic and Atmospheric Administration, Department of Defense, Department of Energy, Department of Health and Human Services, National Institutes of Health, Department of State, Department of Transportation, Department of the Interior, U.S. Geological Survey, Environmental Protection Agency, National Aeronautics and Space Administration, National Science Foundation, and the Smithsonian Institution.

The Office of Science and Technology Policy, the Office of Management and Budget, and the Council on Environmental Quality supervise the activities on behalf of the Executive Office of the President. Since its establishment, the USGCRP has funded research and activities, together with several other national and international science programs, to document important aspects of the sources and lifetimes of greenhouse gases. The program has also established extensive space-based systems for global monitoring of climate and ecosystem. Its researchers have started to analyze the complex issues of various aerosol species that have a significant effect on the climate. They have also furthered understanding of the global water and carbon cycles and made major progress in computer modeling of the global climate.

The USGCRP carries out research in several focus areas. The research in atmospheric composition focuses on how human activities and natural phenomena affect the atmosphere and on how those changes relate to important issues such as climate change and ozone layer depletion. The research in this area aims to develop a framework for observation that will provide decisionmakers with sound scientific information both in the United States and abroad. The research carried out in this area has contributed to the approval of laws and international treaties that protect the national and global environment. In addition, it has shown connections between global change and ozone depletion, as well as air-quality degradation at local, regional, and global levels. Scientists have been able to improve predictive models on climate change by taking into account the interconnectedness of these factors. This area of study has also tackled the important problem of atmospheric aerosols (particulate matter). Similar to greenhouse gases, aerosols have increased greatly in their atmospheric concentration since the Industrial Revolution and cause changes to the energy balance of the planet. Unlike greenhouse gases, however, aerosols can have either a warming or a cooling influence on the climate.

Since 2002, the Global Change Research Program and the administration's U.S. Climate Change Research Initiative (CCRI) established the Climate Change Science Program (CCSP) to allow the United States and the global community with scientific knowledge to manage risks and opportunities of change in the climate and the related environmental systems. Every year the CCSP produces the report "Our Changing Planet," which supplements the president's budget for that fiscal year. The preview of the report for year 2008 unmistakably states that "climate research conducted over the past several years indicates that most of the global warming experienced in the past few decades is very likely due to the observed increase in greenhouse gas concentrations from human activities. Research also indicates that the human influence on the climate system is expected to increase." Because of these findings, the report recommends that society should be "equipped with the best possible knowledge of climate variability and change so that we may exercise responsible stewardship for the environment, lessen the potential for negative climate impacts, and take advantage of positive opportunities where they exist."

The scientists working in climate variability and change have made significant progress in identifying the causes of climate change. USGCRP projects in this area have also attempted to incorporate this new knowledge into models for the prediction of future climate variability and for the exploration of the effects of human activities on climate. A new generation of climate models improved representations of physical processes, as well as increased resolution. Despite these improvements, there are still significant uncertainties associated with certain aspects of climate models.

Research on the global carbon cycle has attempted to quantify the extent of the dynamic reservoirs and fluxes of carbon within the Earth system. Researchers have also tried to predict how carbon cycling might change and be managed in future years. This research should supply guidelines on how to achieve an appropriate balance of risk, cost, and benefit.

The Global Water Cycle was selected as a focus area in USGCRP research, as the cycle plays a critical role in the functioning of the Earth system, and an incorrect understanding of such a cycle is one of the main sources of uncertainty in climate prediction. The water cycle includes all the complex physical, chemical, and biological processes that are necessary for ecosystems and that influence climate. The research in this area aims at developing responses to the consequences of water cycle variability. The changing ecosystems area is motivated by the awareness that global change can affect the structure and functioning of ecosystems in complex ways. The role of ecosystems research is to assess the potential effects of global change on ecosystems to help society respond effectively to such change. Research focuses on modifications in ecosystem structure and functioning and on potential alterations in the frequency and intensity of climate-related disturbances that may have significant effects on society.

The area of land use and land cover change acknowledges that land use and land cover are connected to climate. They can be the determining factors in the exchange of greenhouse gases between the land surface and the atmosphere, the radiation balance of the land surface, and the exchange of sensible heat between the land surface and the atmosphere. Researchers in this area analyze how changes in land use and land cover contribute to climate change and variability.

The research in human contributions and responses is based on the assumption that decision makers and other interested citizens need reliable scientific data to make decisions and actions that address the risks of and opportunities for changes in climate and related systems. The results of these USGCRP researchers are intended to shape public debates about climate-related issues. They should point at ways to reduce climate change and to adapt to climate variability.

In addition to these focus areas, the USGCRP also has a series of cross-cutting activities. The Observing and Monitoring the Climate System interagency working group develops research in the planning and operation of observing systems, including several new Earth-observing satellites, suborbital systems, surface networks, reference sites, and process studies. These can supply reliable data on the Earth's climate system and can be helpful in the prevention of natural disasters. USGCRP sections and researchers are all involved in communications initiatives to improve public understanding of climate change research and to make scientific findings more accessible to different audiences. Finally, the interagency working group of International Research Cooperation works with major international scientific organizations on behalf of the U.S. government and the scientific community.

Luca Prono
University of Nottingham

Utah

THE EARTH'S CLIMATE has changed since the Industrial Revolution, and there is substantial evidence that man is influencing the change through greenhouse gas production. Utah's contribution to global climate change is significant and comes mostly from carbon dioxide (CO_2) emissions from electricity production, mainly from coal consumption in power plants. Other leading contributors to Utah's greenhouse gas emissions are transportation, oil and gas production, and emissions from livestock and microbial processes. By 1993, Utah's per capita greenhouse gas emissions were twice the global average, and Utah's total emissions were 1.2 percent of the global total. Baseline CO_2 emissions for Utah are projected to be 54 percent above 1990 levels by 2010 and 95 percent above 1990 levels by 2020, mainly as a result of its growing population.

The effect of climate change on Utah is likely to be significant as well. The western United States is warming faster than the global average, and Utah's average temperature for the last decade (1996–2006) was 2 degrees F (1 degrees C) warmer than the state's average over the past 100 years. This trend is causing earlier springs, less snowfall and more rain, earlier plant blooms, and a shorter frost season, although Utah's mountain snowpack has shown no long-term changing trends. Furthermore, climate models project that, even if greenhouse gas emissions stabilize, global average temperatures will continue to increase for centuries, and current and future emissions will affect Earth's temperature more over the next 100 years than in the past 100 years. The effect is projected to be even greater on Utah. For example, a climate model based on a 2.5-times atmospheric CO_2 increase by 2100 projects that Utah's mean annual temperature will increase by approximately 8 degrees F (4.4 degrees C), whereas the global average will increase by 5 degrees F (2.7 degrees C).

Higher temperatures will likely mean earlier springs and less water storage in Utah. Earlier Utah springs will cause rainfall instead of snowfall. This will replenish the reservoirs, but the mountain snowpacks will receive less snowfall and melt earlier in the season, and the increased temperatures will increase evaporation in the reservoirs. The combination of these factors could jeopardize the state's already-taxed water supply. Climate model projections show that there may be heavier episodes of precipitation, but there also will be longer time spans between them.

This weather pattern may induce a higher chance of flash flooding and a larger amount of runoff to the rivers and reservoirs, instead of steady groundwater replenishment through more frequent, but less intense, rainfall. In addition, there will likely be ecological impacts from warming rivers and lakes—animal and insect populations may migrate, and insect migration times may no longer be synchronized with the plants they pollinate. Utah's agricultural economy may also be affected. With a 2 to 5 degree F increase, Utah's crops may thrive, but with the decreased water supply and infrequent rainfall, more frequent and severe droughts may counter the positive effects of a slight warming. Beyond an increase of a few degrees, crops may no longer endure the heat, and Utah's agriculture would need to change to accommodate the increased temperature.

GRASSROOT EFFORTS

Statewide, grassroots campaigns designed to educate the general public on the state of the science on climate change and its potential effect are neither common nor well received in Utah. However, over the past several years, state officials of this politically conservative state have become increasingly aware and proactive in climate discussions and policymaking. Recent policies have focused on energy efficiency in the form of corporate and personal tax credits for renewable energy, sales tax exemptions for renewable energy, and grants and loan programs for clean fuels and vehicle technology.

In May 2007, Utah was the sixth state to sign the Western Region Climate Action Pact, an agreement between states designed to set standards for reducing greenhouse gas emissions under a market-based program. In line with this new pact and Utah's focus on energy efficiency, Governor Jon Huntsman established a goal for increased energy efficiency in all state facilities of 20 percent by 2015. To aid in reaching this goal and in developing future policies, the governor formed the Blue Ribbon Advisory Council (BRAC). BRAC is a council of atmospheric, climate, and environmental scientists within Utah who advise the governor on the state of science on climate change. These scientists work alongside politicians and economists to evaluate the potential effect of policies designed to control and mitigate future climate change in Utah.

The scientific and political communities recognize that there is sound scientific evidence of human-induced climate change in Utah. This, in combination with the projections of future climate change and the concern over future water availability in the region, has spurred local and state leaders to take a close look at current climate initiatives and future policies. Although some of the general populace and politicians of Utah remain skeptical, many state officials are embracing advice from atmospheric scientists and climatologists and are making efforts to decrease Utah's footprint on global and regional climate change.

Utah Climate Center

THE UTAH CLIMATE Center aims to disseminate climate data and information and to use expertise in atmospheric science to interpret climate information in an accurate and original way for the public. The mission includes the design of new products to meet the present and future needs of agriculture, natural resources, government, industry, tourism, and educational organizations in Utah and the intermountain region. It is part of Utah State University and has been recognized as a state center by the American Association of State Climatologists.

Much of climate information requested from the center comes from published records and computerized databases. Published records in print form extend through 2006 and are available at the National Climatic Data Center (NCDC). Many original historical data records for Utah for the 19th and early 20th centuries have been transferred to and archived in the Utah State University Merrill-Cazier Library. The Utah Climate Center serves as an official repository for both published climate data records and official publications from the NCDC, encompassing several decades, as part of an official agreement with the NCDC.

The weather and climate data provided by the Utah Climate Center are elaborated with the cooperation of the National Oceanic and Atmospheric Administration, the Federal Aviation Administration, and other federal, state, and local authorities. The Utah Climate Center strives to provide quality climate data.

In the past, the Utah Climate Center has provided information through paper via the postal service, via fax, or via electronic mail, but it now uses a GIS search facility. The Utah Climate Center gathers and archives climatic data from 22 networks throughout the state. It also monitors and compiles information from networks used by the Forest Service, the University of Utah, the Department of Agriculture, the Bureau of Land Management, the Natural Resource Conservation Service, and others. Data such as maximum and minimum temperature, precipitation, evaporation and evapotranspiration (a measure of water lost from the soil as a result of transfer to plants, rather than straight evaporation), and solar radiation are collected from various sites. The center collects 57,000 pieces of information from hundreds of locations each day. The earliest data at the UCC date back to the 1870s and 1880s, although most of the stations were put in place in the 1900s.

The center was initially timid in assessing global warming. In 1998, then-director Donald T. Jensen stated that any signals of global warming in Utah "have been lost in the noise of other temperature fluctuations. … It's hard to find any real evidence here because temperatures here have always bounced up and down." However, with the passing years, the center has expressed views that are more attuned to the general opinion on global warming. Robert Gillies, the present director of the center, has pointed out that "the massive and growing scientific evidence has convinced the atmospheric science community that climate change is occurring, and is the result of human activities, specifically the release of greenhouse gases."

Uzbekistan

UZBEKISTAN IS LOCATED in central Asia, south of Kazakhstan. It is one of the world's two doubly-landlocked countries, being totally surrounded by other landlocked countries. The terrain is mostly rolling desert, with about 10 percent of the land lying within fertile river valleys. Poor conservation practices during the Soviet era had already caused enormous environmental damage, and many believe that this damage will exacerbate the effects of climate change in coming years.

The Aral Sea, which Uzbekistan shares with neighboring Kazakhstan, is one of modern history's great environmental disasters. The inland sea is over 5 million years old and used to be the world's fourth largest lake; today it is the world's eighth largest and is shrinking fast. During the Soviet era, massive amounts of water were diverted to irrigate crops, both from the Aral itself and from its feeder rivers. At the same time, it was used as a dumping ground for pesticides, raw sewage, and even nuclear waste.

Over the last two decades, 90 percent of the lake's source flow has dried up. Its surface area has decreased by 50–60 percent, and it has lost 80 percent of its volume. Salinity has increased from 10 grams per liter in 1960 to over 45 grams per liter in 2000. Many fish populations within the lake have long since died out. The lake has shrunk so much that it has actually split into separate parts, which had to be reconnected with a man-made channel.

Climate change will have an equally negative effect on the Aral. The glaciers that form an important part of the Aral Sea Basin shrank by 34 percent between 1960 and 2000. Runoff from mountain snow packs and annual rainfall has also decreased. The Amudarya River, a critical irrigation source, has decreased in flow to the point that it no longer reaches its outlet on the Aral.

Climate models expect the country's two main climate zones, the dry/tropical and moderate zones, to shift 93 to 124 mi. (150 to 200 km.) to the north by 2100. Air temperature is expected to increase by between 2.7–3.6 degrees F (1.5–2 degrees C). In the initial phases, the shift in climate zones and increased temperature, along with higher atmospheric concentrations of CO_2, might help the country's agricultural output, but with water sources already strained, that increase will be shortlived. Warmer temperatures and less water will damage the fertility of the grasslands, increase desertification, and reduce the country's livestock population.

Uzbekistan has a population of about 28 million people and is not a significant contributor to global carbon emissions. In 1998, per capita emissions were about 4,600 metric tons. About 80 percent of these emissions came from the release of gaseous fuels, 16 percent from liquid fuel sources, and 5 percent from cement manufacturing and solid fuel use.

The Uzbeki government has worked to study the potential effects of climate change and to raise public awareness of the problem. It is currently formulating plans to change damaging agricultural and industrial practices and move toward more sustainable growth.

Validation of Climate Models

THE CLIMATIC SYSTEM is constituted by four intimately interconnected subsystems—atmosphere, hydrosphere, cryosphere, and biosphere—which evolve under the action of macroscopic driving and modulating agents, such as solar heating, Earth's rotation, and gravitation. The climate system features many degrees of freedom, which make it complicated, and nonlinear interactions taking place on a vast range of time-space scales accompanying sensitive dependence on initial conditions, which makes it *complex*. The climate is defined as the set of statistical properties of the observable physical quantities of the climatic system.

The evaluation of the accuracy of numerical climate models and the definition of strategies for their improvement are crucial issues in the Earth system scientific community. On one hand, climate models of various degrees of complexity constitute tools of fundamental importance to reconstruct and project in the future the state of the planet and to test theories related to basic geophysical fluid dynamical properties of the atmosphere and of the ocean, as well as of the physical and chemical feedbacks within the various subdomains and between them. On the other hand, the outputs of climate models, and especially future climate projections, are gaining an ever-increasing relevance in several fields, such as ecology, economics, engineering, energy, and architecture, as well as for the process of policymaking at a national and international level. Regarding influences at the societal level of climate-related finding, the effects of the fourth assessment report of the Intergovernmental Panel on Climate Change (IPCC4AR) are unprecedented.

The validation or auditing—overall evaluation of accuracy—of a set of climate models is a delicate operation that can be decomposed in two related, albeit distinct, procedures. The first procedure is the intercomparison, which aims at assessing the consistency of the models in the simulation of certain physical phenomena over a certain time frame. The second procedure is the verification, the goal of which is to compare the models' outputs with corresponding observed or reconstructed quantities. Difficulties emerge because we always have to deal with three different kinds of attractor: the attractor of the real climate system, its reconstruction from observations, and the attractors of the climate models. Depending on the timescale of interest and on the problem under investigation, the relevant active degrees of freedom (mathematically corresponding to the separation between the slow and fast manifolds) needing the most careful representation change dramatically. For relatively short timescales (below 10 years), the atmospheric degrees of freedom are active, whereas the other subsystems can be considered to be essentially frozen. For longer timescales (100–1,000 years), the ocean dominates the dynamics of climate, whereas for even longer timescales (over 5,000 years), the continental ice sheet changes are the most relevant factors of variability. Therefore, the scientific community has produced different families of climate models, spanning a hierarchical ladder of complexity, each formulated and structured for specifically tackling a class of problems.

COUPLED GLOBAL CLIMATE AND REGIONAL CLIMATE MODELS

Here, whereas most considerations are quite general, we mainly refer to the coupled global climate models (GCMs) and regional climate models (RCMs) currently used for the simulation of the present climate and for the analysis of the climate variability up to centennial scales. In these models, whereas the dynamical processes of the atmosphere and of the hydrosphere are represented within a wide framework of numerical discretization techniques applied to simplified versions of thermodynamics and Navier-Stokes equations in a rotating environment, the continental ice sheets are typically taken as fixed parameters of the system. In contrast, the so-called subscale processes, which cannot be explicitly represented within the resolution of the model, are taken care of through simplified parameterizations.

Several crucial processes, such as radiative transfer, atmospheric convection, microphysics of clouds, land-atmosphere fluxes, ice dynamics, and eddies and mixing in the ocean, as well as most of those controlling the biosphere evolution, undergo severe simplifications. With time, the formulation of the GCMs has developed through refinements to the spatial resolution, ameliorations of numerical schemes, and improved parameterizations, as well as through the inclusion of a larger and larger set of processes, such as aerosol chemistry and interactive vegetation, which are relevant for the representation of the system feedbacks and forcings.

In addition, limited-area climate modeling faces the mathematical complication of being a time-varying boundary conditions problem, as RCMs are nested into driving GCMs. Therefore, RCMs tend to be enslaved on timescales, depending on the size (and position) of their domain, and in principle, the balances evaluated over the limited domain are constrained at all times. Therefore, climate reconstructions and projections performed with an RCM can critically depend on the driving GCM. Other more technical issues arise from the delicate process of matching the boundary conditions at the models' interface, where rather different spatial and time grids have to be joined.

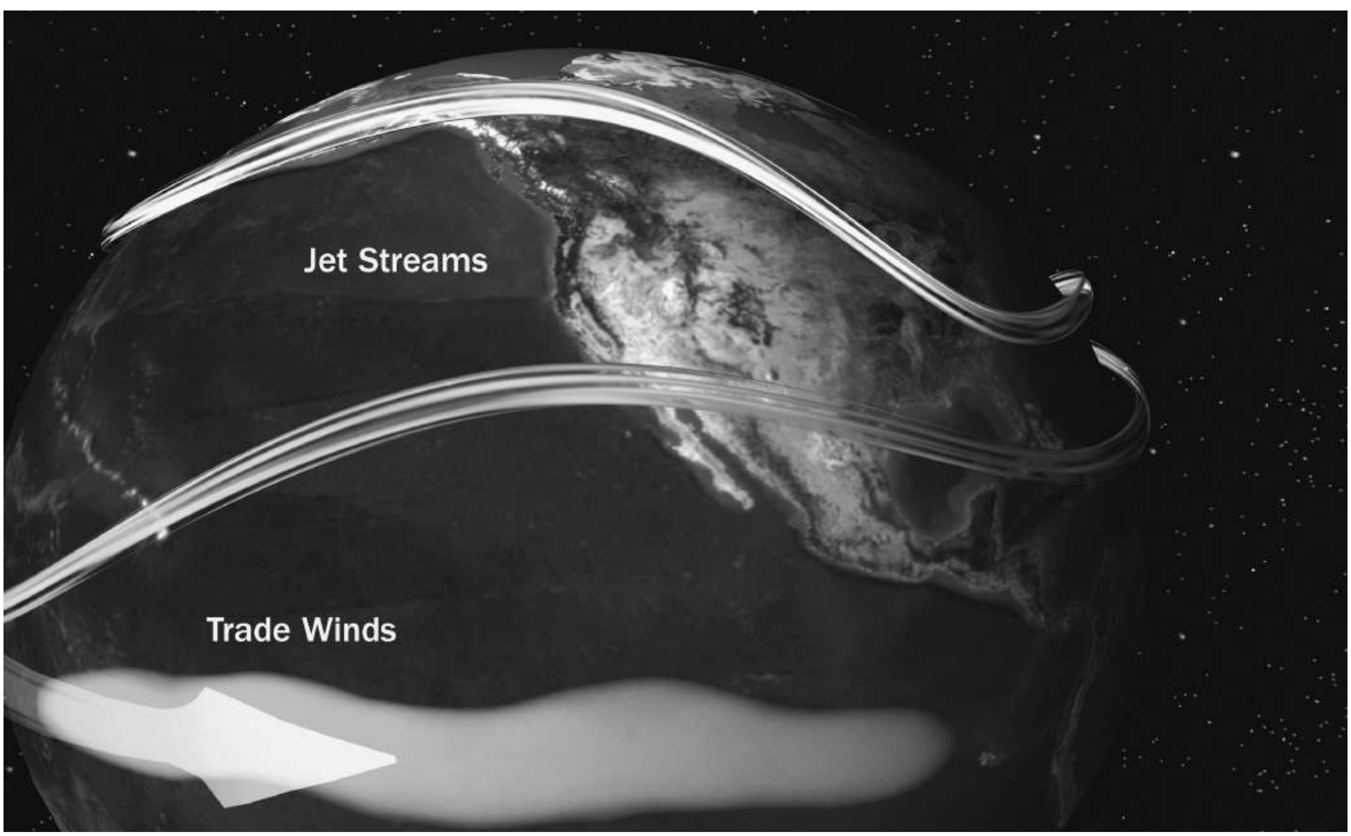
Model results and approximate theories can be tested only against past observational data of nonuniform quality and quantity, essentially because of the space and the timescales involved. The available historical observations sometimes feature a relatively low degree of reciprocal synchronic coherence and individually present problems of diachronic coherence, as a result of changes in the strategies of data gathering with time, whereas proxy data, by definition, provide only semiquantitative information on the past state of the climate system. Extensive scientific effort is aimed at improving the quality and quantity of the climatic databases. In particular, the best guess of the atmospheric state of roughly the last 50 years has been reconstructed by two independent research initiatives, through the variational adaptation of model trajectories to all available meteorological observations, including the satellite-retrieved data, producing the so-called reanalyses.

Given all the above mentioned difficulties, as well as the impossibility, because of the entropic time arrow, of repeating world experiments, the validation of GCMs is not epistemologically trivial, as the Galilean paradigmatic approach cannot be followed. Validation has to be framed in probabilistic terms, and the choice of the observables of interest is crucial for determining robust metrics able to audit effectively the models. Recently, the detailed investigation of the behavior of GCMs has been greatly fostered and facilitated, as some research initiatives have been providing open access to standardized outputs of simulations performed within a well-defined set of scenarios. Relevant examples to be mentioned are the project PRUDENCE (RCMs) and the PCMDI/CMIP3 initiative (GCMs included in the IPCC4AR).

One aim—from the end-user's viewpoint—is checking how realistic the modeled fields of practical interest are, such as surface temperature, pressure, and precipitation. In these terms, current GCMs feature a good degree of consistency and realism when considering present climate simulation, and they basically agree on short-term climate projections down to seasonal averages on continental scales. When decreasing the spatial or the temporal scale of interest, the signal-to-noise ratio of climatic signals—both observative and model generated—typically decreases, so that the validation of GCMs in control runs and climate change simulations becomes more difficult, even if improvements are observed over time by state-of-the-art models. Statistical and dynamical—provided by nested RCMs—downscaling of climatological variables enlarges the scopes of model validation. In particular, RCMs provide a better outlook on small-scale and nonlinear processes, such as surface-atmosphere coupling, precipitation, and effects of climate change on the biosphere.

However, the above-mentioned quantities can hardly be considered climate state variables, whereas strategies for model improvement can benefit from understanding the differences in the representation of the climatic machine among GCMs. The comparison of the statistical properties of bulk quantities defining the climatic state, such as top-of-the-atmosphere energy fluxes, tropospheric average temperature, tropopause height, geopotential height at various pressure levels, tropospheric average specific humidity, and ocean water structure, allows the definition of global metrics that constitute robust diagnostic tools. Moreover, to capture the differences in the representation of specific physical processes, it is necessary to use specialized diagnostic tools—process-oriented metrics—as indexes for model reliability.

Examples of these metrics are major features of atmospheric variability, such as tropical and extratropical cyclones; detailed balances, such as water vapor convergence over continents or river basins; teleconnection patterns, such as El Niño–Southern Oscillation or Madden–Julian Oscillation; or oceanic features, such as the overturning circulation and the Antarctic current intensity. The latter approach may be especially helpful in clarifying the distinction between the performance of the models in reproducing diagnostic and prognostic variables. Even if improvement



A NASA diagram of a strong El Niño striking surface waters in the Pacific Ocean. Warm water anomalies develop (indicated by shape at bottom) and westerly winds weaken, allowing the easterly winds to push the warm water against the South American coast.

is ongoing and promising, in these more fundamental metrics describing the climatic machine, current GCMs do not generally feature a comparable degree of consistency and realism at a quantitative level, and further investigations on basic physical and dynamical processes are needed.

Because the goal of a climate model is to reproduce the most relevant statistical properties of the climate system, the structural deficiencies, together with an unavoidably limited knowledge of the external forcings (uncertainties of the second kind) limit intrinsically the possibility of performing realistic simulations, especially affecting the possibility of representing abrupt climate change processes. The uncertainties of the initial conditions (uncertainties of the first kind), constituting, because of the chaotic nature of the system, probably the most critical issue in weather forecasting, are not in principle so troublesome—assuming that the system is ergodic—when considering the long-term behavior, where "long" is evaluated with respect to the longest timescale of the system. Nevertheless, to avoid transient behaviors, which may induce spurious trends in the large-scale climate variables on the multidecadal and centennial scales, it is crucial to initialize efficiently the slowest dynamical component of the GCMs, namely, the ocean. The validation of GCMs requires considering such uncertainties and devising strategies for limiting their influence when control run and, especially, climate change experiments are performed.

As for taking care of possible issues related to initial conditions, often an ensemble of simulations, where the same climate model is run under identical conditions from a slightly different initial state, allows a more detailed exploration of the phase space of the system, with a better sampling—on a finite time—of the attractor of the model. Some climate models have recently shown a rather encouraging ability to act as weather forecasting models, thus featuring encouraging local, in-phase space properties. Although such an ability gives evidence that short timescales' physical processes are well-represented, it says little on the overall performances when statistical properties are considered.

The structural deficiencies of a single GCM and the stability of its statistical properties can be addressed, at least empirically, by applying Monte Carlo techniques to generate an ensemble of simulations, each characterized by different values of some key uncertain parameters characterizing the global climatic properties, such as the climate sensitivity. Therefore, in this case, sampling is performed by considering attractors that are parametrically deformed.

To describe synthetically and comprehensively the outputs of a growing number of GCMs, recently it has become common to consider multimodel ensembles and to focus the attention of the ensemble mean and the ensemble spread of the models, taken respectively as the (possibly weighted) first two moments of the models outputs for the considered metric. Then information from rather different attractors is merged. Although this procedure surely has advantages, especially for GCMs intercomparison, such statistical estimators should not be interpreted in the standard way—with the mean approximating the truth and the standard deviation describing the uncertainty—because such a straightforward perspective relies on the (false) assumptions that the set is a probabilistic ensemble, formed by equivalent realizations of given process, and that the underlying probability distribution is unimodal.

Vanuatu

VANUATU IS A country located in the South Pacific Ocean, composed of an archipelago of 83 volcanic islands with a population around 220,000. It has been a global leader in the development of renewable resources for sustained energy.

Vanuatu is governed by a parliamentary democracy, with the prime minister, elected by Parliament, being the leader of the government.

Its economy is primarily agricultural, with 80 percent of the population engaged in agricultural activities. Coconut is by far the most important cash crop, making up more than 35 percent of the country's exports, with petroleum fuels making up the majority of its imports. Interestingly, Vanuatu is a tax haven and international financial center. Despite this, Vanuatu is still a country in need of substantial foreign aid.

Vanuatu is also member of Alliance of Small Island Developing States, which is a progressive force in the United Nations for initiating climate change protocols.

In 1999, coral reef scientists reported massive coral reef death directly attributed to global warming. This, along with the high price of importing oil, led Vanuatu to commence switching from reliance on fossil fuels to becoming dependent on renewable energy economies based on hydrogen fuel technologies.

Thus, in September 2000 at the Eco-Asia conference, the chairman of the conference, Vanuatu Parliament member and former prime minister Maxime Carlot Korman challenged top scientists in the field to find realistic solutions for sustainable resources.

Korman proposed that his country would be the testing site for these solutions because of a variety of social and economic issues. First of all, the country had an electricity consumption of around 35 GWh (by comparison, in 1998, California used 570,000 GWh), all of which produced by fossil fuels, which is an amount that could feasibly be replaced by renewable resources. Second, this project would need to be funded by private investors, and Vanuatu's status as a tax haven provided incentive. Finally, the combination of reducing the country's dependence on foreign oil at the same time it was bringing in foreign investors would help the country reduce its need for outside aid.

The plan was to primarily use geothermal and solar energy to produce hydrogen to be used in hydrogen-cell-powered generators. In addition, this would be supplemented by directly converting wind and water currents into energy and storing them in batteries. The endpoint was to stop importing fossil fuels by 2010 and by 2020, to eliminate remaining internal combustion engines. Some privately funded projects currently being undertaken include Pacific Energy installing solar panels to supply energy to schools, Unelco using Vanuatu's natural resources and producing a coconut oil-diesel fuel blend, and the VANREPA research company installing wind turbines and solar panels to generate electricity for local schools and a solar still to desalinize ocean water.

Although it appears imminent that, as of 2007, Vanuatu appears to be heading toward failing to meet its objective of independence of foreign oil by 2010, the country has made tremendous strides in becoming a green nation. Despite this, Vanuatu was listed as the world's happiest nation in 2006 by the Happiest Planet Index, a New Economics Foundation index based on human well-being and environmental impact.

Venezuela

VENEZUELA IS A major oil-producing state and a founding member of the Organization of Petroleum Exporting Countries (OPEC). Its leaders resist global efforts to accelerate cuts in carbon dioxide emissions, and the country's low-cost oil supply to Latin America and the Caribbean countries may stall regional transition to alternative energy sources. Venezuela has been criticized for encouraging energy inefficiency with oil subsidies, but new state environmental programs promote conservation.

Venezuela has proven crude oil reserves of 80,012 million barrels, and the state-owned Petróleos de Venezuela (PDV) is one of the world's largest oil companies. Most of the nation's oil exports enter the United States. PDV's subsidiary Citgo refines the crude oil in Texas. In addition to Venezuela's petroleum trade with the United States, its Chinese oil investments are growing. Venezuela recently signed energy agreements guaranteeing petroleum to many Latin America and Caribbean countries. These pacts include subsidized oil, an exchange of goods and services for oil, and interest-deferred financing for oil purchases.

Angel Falls in Venezuela is the world's highest free-falling, freshwater waterfall, with a drop of 2,648 feet.

There are many uncertainties about the potential effect of climate change on Venezuela. As a precautionary method, the development of agricultural varieties resistant to drought and adverse climate conditions has been recommended. Flooding is likely in other areas. In December 1999, Venezuela experienced its highest monthly rainfall in a century. Massive landslides and flooding led to the deaths of more than 30,000 people. The risk of increased mortality from diseases with mosquito vectors such as yellow fever increases after floods, and malaria has been documented to increase in the country's coastal regions after the onset of El Niño.

Although the country has been criticized for contributing to global warming, some conservation measures are in place. Venezuela ratified the UN Framework Convention on Climate Change in 1994 and the Kyoto Protocol in 2005. In 2006, President Hugo Chavez launched a reforestation program to plant 100 million trees. These trees will be intercropped with cacao and coffee to give farmers an incentive to abandon environmentally destructive farming methods. Chavez also launched an energy efficiency program that promotes improved light bulbs and natural gas, wind, and solar power. Venezuela's large reserves of natural gas remain largely untapped.

Venezuela is among the top 20 countries in terms of endemism, and more than 200 protected areas cover in excess of 70 percent of the nation. Its diverse climatic and biogeographical regions cover a range of elevations, and there are 1,740 mi. (2,800 km.) of coastline, including vast mangrove swamps and numerous islands. There has been a documented retreat of glaciers in the Sierra Nevada range, however, and the glacier on Pico Bolivar may completely disappear during the next decade.

A climate change mystery occurs in Venezuela: methane builds up over the country at night. Scientists that researched this peculiar phenomenon have recently suggested, amid some skepticism, that the methane is being released from certain plants growing in the savanna.

Vermont

KNOWN AS THE Green Mountain State, Vermont underwent widespread reforestation following farm abandonment in the mid-1800s. In addition to the existence of several land trusts, the Green Mountain Club has protected more than 55 mi. (88 km.) along a hikers' Long Trail. There is a strong state environmental movement, with local groups and chapters of national organizations. Vermont hosts one of the nation's leading environmental law and policy programs at the Vermont Law School. The state government has invested in energy efficiency and joined regional efforts to reduce greenhouse gas (GHG) emissions. Climate change and global warming concern Vermonters because of the economic revenue the state gains from nature tourism, particularly during the autumn foliage and winter skiing seasons.

In spite of some local variation, the northeastern United States has experienced a temperature increase of 1.8 degrees between 1899 and 2000. The average length of the annual growing season has been extended by eight days, and bloom dates have changed. Scientists have documented quicker thawing of lakes, known as ice-in and ice-out dates, as well as earlier runoff from mountains.

Data have suggested that maple production from the sugar maple (*Acer saccarum*), the Vermont state tree, may be vulnerable to climate shifts. Under several climate change models, this species may entirely shift out of the United States. Studies suggest that seven of 80 eastern tree species may decline by as much as 90 percent in the next century if temperature changes continue at current rates.

In terms of GHG emissions, Vermont's energy portfolio is one of the greenest in the nation. Vermont Yankee Nuclear Power Plant, online since 1973, provides approximately 35 percent of the state's energy requirements. Its license is scheduled to expire in 2012, but petitions are in place for renewal and expansion of production. There is some local opposition to both proposals.

Energy from Hydro-Quebec, an extensive series of dams across Quebec Province in Canada, provides a third of Vermont's energy needs. Although hydropower is a renewable energy source, the creation of the project's dams has been controversial, in that it caused flooding of indigenous lands. Research on dam building also suggests that methane may be released from the decomposition of flooded forests. Releases are expected to be considerably higher in tropical ecosystems, but more research is needed to determine the exact levels. Fossil fuels are also used in the creation and maintenance of dam structures.

Nearly one-third of Vermont's energy is created from a mixture of in-state renewable energy resources. The Cow Power program uses manure to create energy and provide income to dairy farmers. Efficiency Vermont is the nation's first statewide provider of energy efficiency services. The program is operated by an independent, nonprofit organization under contract to the Vermont Public Service Board. It provides technical advice, financial assistance, and design guidance to make homes, schools, and businesses more energy efficient. The program is funded by a charge on users' electric bills.

In 2006, Governor Jim Douglas announced a public-private partnership that will invest $20 million in energy efficiency. He also extended state energy efficiency programs. In addition to $8 million in weatherization grants available to low-income Vermonters each year, Douglas' program also created private capital to provide $20 million no- or low-interest loans to assist homeowners and small businesses to make buildings more fuel efficient.

Vermont has joined regional climate change mitigation initiatives. The state joined seven others in 2004 in a legal suit against several energy companies to require them to reduce carbon dioxide emissions and control GHG outputs. Vermont is part of the Regional Greenhouse Gas Initiative's cap-and-trade program for power plants, aimed at reducing carbon emissions. Six New England states and five eastern Canadian provinces adopted a joint Climate Change Action Plan to reduce GHG emissions.

Vermont Law School

VERMONT LAW SCHOOL'S (VLS's) environmental law program is ranked number one in the nation by *U.S. News & World Report*. Students at VLS participate in a variety of legal and environmental study programs, many of which focus on climate change and related policies. The Environmental Law Center at VLS includes several specialized institutes and clinics that are involved in various aspects of climate change research and litigation. At present, VLS is home to 612 students, participating in four different degree programs: Juris Doctor (JD), Master of Studies in Environmental Law (MSEL), Master of Laws in Environmental Law (LLM), and Master of Laws in American Legal Studies (LLM) for international students.

VLS is known not only for its academic commitment to reducing the effects of global climate change but also for putting this commitment into action in its day-to-day operations. The U.S. Green Building Council awarded Debevoise Hall, VLS's main administration and academic building, with a Leader in Energy Efficiency and Design Silver Certification. The renovated 1893 school building features an energy-efficient, compact fluorescent lighting system that is linked to sensors that turn off the lights when no one is present. A cross-flow heat exchanger and desiccant wheel provide temperature- and humidity-adjusted airflow year-round. Debevoise Hall and the adjacent classroom building Oakes Hall (constructed in 1998) both feature composting toilets and other water conservation measures. In Oakes Hall, these measures have decreased the projected water consumption rate from 15 gallons used per person, per day, to 15.5 gallons used per day, total, for the entire facility.

VLS contains several academic centers that support climate change research, litigation, and problem solving. The Institute for Energy and the Environment is VLS's premier research institution on energy policy and law. Professor Michael H. Dworkin, former chair of the Vermont Public Service Board (1999–2005), directs the institute. The institute provides conferences and produces scholarly publications on topics such as biofuels and related policy recommendations; net-metering legislation; energy efficiency and the need for demand-side regulation; and health and environmental costs of burning fossil fuels.

The Land Use Institute, directed by Professor L. Kinvin Wroth, seeks to address the legal and planning issues surrounding current forms of land use. This includes sustainable design and ecology planning, siting of new energy facilities, revisions to permit composition and process, and the scope of eminent domain.

The Climate Legacy Initiative, under the directorship of Professor Burns Weston, has been established to clarify and advocate the legal rights, including human rights, of present and future generations relative to the harms likely to result from global warming both in the United States and internationally.

VLS also offers an Environmental and Natural Resources Law Clinic, the *Vermont Journal of Environmental Law*, the Environmental Tax Policy Institute, and an environmental summer session. Because global climate change is one of the world's most expansive environmental challenges, each of these programs are working to address global warming–related issues and inspire future problem solvers. In all, VLS promotes a commitment to bettering the environment through education.

Vienna Convention

THE VIENNA CONVENTION for the Protection of the Ozone Layer came into being in March 1985. The convention was developed initially out of recognition of the international concern over the loss of the ozone in the stratosphere. Subsequently, the Montreal Protocol in 1987 strengthened the convention, which was further adjusted and amended on June 29, 1990.

The concern over ozone was linked to attention to the observed phenomena of climate change. Eventually, the issue of the ozone appears to have been stabilized, and the issue of climate change evolved into a larger international concern.

The attention to the ozone issue relied on the scientific understanding of the effects of chlorofluorocarbons in the context of the atmosphere. As a result of the interest in the subject, scientific research invested in developing increasingly complex models of the atmosphere to more accurately address climate issues.

Over time, concern over the issue of the loss of ozone in the stratosphere declined, as international efforts appeared to have improved the condition of the stratospheric ozone layer. Ozone levels in the troposphere continue to be a contributor to local pollution.

As the concern over stratospheric ozone declined, the broader concern over climate change that was noted in the convention continued and assumed a proportionately larger role. The improved science used to address the ozone issues then also became valuable in addressing the more complex climate change matter.

The development of the convention and climate change regulations through the United Nations Environment Programme has been closely associated with the science and models of the atmosphere. The science was addressed in related conferences and workshops including the Villach Conference in 1985. Eventually, the convention led to the formulation of the UN Framework Convention on Climate Change.

The preamble to the convention indicates the generally accepted views of the international community. This preamble mentions the relationship between the environment, its modification, and the potentially harmful effects on human health.

The awareness noted in the preamble is an acknowledgement that human activity can and does modify the environment. It also permits the recognition of the association between modifying the environment and its effect on human health itself. This awareness then establishes the possibility of regulating human activity.

Human activity is also associated with relevant scientific and technical considerations. There is then a recognized need for research and systematic observations into the phenomena. The use of science and technology is an important part of the convention and its implementation.

The intended result of the convention is twofold. First, the twin concerns are to protect human health and the environment. The particular focus then is the concern about adverse effects to both humans and the environment, which result specifically from modifications of the stratospheric ozone layer.

The convention is not concerned with all modifications of the ozone layer but only those that have adverse effects on human health and the environment. In fact, any modification of the ozone layer that has a positive effect on human health and the environment would be favorable. Under the definitions in Article 1, "adverse effects" refer to changes in the physical environment or biota, including changes in climate. The relevant changes are those that have significant deleterious effects on human health, on ecosystems whether natural or managed, and on "materials useful to mankind."

To achieve the intended result, the preamble raises some significant considerations. The reference to principle 21 of the Declaration of the UN Conference on the Human Environment highlights the context for the convention, which includes the sovereignty of each country, also known as a state, over its own domain and resources. It also underlines the responsibility of each such state not to cause damage beyond its national jurisdiction or to other states.

In such circumstances, a state's performance can then be evaluated in the international context against its own sovereign jurisdiction and its effect beyond its boundaries.

The sovereignty of each state also necessarily involves the recognition of cooperation between states. It is through cooperation and action that states can then be brought within the scope of international law and the Charter of the United Nations.

The preamble discloses its relatively recent formulation when it includes nonsovereign entities in its discussions. It generally acknowledges international and national organizations, whose work and studies are pertinent to the scope of the convention. An example of such an organization noted in the convention is the World Plan of Action on the Ozone Layer of the UN Environment Programme.

Another significant feature of the convention is the attention to developing countries in the global effort. The preamble generally recognizes the circumstances and particular requirements of developing countries. This recognition eventually leads to the more complex form of differentiated contributions to the total human activities and their consequences.

The agency responsible for the Convention is the Ozone Secretariat of the UN Environment Programme. In 1988, the assessment panel process was initiated under the Montreal Protocol, Article 6, and four panels were established. These are the panels for scientific, environmental, technology, and economic assessments. In 1990, the Panels for Technical Assessment and for Economic Assessment were merged into the Technology and Economic Assessment Panel.

Under Article 6 of the convention, a Conference of the Parties was established. The Conference of the Parties to the Convention, in its decision VCV/2 of its fifth meeting, acknowledges and encourages the collaboration of the three assessment panels with other entities. These entities link the convention with other international entities involved in addressing climate change issues. These other entities named in this decision are the Intergovernmental Panel on Climate Change, the Subsidiary Body on Scientific, Technical and Technological Advice under the UN Framework Convention on Climate Change, the International Civil Aviation Organization, and the World Meteorological Organization.

These entities were in addition to those recognized in Article 6, which included the World Health Organization and the International Atomic Energy Agency. Within limits, it also allowed for any state not a party to this convention and for any body or agency, whether national or international, governmental or nongovernmental, to be represented at the Conference of the Parties by observers.

The convention is specifically referred to in the preamble of the UN Framework Convention on Climate Change, signed in 1992, which came into force in 1994.

Vietnam

THIS SOUTHEAST ASIAN country, with a long coastline on the South China Sea, has a land area of 128,065 sq. mi. (331,689 sq. km.), with a population of 87,375,000 (2006 est.) and a population density of 655 people per sq. mi. (253 people per sq. km.). The largest city and the former capital of South Vietnam, Ho Chi Minh City (formerly Saigon) has a population of 3,525,300, making it the 49th largest in the world. Some 17 percent of the land in Vietnam is arable, with 4 percent being under permanent cultivation and 1 percent used as meadow or pasture. In addition, 30 percent of the country is forested, with an increasing logging industry operating in the country.

As there are three major rivers in Vietnam—the Red River, the Pearl River, and the Mekong—there has been a heavy investment in hydropower. In 1964, at a speech at Johns Hopkins University, U.S. President Lyndon B. Johnson offered a hydroelectric scheme for the Mekong River that was quickly dubbed the TVA for the Mekong. It was rejected by Ho Chi Minh, and the Vietnam War, which was escalating at that time, led to massive bombing of parts of the country, destruction of much of the infrastructure of both North Vietnam and South Vietnam, and the defoliation of some parts of the jungle. Following the end of the war in 1975 and the nation's reunification in the following year, the country was desperately poor. In spite of this, heavy government investment in hydropower then results in it now accounting for 59.3 percent of the country's electricity production, with the rest coming from fossil fuels. Electricity production accounts for 25 percent of the carbon dioxide emissions in the country, with 38 percent from transportation and 30 percent from manufacturing and construction.

During the 1990s, Vietnam became a major tourist destination, and this has led to a significant rise in the rate of per capita carbon dioxide emissions, from 0.3 metric tons per person in 1990 to 1.18 metric tons per person by 2004. In 1998, 48 percent of carbon dioxide emissions in the country was from liquid fuels, 37 percent from solid fuels, 8 percent from gas flaring, and 7 percent from cement manufacturing.

The Vietnamese government of Vo Chi Cong took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992. The Vietnamese government signed the Kyoto Protocol to the UN Framework Convention on Climate Change on December 3, 1998, which was ratified on September 25, 2002, with it entering into force on February 16, 2005.

Villach Conference

THE CONFERENCE HELD in Villach, Austria, from October 9 to 15, 1985, was the result of the continuing work of several international entities. In some views, the background to the conference and the starting point for internationally cohesive attempts to understand the issues related to the stratospheric ozone layer depletion and climate change have been traced to the UN Conference on Human Development in Stockholm in 1972. The technical, scientific understanding of the possibility of human-induced effects on the ozone layer and of climate change developed in the diplomatic context as complementary efforts linked through a reliance on common research initiatives.

A World Climate Conference held in Geneva in 1979 continued the efforts of the 1972 UN Conference on Human Development and led to the World Climate Programme. The World Meteorological Organization, the UN Environment Programme, and the International Council of Scientific Unions collaborated to hold a series of workshops that have come to be known as the Villach Conference.

The UN Environment Programme Ad Hoc Working Group of Legal and Technical Experts for the Elaboration of a Global Framework Convention for the Protection of the Ozone Layer was established by decision of the UN Environment Programme Governing Council decision 12/14, part I. The first part of the fourth session of the working group was held at the Palais des Nations, Geneva, from October 22 to 26, 1984.

The Working Group was also informed of the collaborative effort of the UN Environment Programme, the World Meteorological Organization, and the International Council of Scientific Unions to hold a major scientific conference to assess the carbon dioxide/ozone and climate question in October 1985 at Villach, Austria, with the support of the government of Austria.

Located at the intersection of the ozone and climate change issues, the Villach Conference became immediately significant to the Working Groups of both UN endeavors and to the overall development of international initiatives to address atmospheric environmental issues. A workshop on chlorofluorocarbons at Villach initiated the processes that led to a protocol to the Vienna Convention, which had been signed earlier that year in March 1985. The same conference augmented the UN Environment Programme's role in determining the assessment of the greenhouse gas/climate issue. In this regard, the October 1985 Villach Conference was significant.

The participants at the Villach Conference were a small group of environmental scientists and research managers in nongovernmental organizations. The dominant contribution of these participants was their expertise in climate modeling. With accreditation from recognized scientific institutions such as the International Institute for Applied Systems Analysis and from Harvard University, the results of this series of workshops carried considerable weight internationally. Even before the conference, a majority of the scientists who attended had publicly advocated what they considered an imperative to respond to a perceived threat to planetary climate stability within a strategy that was consistent with sustainable development, which was eventually incorporated in the Brundtland Report. Through affiliations with nongovernmental institutions, the scientists had improved modeling techniques that they relied on and that led them to generally agree with the conclusions and recommendations of the conference.

It was at the Villach Conference that the scientific community present arrived at an initial consensus as to the technical features of greenhouse gases, the depletion of the stratospheric ozone layer, and the chemical reactions that were relevant.

The general conclusion of the scientists and participants at the conference was that they could anticipate an unprecedented rise of global mean temperature in the first half of the 21st century. The scale and actual increase in global mean temperature was expected to be higher than any rise in the record of the planet's history. To mitigate the perceived events, the participants recommended a strategy that relied on technical and science-based research to establish target emission or concentration limits. In doing so, they sought to regulate the rate of change of global mean temperature within specific parameters.

Another result of the work by the participants at Villach was the establishment of the Advisory Group on Greenhouse Gases in 1986. This group was established to ensure continued academic and public interest in the effect of rising levels of greenhouse gases on the ozone layer and on climate change. The Advisory Group on Greenhouse Gases was jointly sponsored by the World Meteorological Organization, the UN Environment Programme, and the International Council of Science Unions.

The Brundtland Report, published in 1987, popularized sustainable development and advocated the development of a low-energy economy. This publication included a section on energy authored by Professor Gordon Goodman, who was by then a prominent member of the Advisory Group on Greenhouse Gases.

Work by the Advisory Group on Greenhouse Gases subsequently led to the 1988 Conference on the Changing Atmosphere: Implications for Global Security in Toronto, Canada, which called for 20 percent reductions in CO_2 emissions. The Advisory Group followed that up by preparing the Meeting of Legal and Policy Experts in February 1989 in Ottawa, which recommended an umbrella consortium to protect the atmosphere. The 1988 Toronto Conference then led to the establishment of the Intergovernmental Panel on Climate Change, with the mandate for continuing international research on climate change phenomena.

Virginia

THE COMMONWEALTH OF Virginia is a southern Atlantic state on the eastern seaboard of the United States of America. Virginia is the 35th largest state in the United States, with an area of over 42,000 sq.

mi. (108,780 sq. km.) and an estimated population of about 7.6 million. Virginia's state capital is Richmond, located in central Virginia, and the largest city is Virginia Beach, on the coast. Cities in the commonwealth are considered independent and function in the same manner as counties. Virginia's geography is divided into six different regions, from the tidewater along Chesapeake Bay on the eastern coast, to the Appalachian Plateau in the West. Virginia's climate is considered mild for the United States but can be quite variable because of significant topographic differences across the state and the influence of the Atlantic Ocean. The regions east of the Blue Ridge, as well as the southern part of the Shenandoah Valley, are considered a humid subtropical climate (Koppen climate classification *Cfa*). In the mountainous areas between the Allegheny and Blue Ridge mountains in the west, the climate becomes humid continental (Koppen climate classification *Dfa*).

Virginia was founded on May 13, 1607, at Jamestown, the first permanent English settlement in North America, and is one of the original 13 colonies of the American Revolution. Virginia joined the Union on June 25, 1788, and was the 10th state to ratify the U.S. Constitution. More U.S. presidents (eight) have come from Virginia than from any other state. The current and 70th governor of Virginia is Democrat Tim Kaine, who assumed office in January 2006. Virginia's geography varies considerably across the state, including the Shenandoah Valley, bordered by the Allegheny and Blue Ridge mountains in the west; the rolling hills of the central piedmont; and the flat eastern coastal plain extending from the piedmont to the Atlantic Ocean. Elevations in Virginia range from sea level to nearly 6,000 ft. at the summit of Mt. Rogers.

The state is divided into six distinct geographical regions: the ridge and valley between the Blue Ridge Mountains to the east and the Appalachian and Allegheny plateaus to the west; the Shenandoah Valley, located within the ridge and valley; the Blue Ridge Mountains between the ridge and valley to the west and the piedmont region to the east; the foothills between the piedmont and the Blue Ridge Mountains; the piedmont between the Blue Ridge Mountains to the west and the tidewater region to the east; and, the tidewater between the fall line to the west and the Atlantic east, including the eastern shore.

The southern area of Virginia's Shenandoah Valley is considered a humid subtropical climate.

Virginia has five distinct climate regions: tidewater, piedmont, northern Virginia, western mountains, and southwestern mountains. Climate varies significantly across the state because of differences in topography, the influence of the Atlantic Ocean and the Gulf Stream in the east, and the complex pattern of rivers and streams. Much of the precipitation that Virginia receives results from storms associated with low-pressure (cyclone) frontal systems—warm and cold fronts that typically move from west to east across the state, curving northwestward as they reach the Atlantic Ocean. Virginia also experiences occasional tropical storm activity, most often in early August and September, and typically through the venue of the mouth of the Chesapeake Bay. The tropical storms can provide significant amounts of precipitation. In recent years, development trends in northern Virginia extending out from Washington, D.C., have created an urban heat-island effect characteristic of other large urban areas.

In Virginia, emissions of carbon dioxide, one of the primary greenhouse gases that alter the Earth's climate, have risen by over 30 percent since 1990, driven by economic growth, development patterns, and increased transportation trends. Human-induced climate change is expected to have many effects on Virginia's weather, wildlife, food production, and water supplies. Sea level in the mid-Atlantic region is estimated to rise several inches in the coming decades, threatening low-lying areas and coastal developments. Changes in precipitation and temperature regimes have the potential to disrupt agriculture and forestry. Although at present it is rare for a major hurricane to threaten the Virginia coast, hurricanes make the coastal area of Virginia vulnerable. Increased tropical storm activity that might result from climate change would carry the threat of damage to Virginia's communities.

Virginia has begun to address the issue of climate change in several ways. Virginia is one of several states to have completed, in 2007, a comprehensive Climate Action Plan, manifested as the Virginia Energy Plan. The process of developing a climate action plan includes identifying cost-effective opportunities by which a state may reduce emissions of the greenhouse gases that alter climate. However, unless clear policies are stipulated, climate action plans cannot ensure real reductions in emissions. Virginia adopted a voluntary renewable portfolio standard in 2007, and in May 2007, Governor Tim Kaine announced that Virginia had joined the Climate Registry, a state-sponsored initiative to standardize methods to record and measure greenhouse gas emissions.

Volcanism

MEMBERS OF THE scientific community by and large concur that the Earth is undergoing a change in climate and that global warming is occurring at an increasing rate. In fact, scientific modeling suggests that Earth will experience an increase in temperature during the next 100 years at a pace up to four times greater than that in the previous 100 years. To a large extent this acceleration in the late 20th century is attributed to carbon dioxide (CO_2) emissions generated by human activity. Carbon dioxide acts like a glass barrier over the Earth, preventing heat from leaking into the environment, and thus creating a greenhouse effect. Human activity has counteracted global warming to a small degree by emitting aerosols in the environment, causing global cooling.

Volcanism is another contributing factor to climate change. Each volcano affects the climate based on its location and the nature and extent of an eruption.

Similar to human activity, volcanism leads to both global warming and cooling. The effect of volcanism on climate depends on the interaction between the sun's heat and the volcanic debris. In essence, scientists believe that ongoing volcanic eruptions have maintained the Earth's temperate climate for millions of years. Circumstantial evidence suggests that volcanism can influence short-term weather patterns in addition to having an effect on long-term climate change.

Volcanic dust blown into the atmosphere can remain for months and produce temporary cooling, the degree to which is dependent on the volume of dust, and the duration of which is dependent on the size of the dust particles. The strength of gases can vary greatly among volcanoes. Water vapor is typically the most abundant volcanic gas, followed by carbon dioxide and sulfur dioxide. Other principal volcanic gases include hydrogen sulfide, hydrogen chloride, and hydrogen fluoride.

Volcanoes that discharge great quantities of sulfur compounds affect the climate more significantly than those that release only dust. In fact, the greatest volcanic effect on the Earth's short-term weather patterns is caused by sulfur dioxide gas. Sulfur dioxide can form sulfuric acid aerosols that reflect the sun's heat and trigger cooling of the Earth's surface for as long as two years. Scientific literature frequently refers to the drop in global temperature after the eruption of Mount Pinatubo, Philippines, in 1991 and the very cold temperatures leading to crop failures and famine in North America and Europe for two years following the eruption of Mt. Tambora, Indonesia, in 1815 as examples of this effect. Furthermore, sulfuric dioxide can form acid rain, a combination of sulfuric acid and nitric acid. Acid rain, which is also caused by the burning of fossil fuels, is a critical environmental problem that can

Yasur volcano in Vanuatu is one of the world's most active volcanoes, erupting dozens of times a day for about 800 years.

injure lakes, streams, and forests and the inhabitants of these ecosystems.

In addition, volcanoes discharge water and carbon dioxide in large quantities in the form of atmospheric gases, and can absorb and retain in the atmosphere heat radiation emanating from the ground. Estimates suggest that water makes up to 99 percent of gas in volcanic expulsions. This short-term warming of the air leads the water to become rain within a matter of hours or days and the carbon dioxide to dissolve in the ocean or to be absorbed by plants. The majority of the heat energy connected to global warming exists in the ocean. If the oceanic depth at which heat is stored is decreased, then global temperature increases are expected to be greater than predicted.

Volcanic eruptions combined with man-made chlorofluorocarbons (CFCs) also can contribute to ozone depletion. CFCs were developed in the early 1930s and were used in industrial, commercial, and household applications, such as refrigeration units and aerosol propellants, because they were nontoxic and nonflammable and met a number of safety criteria. In February 1992, however, following evidence that CFCs contributed to depletion of the ozone layer, the United States announced the phase-out of the production of CFCs by December 1995. Members of the Montreal Protocol in 1992 followed suit and agreed to an accelerated phase-out by the end of 1995 as well.

The ozone layer, which rests in the stratosphere and begins at 7.5 mi. (12 km.) above the Earth, is a shield that protects living beings from ultraviolet-B (UV-B), the sun's most harmful UV radiation. In high doses, UV-B can lead to cellular damage in plants and animals. Scientists believe that global warming will lead to a weakened ozone layer, because as the Earth's surface temperature rises, the stratosphere will get colder, slowing the natural repairing of the ozone layer. Decreased ozone in the stratosphere results in lower temperatures.

Unlike ozone depletion created by man-made CFCs, which will take decades to repair, theories indicate that repair of damage to the ozone layer caused by volcanoes occurred as volcanic activity diminished. Recent mathematical models intimate that a volcanism in Siberia of great proportion significantly depleted the ozone layer.

Finally, hydrogen fluoride gas can concentrate in rain or on ash particles, contaminating grass, streams, and lakes with excess fluorine. Excess fluorine in grass and water supplies can poison the animals that eat and drink at contaminated sites, eventually causing fluorisis, which destroys bones.

Von Neumann, John (1903–57)

JOHN VON NEUMANN is a Hungarian-born American mathematician who contributed important theories to all the different branches of the discipline. His discoveries influenced quantum theory, automata theory, economics, and defense planning. Von Neumann was one of the founders of game theory and, along with Alan Turing and Claude Shannon, was one of the conceptual inventors of the stored-program digital computer. He is mostly remembered in the field of global warming for his elaboration of general circulation models and for his 1955 article in *Fortune*, in which he stated that "microscopic layers of colored matter spread on an icy surface, or in the atmosphere above one, could inhibit the reflection-radiation process, melt the ice, and change the local climate." This is one of the earliest conceptualizations of the problem of global warming.

John Von Neumann was born János Neumann in Budapest, Hungary, on December 28, 1903, into a wealthy and completely assimilated Jewish family. His father was a banker, and his mother originally came from a family who made a fortune selling farm equipment. John was a child prodigy and was initially educated by private tutors in mathematics and foreign languages. In 1911, he entered Budapest's most prestigious school, the Lutheran Gymnasium. When Bela Kun established his revolutionary government, Von Neumann's family fled Hungary and briefly emigrated to Austria. Kun's government failed after only five months. Because it was mainly composed by Jews, Von Neumann's family, no matter how hostile to the regime, was blamed, together with many other Jews, for the brutality of the revolutionary government. In 1921, Von Neumann completed his education at the gymnasium and his father strongly advised him to take up a career in business and not in mathematics, where Von Neumann's talent was already obvious. His father was afraid that mathematics would not allow Von Neumann to lead a wealthy and comfortable existence. As a compromise, it was decided that Von Neumann would study both chemistry and mathematics. In spite of the strict quotas for Jewish entry to university, Von Neumann succeeded in attending the University of Budapest for mathematics and the University of Berlin for chemistry. He later switched to the Swiss Federal Institute in Zürich, from where he graduated with a degree in chemical engineering in 1925. The following year, he obtained a doctorate in mathematics from the University of Budapest.

Von Neumann quickly gained a reputation in set theory, algebra, and quantum mechanics. In particular, his paper "An Axiomatization of Set Theory" (1925) was read and appreciated by the famous mathematician David Hilbert. Because of Hilbert's interest, Von Neumann worked at the University of Göttingen in 1926 and 1927. Von Neumann was then employed as a *Privatdozent* ("private lecturer") at the Universities of Berlin (1927–29) and Hamburg (1929–30). At a time when Europe was characterized by political unrest and totalitarianism, he was invited to visit Princeton University in 1929 to lecture on quantum theory. He was then hired at Princeton as visiting professor the following year, although teaching was not one of his strongest assets, and when the Institute for Advanced Studies was founded there in 1933, he was appointed to be one of the original six professors of mathematics, a position he retained for the rest of his life. In 1930, Von Neumann married Mariette Koevesi. They had one child, Marina, who later became an economist. The couple separated amicably in 1937, and the following year Von Neumann married his childhood sweetheart Klara Dan, with whom he remained until his death. After his appointment at the Institute for Advanced Studies, Von Neumann resigned from all his German academic positions. Being a Jew, he could not work for a Nazi state. He prophetically stated that if Hitler remained in power, it would ruin German science for a long time.

During the World War II, Von Neumann worked for the Manhattan Project at the invitation of its director Robert Oppenheimer. His expertise in the nonlinear physics of hydrodynamics and shock waves was instrumental in the design of the Fat Man atomic bomb dropped on the Japanese port of Nagasaki. Von Neumann argued against dropping the bomb in Tokyo on the Imperial Palace. In the postwar years, Von Neumann continued to work as a consultant to government and industry. Starting in 1944, he contributed important insights for the development of the U.S. Army's ENIAC computer, initially designed by J. Presper Eckert, Jr., and John W. Mauchly. In a crucial contribution, Von Neumann modified the ENIAC to run as a stored-program machine. Von Neumann did not invent the computer itself, but he invented the software that made it run. The ENIAC machine was a combination of electronic hardware and punch-card software that allowed it to be employed for a variety of uses including weather forecast. Von Neumann then campaigned to build an improved and faster computer at the Institute for Advanced Study. The institute's machine, which began operating in 1951, used binary arithmetic where the ENIAC had used decimal numbers. Von Neumann's publications on computer design (1945–51) caused a clash with Eckert and Mauchly, who wanted to patent their contributions, and paved the way for the independent construction of similar machines around the world. Von Neumann's intuition for a single-processor, stored-program computer became the accepted standard.

As a consultant for RAND Corporation, Neumann was given the task of planning a nuclear strategy for the U.S. Air Force. In this capacity, he was a strong advocate of nuclear weapons, and he became one of President Dwight Eisenhower's top advisers on his nuclear deterrence policy. Von Neumann was diagnosed with bone cancer in 1955. In spite of his deteriorating health, he continued to work, and in 1956 he was honored with the Enrico Fermi Award. He converted to Roman Catholicism just before his death on February 8, 1957, in Washington, D.C.

Vostok Core

RUSSIA'S VOSTOK STATION is located in east Antarctica. Vostok Station holds the record for lowest temperature ever recorded at minus 129 degrees F (minus 89 degrees C). Soviet researchers began deep drilling at the Vostok Station in 1980. The ice cores brought to the surface in segments provide information (chemistry, structure, inclusions) about climate conditions similar to tree ring samples. The information from air bubbles allows for measurement of the atmospheric concentration of greenhouse gases (carbon dioxide, methane, nitrogen, helium, sodium, and organic carbon). Besides presenting an extraordinary human effort spanning two decades in one of the most inhospitable places on earth, the drilling at Vostok has produced one of the richest scientific treasure troves of all time. Previously, analysis revealed tracking between carbon dioxide and temperature and that the magnitude of the carbon dioxide swings could account for the magnitude of the temperature swings.

The first hole drilling stopped in 1985 because of problems. A second hole drilled with French-Russian cooperation produced an ice core 2,083 m. long, or 1.33 mi. With a climate record of 160,000 years, drilling on this hole ended in 1990. A third hole was drilled with collaboration among Russia, France, and the United States. The drilling reached a depth of 2.25 mi. (3.6 km.) and in January 1998 produced the deepest ice core recovered at the time (now exceeded by the European Project for Ice Coring in Antarctica)—11,886 ft. (3,623 m.) deep, containing a climate record of 420,000 years, for a total of four climate cycles. Drilling stopped at this depth because the researchers were recovering accretion ice refrozen to the bottom of the glacier, indicating the presence of an underlying lake, and did not want to put themselves in danger from the release of pressurized lake water or risking contamination of the lake. Researchers have found microbes in the glacial ice from the Vostok core and four times more in the glacial-accretion ice transition, suggesting that the underground lake contains microbes and organic carbon.

Polar snowfall can be preserved in annual layers within an ice sheet to provide a climate record. These layers can be studied to develop an accurate picture of the climate history extending over the time periods (the deepest Vostok core extends over a 400,000 year time frame). Impurities (volcanic debris, sea salt, organic material, and interstellar particles) are also deposited with snow, making those layers distinctive.

Air bubbles trap gases in the ice and allow for testing to determine the air's composition at distinctive periods in the climate record. Water pockets may also become trapped the deeper the ice core is, and closer to the underlying rock or water. Researchers can determine the composition of water in comparison with heavy water isotopes to indicate environmental temperature; cold periods are those with moisture being removed from the atmosphere.

Studies on the second Vostok core showed a correlation between carbon dioxide and temperature over the past 160,000 years and provided evidence linking climate change with the greenhouse effect. The trapped air bubbles provided gas isotopes and, when compared with the temperature variations, matched up to show that greenhouse gases were the primary driver of climate change over time. The climate variation of ice ages also matched the solar records.

Initial Vostok studies, when combined with later research, provide an inclusive representation of the multiple factors involved in climate change by using a multidisciplinary approach to climate change research by using astronomical tables, chemistry, and physics. The Vostok ice cores indicate periods of ice ages, contain gases for comparison with temperature changes, and highlight the last ice age of 8 degrees F (4.4 degrees C) cooler than the present, taking place about 18,000 years ago.

Vostok's cores have provided significant evidence of greenhouse gas variations driving climate change and have provided information for the modeling of future climate changes in relation to greenhouse gas concentrations.The third Vostok core, recovered in 1998, provides additional confirmation and extends the historical record through the four most recent glacial cycles, showing that increased concentrations of greenhouse gases have forced the temperature higher and can be compared with the geological record of the same time frames.

The Vostok ice core has become the standard for creating timescales from cores recovered from other parts of the world. Researchers are able to plot the isotopes of their samples with similar isotope ratios of the known sample to provide an accurate time period reference.

Walker, Gilbert Thomas (1868–1958)

GILBERT THOMAS WALKER is the British physicist and statistician who first described the phenomenon of Southern Oscillation, a coherent interannular fluctuation of atmospheric pressure over the tropical Indo-Pacific region that produces wind anomalies. This was part of Walker's project to determine the connections between the Asian monsoon and other climatic fluctuations in the global climate in an effort to predict unusual monsoon years that cause drought and famine to the Asian sector. Although he was not a meteorologist by education, Walker greatly advanced the study of global climate with his discovery.

Gilbert Thomas Walker was born on June 14, 1868, in Rochdale, Lancashire. He was the eldest son and fourth child in a large family of eight. Soon after his birth, his family relocated to Croydon, where his father became the borough's chief engineer. From 1876 on, Gilbert attended Whitgift School, and in 1881 he won a scholarship to St. Paul's School. He already excelled in mathematics from these early years and passed the London matriculation in 1884. However, he did not stay in London for his degree, opting instead for Trinity College, Cambridge, where he enrolled in 1886, thanks to a scholarship. In 1891, he was elected a Trinity Fellow. He received an M.A. in 1893, and two years later, he was appointed a lecturer in mathematics. The heavy work necessary to attain these successes eventually took their toll on Walker's health, which broke down in 1890, forcing the mathematician to spend the next three winters in Switzerland. As a result of his precarious health, Walker did not publish many significant papers in the following years, but his 1899 work "Aberration and Some Other Problems Connected With the Electromagnetic Field" earned him the prestigious Adams Prize from Cambridge University. Walker was elected a fellow of the Royal Society in 1904, the same year that he received a Sc.D. from Cambridge University.

In the summer of 1903, Walker resigned his academic positions to become assistant to Sir John Eliot, who was the meteorological reporter to the government of India and director-general of Indian Observatories. The choice of Walker as special assistant was surprising, as Walker was not a meteorologist but a mathematician. At the end of 1903, Eliot retired, and Walker became the sole person responsible for the Indian Meteorological Department. He continued Eliot's quest for professional individuals to become members of his staff. He made prestigious appointments including J.H. Field, J. Patterson, and G.C.

Simpson, who later became directors of meteorological services in India, Canada, and the United Kingdom, respectively. From the beginning of his appointment, Walker devoted his research to the problems of monsoon and, in 1909, published his first meteorological papers. In 1908, Walker also gave lectures at the University of Calcutta, which were then published in 1910 by Cambridge University Press. Walker married May Constance Carter in 1908, and the couple had a son and a daughter.

Walker's interest in the monsoon resulted from the famine that the absence of rains had caused in India in 1899. Walker soon understood that he could not tackle meteorological problems through mathematical analysis and tried to develop more empirical techniques. He called his methodology seasonal foreshadowing, rather than weather forecasting, as the phrase indicated a vaguer prediction. Walker calculated statistical delay correlations between antecedent meteorological events both within and outside India and the subsequent behavior of the Indian monsoon. He was one of the first scientists to establish relationships between apparently separate events. The sets of relationships that he established, subsequently called Walker circulation in his honor, create a system resembling a global heat engine influencing the world's climate. The Walker circulation works like a swing in which warm, moist air rises in the western Pacific, becomes drier at high elevation, and displaces eastward, where heavy air sinks and returns westward. The phenomenon thus creates high air currents moving from the west to the east and, at the same time, east-to-west trade winds near the ocean surface. Global warming theorists have predicted that the rising temperatures will eventually slow down this mechanism.

Walker retired as director of the Indian Meteorological Department in 1924 and became a professor of meteorology at the Imperial College of Science and Technology in London. There, Walker continued his research into global weather and simultaneously carried out laboratory experiments in physics to study the convection of unstable fluids, particularly in its applications to cloud formations. He retired from Imperial College in 1934 and moved to Cambridge, where he lived until 1950. Although retired, Walker remained an active researcher and served as the editor of the *Quarterly Journal of the Royal Meteorological Society* from 1934 to 1941. He died in Coulsdon, Surrey, on November 4, 1958. Although he had only mixed success in his original goal, the prediction of monsoonal failures, Walker conceived theories that allowed his successors to move beyond local observation and forecasting toward comprehensive models of climate worldwide

Throughout his distinguished career, Walker was a member of prestigious societies and received numerous honors. He was elected a fellow of the Royal Meteorological Society in 1905 and served as president of the society in 1926 and 1927. He was also vice president of the society three times and was an ordinary member of council in 1925 and from 1935 to 1939. He was awarded the society's Symons Gold Medal in 1934. While working in India, Walker was the president of the Royal Society of Bengal and president of the Indian Science Congress. He became a Companion of the Order of the Star of India in 1911 and was knighted on the king's birthday in 1924. Walker was also an honorary fellow of Imperial College and a fellow of the Royal Astronomical Society.

Walker Circulation

THE WALKER CIRCULATION is an atmospheric system of air flow in the equatorial Pacific Ocean. The trade winds across the tropical Pacific flow from east to west: air rises above the warm waters of the western Pacific, flows eastward at high altitudes, and descends over the eastern Pacific. A weaker Walker circulation (in the reverse direction) occurs over the Indian Ocean.

Sir Gilbert Walker assumed the post of director-general of the observatory in India following catastrophic famines in the late 1800s resulting from a general failure of the South Asian monsoon. In an effort to predict the monsoons, Walker undertook an investigation into the regional climate system. Over time, he recognized that the monsoonal system extended to a panoceanic scale. Walker observed that an inverse relation of atmospheric pressures at sea level generally existed between the two sides of the Pacific Ocean. A high-pressure phase in South America was usually accompanied by low pressure in the western Pacific and vice versa—the Southern Oscillation (SO). The generally accepted measure of the SO is the inverse relationship between surface air pressure at Darwin, Australia, and Tahiti (stations used by Walker); indeed, the SO is normally identified by the SO Index (SOI), that is, the difference in atmospheric pressure at sea level between these stations (Tahiti minus Darwin). The greater the SOI, the greater the intensity of the trade winds. Historically, the SO has exhibited a more or less cyclical pattern, in that it weakens or reverses every few years.

On the basis of data collection initiated during the International Geophysical Year in 1957 to 1958, in the 1960s Jacob Bjerknes of the University of California described the general nature of the mechanism linking the system. He extended the horizontal picture of the SO vertically by theorizing that to complete the system of the trade winds and atmospheric air pressure, there needed to be a countercirculation of air from west to east at high altitudes, descending over the eastern Pacific.

Atmospheric circulation is intimately coupled with the movement of water in the tropical Pacific. At the surface, the trade winds initiate a westward flow of surface water across the Pacific Ocean, producing an increase of sea level in the western Pacific of approximately 40 cm. The equatorial heating of this water produces high seasurface temperatures (SSTs) in oceanic waters near Indonesia. The resulting low atmospheric pressure and evaporation fuels the pan-Pacific upper-atmospheric circulation characterized by convection (low atmospheric pressure) in the west and subsidence (high atmospheric pressure) in the east. This is termed the Walker circulation in honor of Sir Gilbert.

The Walker circulation is closely connected to oceanic upwelling off the coast of South America. Fluctuations in the circulation are closely linked to El Niño and La Niña events—together termed the El Niño/SO system (ENSO). A weakening or reversal of the Walker circulation is closely linked with the El Niño phenomenon, with warmer-than-average SSTs in the eastern Pacific as upwelling diminishes. In contrast, the opposite phase, a particularly strong Walker circulation, produces a La Niña event, with cooler SSTs caused by increased upwelling. Interannular switches in the dipole are linked to global-scale changes in patterns of weather. Several explanations for the variation in the Walker circulation have been hypothesized, but the nature of the mechanisms initiating the change in phase has not been fully identified.

Evidence suggests that the Walker circulation may have been weakening since the mid-19th century. However, there is a high degree of uncertainty concerning the potential effects of climate change on the Walker circulation. Transient warming may dominate before the ocean has had a chance to reach equilibrium. In the short term, warming may occur more quickly in the western Pacific, thereby enhancing the circulation. In contrast, atmospheric models have indicated that climate change will, as part of a weakening of the entire tropical circulation, lead to a general decrease in the strength of the Walker circulation. The specific mechanisms involved are not fully known, and projections remain rather speculative and are a focus of intense research.

Washington

WASHINGTON STATE IS 71,300 sq. mi. (184,666 sq. km.), with inland water making up 1,553 sq. mi. (4,022 sq. km.), coastal water making up 2,535 sq. mi. (6,565 sq. km.), and access to territorial water making up 666 sq. mi. (1,725 sq. km.). Washington's average elevation is 1,700 ft. (518 m.) above sea level, with a range in elevation from sea level on the Pacific Ocean to 14,410 ft. (4,392 m.) at the peak of Mt. Rainier. Western Washington lies on the Juan de Fuca Plate, with overriding by the North American Plate.

Washington is fairly warm and is kept that way by ocean currents including frequent rain and the rain shadow effect. Moist air streams up slopes of mountains, and rainfall or snowfall is increased. However, when the air, depleted of much of its moisture, begins to descend down the slopes, the temperatures warm, clouds dissipate, and very little precipitation falls. Western mountains take Pacific moisture that flows onshore all year long. The western slopes of the Olympic Mountains have a true rainforest, but the rain shadow on the eastern slope means it receives less than 15 in. of rain per year. The highest temperature recorded in the state is 118 degrees F (48 degrees C) in Ice Harbor Dam on August 5, 1961, and the lowest temperature recorded in the state is minus 48 degrees F (minus 44 degrees C) in Mazama and Winthrop on December 30, 1968. Mount St. Helens, an active volcano, spouted volcanic ash into the atmosphere in 1980. In 1993, the year of the flood in Iowa, Washington recorded the coolest summer on record in Spokane.

The state supports a population of over 6 million people. Major industries include agriculture, with the major products being apples, beef, milk, timber, and wheat; manufacturing computers, food, machinery, and paper products; and mining coal, gold, sand, and gravel.

The Columbia River is the second largest river in the country based on volume. The Grand Coulee Dam retains some water from spring runoff for summer use. It is the largest concrete structure at 55 ft. (16.7 m.) tall. It holds 24 generators supplying 65 mil-

Mount St. Helens in Washington is an active volcano, and had an enormous eruption at 8:32 in the morning on May 18, 1980. The debris blasted down nearly 230 sq. mi. (596 sq. km.) of forest and buried much of it beneath volcanic mud deposits.

lion kilowatts of electricity. This electricity is carried throughout the west and east to Chicago.

Commercial logging started in the 1800s and has claimed 90 percent of the forests that once grew in the Pacific Northwest. Logging in the national forests since World War II has divided mountainsides and river valleys into checkerboards of clear-cut and uncut forest, creating vulnerable areas to succumb to environmental pressures. More than half of the remaining untouched forest areas in Olympic National Forest are slated for cutting during the next 50 years, as is 69 percent of the old growth in Oregon's Siuslaw National Forest. In 1990, Congress voided all court injunctions brought to stop cutting of ancient trees on lands administered in Washington and Oregon by the Bureau of Land Management and the Forest Service and removed the right of citizen and conservation groups to seek further injunctions in any future cuts planned.

The Climate Impacts Group at the University of Washington is working to further understanding of the patterns and predictability of regional climate variability, the influence of climate variation on the Pacific Northwest, and providing strategies to prepare for climate change.

Washington is a member of the Western Regional Climate Action Initiative, along with Arizona, California, New Mexico, Oregon, Utah, and the Canadian provinces of British Columbia and Manitoba. This cooperative group works together to identify, evaluate, and implement ways to reduce greenhouse gas emissions on the regional level.

The effects of climate change that are already being experienced by Washington include weather changes, reduced summer water supply dependent on winter snowpack, and rising water levels along the coastline. Because of these effects, Washington is taking steps to prepare for climate change and reduce human-induced contributions to global warming. In February 2007, the governor signed an executive order establishing goals for reduction in climate pollution, increases in jobs, and reductions in expenditures on imported fuel. Because the United States has not ratified the Kyoto Protocol calling for greenhouse gas emission reduction, some states and regions have taken voluntary initiatives to reduce these emissions on their own. Washington's goal is to cut emissions by 20 percent by 2050, with reduced auto emissions, use of renewable fuels, green building standards, and energy efficiency; passing a clean renewable energy initiative; and adopting a CO_2 emissions performance standard for electric generating units.

Not only is Washington proactive on reduced emissions but they provide education and call for public support by using more energy-efficient transportation (public transportation, ride sharing, walking, or bicycling), improving home energy efficiency (insulation, energy-efficient appliances, and fluorescent lighting), and encouraging the planting of trees and plants.

Though climate models show no precipitation change, a change in temperature of 2 degrees to 3 degrees may mean less snowfall. An expected decrease this century of 60 percent in Cascade snowpack—even in the most reassuring of global warming scenarios—stands to have devastating consequences in the Pacific Northwest. The Columbia River's Grand Coulee Dam has made it possible for Washington, along with other Pacific and mountain states, to increase in population. A survey of nearly 600 snowfields in the Sierra Nevada, the Rocky Mountains, and the cascades of Washington and Oregon shows that 85 percent of them have lost volume since the 1950s. A higher incidence of wildfires resulting from increasing drought levels, as well as rising sea levels, could displace people from their homes.

The associated costs include those affiliated with fighting wildfires, flood damage, lost revenue from tourism, increase in water pricing because of shortages and drought conditions, and increased costs for healthcare related to poor air quality and increased infection.

With rising temperatures, variable precipitation, and rising sea levels, the quality of the water supply in Washington could be compromised, with an increasing risk of water-borne infections. The potential for agricultural disruption also could lead to risks of malnutrition, and increasing heat waves could cause more heat-related illness.

Washington, Warren (1936–)

WARREN WASHINGTON IS an African-American meteorologist and atmospheric scientist whose research focuses on the development of computer models that describe and predict the Earth's climate. Washington was one of the first developers of atmospheric computer models in the early 1960s at the National Center for Atmospheric Research in Boulder, Colorado. These computer models use the basic laws of physics to predict the future states of the atmosphere. Because these equations are extremely complex, it is almost impossible to solve them without a powerful computer system. Washington's book *An Introduction to Three-Dimensional Climate Modeling* (1986), coauthored with Claire Parkinson, is a standard reference for climate modeling. In his subsequent research, Washington worked with others to incorporate ocean and sea ice physics as part of a climate model. Such models now involve atmospheric, ocean, sea ice, surface hydrology, and vegetation components. Washington is the director of the Climate and Global Dynamics Division of the National Center for Atmospheric Research (NCAR), in Boulder, Colorado. He has advised the U.S. Congress and several U.S. presidents on climate-system modeling, serving on the President's National Advisory Committee on Oceans and Atmosphere from 1978 to 1984.

Washington was born in Portland, Oregon, in 1936. His father, Edwin Washington, Jr., wanted to be a schoolteacher, but in the 1920s, it was impossible for African Americans to be hired as teachers in Portland public schools. Thus, Edwin was forced to work as a waiter in Pullman cars to support his family. His wife Dorothy Grace Morton Washington became a practical nurse after Warren and his four brothers grew up. Washington's interest in scientific research was apparent from an early age, and he was encouraged by his high school teachers. When Washington had to choose what to do after high school, his counselor advised him to attend a business school rather than college. However, his ambition was to be a scientist, so he enrolled at Oregon State University, where he earned his bachelor's degree in physics in 1958. During his undergraduate years, Washington became interested in meteorology while working on a project at a weather station near the campus. The project involved using radar equipment to follow storms as they came in off the coast. Because of his growing interest in meteorology, Washington began a master's degree in meteorology at Oregon State, graduating in 1960. He then began a Ph.D. at Pennsylvania State University, graduating in 1964, thus becoming one of only four African Americans to receive a doctorate in meteorology.

Washington began working for NCAR in Boulder, Colorado, in 1963 and has remained associated with that institution throughout his career. His research at the center has attempted to describe patterns of oceanic and atmospheric circulation. Washington has contributed to the creation of complex mathematical models that include the effects of surface and air temperature, soil and atmospheric moisture, sea ice volume, various geographical traits, and other factors on past and current climates.

Washington's research has helped further our present understanding of the greenhouse effect. He has contributed to determining the process in which excess carbon dioxide in the Earth's atmosphere causes the retention of heat, thus leading to what is known

Warren M. Washington is the head of the Climate Change Research Section, National Center for Atmospheric Research.

as global warming. Washington's research also shed light on other mechanisms of global climate change. In interviews and statements, Washington has made it clear that he firmly believes that global warming is to the result of human actions: "For researchers in climate science, the question of whether or not climate change is attributable to human activity was put to rest several years ago with our DOE-supported simulations showing that the only way to duplicate the sharp increase of the global average temperature observed in the late 20th century was to include human generated greenhouse gases in the simulations. When the same simulation was run without the human-generated greenhouse gas increases, the model simulations show that the Earth would be in a slight cooling trend with the natural forcings of volcanic and solar activities. For us, that was the smoking gun for human-induced climate change." He has thus pleaded for climate science to rise in priority as a science problem for American administrations. He has also claimed that the Department of Energy has a particular responsibility to help find solutions for the global warming problem. According to Washington, "as the impacts of climate change become more apparent with increased severity of heat waves, droughts, water shortages, and more severe hurricanes, there will be more emphasis on understanding how we can better mitigate and adapt to the changes." The meteorologist has suggested that the Department of Energy study the carbon footprint and effect of various technology paths for the production of energy. He has also argued for an increased focus on what strategies to use to mitigate climate change and to find a long-term stabilization for carbon dioxide and other greenhouse gases in the atmosphere.

Throughout his career, Washington has published over 100 professional articles about atmospheric science, scientific textbooks, and an autobiographical volume. He has also served as a member and a director of prestigious institutes and commissions. Washington was appointed the director of the Climate and Global Dynamics Division at NCAR in 1987. In 1994, he was elected president of the American Meteorological Society. He is a fellow of the American Association for the Advancement of Science and a member of its board of directors, a fellow of the African Scientific Institute, a distinguished alumnus of Pennsylvania State University, a fellow of Oregon State University, and founder and president of the Black Environmental Science Trust, a nonprofit foundation that encourages African-American participation in environmental research and policymaking. From 1974 to 1984, Washington served on the President's National Advisory Committee on Oceans and Atmosphere. In 1995, he was appointed by President Bill Clinton to a six-year term on the National Science Board. In 1997, he was awarded the Department of Energy Biological and Environmental Research Program Exceptional Service Award for Atmospheric Sciences in the development and application of advanced coupled atmospheric-ocean general circulation models to study the effects of anthropogenic activities on future climates.

Waves, Gravity

ATMOSPHERIC GRAVITY WAVES are generated by atmospheric disturbances such as storm fronts, strong wind shears, and flow over mountains and play a key role in coupling the lower and upper atmosphere, causing a redistribution of momentum and energy from the troposphere and lower stratosphere into the upper atmospheric regions of the middle stratosphere, mesosphere, and lower thermosphere. Gravity waves trigger convection and induce mixing and transport of atmospheric chemicals such as ozone. Gravity waves typically form within or near the back edge of a precipitation shield. The strongest upward motions of gravity waves occur just following the surface pressure trough and lead to maximum precipitation rates just ahead of the ridge.

Atmospheric gravity waves can occur at all altitudes in the atmosphere and are important for the transport of energy and momentum from one region of the atmosphere to another, to initiate and modulate convection and subsequent hydrological processes, and to inject energy and momentum into the flow. When the gravity wave breaks, the resulting turbulence mixes atmospheric chemicals. These wave-breaking processes occur globally and affect climate of the mesosphere and stratosphere.

These mesoscale–regional scale processes have global significance because of their accumulative effects from the global distribution of various wave sources. The primary challenges to observational, numerical, and analytical studies are how to better quantify gravity wave excitation as it is related to various tropospheric processes, the global distribution of the wave sources, their propagation and breaking, and the multiscale interactions involving gravity waves.

The difficulty in producing the observed Arctic climate change in models may be a result of not including gravity waves in the models. The most likely energy source mechanisms are latent heat release in deep convection and shear instability, in which waves can extract energy from the jet stream when vertical wind shear is sufficiently strong to reduce the Richardson number below 0.25. Alternatively, wave energy loss can be prevented by an efficient wave duct, which appears to be the most prevalent of the three mechanisms described.

Gravity waves are maintained by wave-ducting processes requiring a layer of static stability (the duct depth near the surface), no critical levels (wind moving in the direction of the wave at the same speed) in the lower stable layer that would absorb the wave's energy, and a reflecting layer above the stable layer to keep the wave from losing its energy.

Gravity waves can affect an existing cloud pattern in several ways as they propagate: through modulating the cloud pattern, with the development of wave cloud formations, the wave and cloud can propagate in tandem with little effect on the overall cloud pattern. Convection can generate a broad spectrum of waves, ranging from short-period waves excited by the development of convective cells along a thunderstorm gust front to large wavelength disturbances resulting from the release of latent heat in a thunderstorm complex.

The challenge of including gravity waves in global climate models stems from the resolution ability of computers; with increasing computer power, more complex equations over smaller distances can be resolved to examine gravity waves. Current models often use one of the available gravity wave drag parameters and assume a fixed gravity wave source for proper representation of turbulence on the small scale.

The vast spatial and temporal extent of gravity waves has important implications for the atmosphere from the mesoscale to the global scale and poses a stiff challenge to improving weather and climate predictions at all ranges.

An important part of the National Center for Atmospheric Research mission is to understand the coupling of the lower and upper atmosphere through dynamical, chemical, and radiative processes. Sudden stratospheric warming involves dynamical changes on vastly different scales from the troposphere to the lower thermosphere, and thus provides us an opportunity to understand the coupling process. Further wave source sensitivity studies and observations will help to define gravity wave sources and behavior.

Waves, Internal

AN INTERNAL WAVE is a wave that develops below the surface of a fluid along changes in density. With increased depth, this change may be gradual, or it may occur abruptly at the interface. Similar to the transmission of energy by wind along the surface of the ocean, the density interface beneath the ocean surface transmits energy to produce internal waves. The greater the difference in density between the two fluids, the faster the wave will move.

Internal waves may have a variety of causes, including the tidal pull of water, wind stress, and energy put into the water by moving vessels. Year-round internal waves caused by tidal forces carry between 30 and 50 percent of their energy away from their source. Seasonal (stormy winter months) internal waves caused by wind and storms carry at least 15 to 20 percent of the energy input from their source.

Internal waves reach greater highs (above 100 m., or 328 ft.) from a smaller energy input than do the waves resulting from large energy input at the ocean's surface. This is because they move along interfaces with less density difference than between the ocean surface and the atmosphere.

Internal waves eventually run out of energy and break, similar to surface waves. When they break in the deep ocean, they create turbulence. Where they create this turbulence, heat can be transferred from the upper ocean and stored in the deep ocean, with the exception of the Arctic Ocean, which is warmer in deeper water than on the surface. In the Arctic, turbulence transfers heat from the deep ocean to the surface.

Beneath the surface of the ocean exists a unique weather and climate resulting from the fluctuating currents driving wind in the atmosphere and from deep waves with similar patterns to those on the surface of the ocean—but unable to be seen from the surface—created by the ocean movement caused by the tides.

Internal tide is an internal wave created from the back-and-forth flows of water over geographic features at lower depths. These internal waves radiate away in the form of tide current carrying energy away from the source.

Internal waves are of special interest to climate modeling researchers because heat transfer is one of the roles of the ocean in regulating and changing climate. For example, the amount of heat transferred from the deep ocean in the Arctic will affect the amount of floating sea ice above. In the same way heat from the sun at the equator is transferred to the atmosphere, the upwelling of water enhances the global ocean circulation; otherwise, the depths of the ocean would be much colder and retain nutrients deeper down and away from supporting life or the ability for continuance of the carbon dioxide cycle absorption and release.

Internal waves occur beneath the water's surface. The reflection of light makes it possible to see them from high altitudes.

Internal waves mix and redistribute heat, salt, and nutrients in the oceans; mixing is accomplished more easily in water having uniform density. Most of this mixing occurs where internal waves break, overturning the density stratification of the ocean and creating patches of turbulence. Scientists have observed that the internal wave rates of dissipation and the redistribution of heat and nutrients is 10 percent less near the equator than at midlatitudes. This ocean dynamic would have to be accounted for in climate models.

Researchers are studying internal waves, as determining where internal wave energy might be high and where it might be low will help researchers distinguish between fluctuations in the data record originating from ocean currents and fluctuations resulting from internal waves/tides. Thus, oceanographic instruments can be deployed in oceanographically interesting locations where scientists can quantify the vertical redistribution of heat or assess the potential contribution to climate change and variability.

Waves, Kelvin

KELVIN WAVES AFFECTING weather and climate occur in both the oceans and the atmosphere. These low-frequency, gravity-driven waves propagate vertically and parallel to boundaries (e.g., equator, coastline, air masses, and topography). Kelvin waves are nondispersive and carry energy from one point to another. The height or amplitude of a Kelvin wave is highest near the boundary where it propagates; the wave height decreases as the wave moves farther away from the boundary. In the Northern Hemisphere, the waves propagate anticlockwise, and in the Southern Hemisphere, the waves propagate clockwise. The flow of the Kelvin wave balances pressure perpendicular to the boundary by the forces of gravity and the Coriolis effect.

Kelvin waves in the ocean form as coastal waves or equatorial waves, both of which are caused by external forces—often a shift in the trade winds or resulting from temperature variations—and the water inside the Kelvin waves is usually a few degrees warmer than the surrounding water. Kelvin waves may be called external (or barotropic) Kelvin waves if the ocean is homogenous, and internal (or baroclinic) Kelvin waves if the ocean is stratified.

In the Northern Hemisphere, the equatorial waves propagate parallel to the equator and to the east, and the coastal Kelvin waves propagate in a counterclockwise direction, using the coastline for direction. These waves can be between 5 and 10 cm. high and hundreds of km. wide. Kelvin waves tend to move quickly, with a typical speed of approximately 250 km. (155 mi.)/day and can cross the Pacific in approximately 2 months.

The tidal cycles can cause Kelvin waves by the mechanism of a progressive tide wave moving from open ocean into and out of a narrowed body of water. Because of the Earth's rotation, resulting in an anticlockwise direction of current flow inside the channel, flood tides will be greater on the right side of the channel.

The effect on climate results from the Kelvin waves causing a variation in the depth of the oceanic thermocline (the boundary between warm waters in the upper ocean and cold waters in the deep ocean). Because of this variation, Kelvin waves can be used to predict and monitor El Niño activity. In comparison with Rossby waves, which carry water back toward the western Pacific and take as long as a decade to move from the eastern Pacific to the western Pacific, the faster-moving Kelvin waves carry warm water eastward in approximately 2 months.

In the atmosphere near the equator, Kelvin waves travel eastward and may propagate upward to higher altitudes. The formation of Kelvin waves is triggered by mountains, thunderstorm updrafts, and anything that interrupts the normal flow of stable air. The trigger forces the air upward, and the stable air sinks by gravity instead of just returning to normal; when air sinks farther, it causes the wave motion. Kelvin waves cannot happen in unstable air because the motion would just allow the movement of air to continue upward to higher altitudes.

Kelvin waves may propagate in the lower and upper stratosphere and mesosphere. In the lower stratosphere, the eastward-moving Kelvin wave is associated with periods of 10 to 30 days, and in the upper stratosphere, the Kelvin wave is associated with periods of 5 to 7 days. In the mesosphere, the Kelvin wave is associated with periods of 3 to 4 days. These Kelvin waves transport energy and eastward momentum upward and contribute to the maintenance of the eastward flow.

For predicting weather and future climate change, climate models including the COMMA-LIM model can reproduce the Kelvin waves to correlate with how the Kelvin wave acts in the atmosphere. The wave action can also interact with other wave types and the flow of air masses.

Waves, Planetary

PLANETARY-SCALE WAVES HAVE their origin relating to the Earth's shape and rotation; the waves are so large that some of them wrap around the whole Earth and can be observed in the atmosphere through the meandering of the jet stream. A long wave or planetary wave is a weather system that circles the world, with one to three waves forming a looping path around the Earth at any given time and displacing air north and south. Planetary waves have ridges (the high points) and troughs (the low points). Warmer upper air is associated with an increasing number of waves or stronger waves.

Planetary waves form in the lowest part of the atmosphere, called the troposphere, and propagate upward, transferring energy into the stratosphere and heating polar air between 9–18 degrees F (5–10 degrees C). Because of a larger landmass, with the majority of the highest mountains and land-sea boundaries in the Northern Hemisphere, planetary waves form more strongly in the Northern Hemisphere. Once the wave dissipates, the polar air begins to cool. In the Southern Hemisphere, landforms also produce planetary waves, although they are weaker there because there are fewer tall mountain ranges and vast open ocean surrounding Antarctica. The warming of the Arctic stratosphere suppresses ozone destruction. Ozone exists in the lower level of the stratosphere and is caused by sunlight splitting the oxygen molecules at cooler temperatures, with less ozone destruction at warmer temperatures.

The Himalayas and other land features create the planetary atmospheric waves that serve to decrease the formation of an ozone hole at the northern pole and therefore limit solar ultraviolet radiation exposure in the Arctic. Climate change could open ozone holes in the Arctic; in the spring of 1997, weak planetary waves created conditions that formed a small ozone hole over the Arctic. The chemistry of ozone destruction requires very cold air temperatures in the stratosphere, and because of planetary wave action, the Arctic stratosphere stays warmer than the Antarctic stratosphere.

In contrast, researchers announced in 1992 that El Niño weather changes and a large number of planetary waves in the atmosphere had caused shrinking of the Antarctic ozone hole, with the ozone hole in September 2002 being half the size it was in 2000. Large-scale weather patterns (similar to the semipermanent area of high pressure) generate more frequent and stronger planetary waves. If the waves are more frequent and stronger as they move from the surface to the upper atmosphere, they warm the upper air. Because ozone breaks down more easily with colder temperatures, the warmer the upper air around the "polar vortex," or rotating column of winds that reach into the upper atmosphere where the protective ozone layer is, the less ozone is depleted.

Researchers working in Esrange, Sweden, studied the main features of planetary waves and variability of the semidiurnal tide, with planetary wave periods observed by meteor radar. They focused observation on 5-, 8- to 10-, 16-, and 23-day planetary waves by meteor radar measurements in the mesosphere and lower thermosphere. In the winter, when the planetary waves are significantly amplified, a very strong periodic variability of the semidiurnal tide is observed as well. This result indicates that the most probable mechanism responsible for the periodic tidal variability during winter is in situ nonlinear coupling between tides and planetary waves. They established a correlation between the planetary wave and semidiurnal tide and secondary waves with frequency, phase, and vertical wavenumber (wavelength) correlation.

The influence of planetary waves on global system dynamics with airflow and temperature distribution include the indirect effect of upper air patterns on lower air patterns through feedback linking all layers of the atmosphere.

Planetary waves (also called Rossby waves) form in the ocean and affect ocean circulation over longer periods of time—from one to 10 years.

Waves, Rossby

NASA RESEARCHERS AT the Goddard Institute for Space Studies describe Rossby Waves as "slow-moving waves in the ocean or atmosphere, driven from west to east by the force of Earth spinning." These are naturally occurring phenomena first recognized in 1939 by a Swedish-American meteorologist named Carl-Gustav Rossby. These waves, which are found in both the atmosphere and the oceans, are important mechanisms for the redistribution of energy around the globe. In three sections, this essay describes the formation of atmospheric Rossby Waves, oceanic Rossby Waves, and the connection between Rossby Waves and global climate change.

ATMOSPHERIC ROSSBY WAVES

This eponymously named phenomenon was first identified as atmospheric oscillations that occurred in the mid-latitudes in the northern and southern hemispheres. In Europe and North America, people typically experience a Rossby wave as a large cold front plunging southward. The jet stream, guised as a tongue of cold air, dips southward as a large tropical air mass moves northward. The interaction between these air masses, affected by the coriolis affect that intensifies at lower latitudes, generates our changing weather on a day-to-day and week-to-week basis. During televised weather reports, we see North American Rossby waves as the large-scale oscillations of clouds moving from west to east across a continent.

OCEANIC ROSSBY WAVES

Scientists later identified a similar phenomenon at work in the water of all ocean basins. Researchers discovered that oceanic Rossby waves represent a mechanism by which the ocean responds to significant atmospheric "forcing" or wind-related disruption. Rossby waves disperse the atmospheric energy across ocean basins and can be measured through satellite imagery. Because of the impact of the earth's axial rotation and the Coriolis Effect, the oceanic Rossby waves tend to spiral away from the equator in both the northern and southern hemispheres.

ROSSBY WAVES AND CLIMATE CHANGE

Scientists are increasingly interested in Rossby Waves because of the possible connection between these atmospheric and oceanic waves and global warming. An understanding of atmospheric Rossby Waves enabled researchers to effectively study long term temperature fluctuations and provide concrete evidence that global warming was occurring.

Rossby waves can affect entire ocean basins. They also tend to move from the eastern part of the Pacific and Atlantic Oceans towards the west on either side of the equator. A complementary Kelvin wave moves in the opposite direction from west to east along the equator. The multiple axes along which the ocean moves has the ability to disrupt oceanic circulation. Researchers propose that global warming will generate stronger weather events with greater frequency. Because oceanic Rossby waves transmit atmospheric disruptions, the theory is that as storms occur more frequently, the wavelength and frequency of Rossby waves will also change—with a potentially disruptive impact on ocean currents such as the Gulf Stream. A disrupted Gulf Stream could cause cooling at higher latitudes in the North Atlantic.

Researchers also see a connection between changes in Rossby Waves and the intensity of El Niño and La Niña ocean surface water temperature fluctuations in the Pacific Ocean. Also known as the El Niño-Southern Oscillation (ENSO), sea surface temperature increases during El Niño events and decreases in La Niña events can alter or intensify the monsoonal rainfall and hurricane patterns in North and South America. The challenge for climatologists and oceanographers is to understand how disrupted Rossby waves are a cause and consequence of global warming. The broader point is that global climate change is a complex process that involves the interplay between large scale atmospheric and oceanic processes operating at multiple scales.

Weather

WEATHER IS THE physical condition or state of the atmosphere at any given time. It is what is happening in the atmosphere at any time or over any short period of time. If there were no atmosphere, there would be no weather. The principal elements of weather are temperature, pressure, winds, moisture, and precipitation. Thus, weather of any place is the sum total of its temperature, pressure, winds, moisture, and precipitation conditions for a short period of a day or a week. Temperature expresses intensity of heat. Unequal distribution of temperature over the Earth's surface causes differences in atmospheric pressure, which causes winds. Moisture is present in the atmosphere as water vapor, often condensed into clouds. It may be precipitated in the form of rain, hail, sleet, or snow. The capacity of air to gather and retain water vapor is largely dependent on its temperature. The higher the temperature, the greater the capacity of air to hold moisture. On cooling, the air is not able to retain all the moisture it gathers while warm. This leads to condensation and precipitation.

Weather is not synonymous with climate. Weather changes from day to day, whereas climate is something more stable, commonly defined as the average weather. Climate is the composite weather conditions over a considerable period of time. Weather conditions can change suddenly. Today may be warm and sunny, tomorrow may be cool and cloudy. Weather conditions include clouds, rain, snow, sleet, hail, fog, mist, sunshine, wind, temperature, and thunderstorms. Weather is driven by the heat stored in the Earth's atmosphere, which comes from solar energy. When heat is moved around the Earth's surface and in the atmosphere because of differences in temperature between places, this makes winds. Winds form part of larger weather systems, the most powerful of which is the hurricane. Other weather features like the thunderstorm also develop because of the movement of heat in the atmosphere. Some thunderstorms result in tornadoes. The Earth's water cycle plays an important role in the development of many weather features such as dew, fog, clouds, and rain.

Weather can be described using terms such as wet or fine, warm or cold, windy or calm. The science of studying weather is called meteorology. Meteorologists measure temperature, rainfall, air pressure, humidity, sunshine, and cloudiness, and they make predictions and forecasts about what the weather will do in the future. This is important for giving people advance notice of severe weather such as floods and hurricanes. Temperature is measured with a mercury thermometer in degrees Celsius. Temperature is the hotness or coldness of an object. Rainfall

Thunderclouds contain a great amount of energy, and the currents of air are strong enough to split apart the raindrops that are forming. This builds up an electric charge, released as lightning. The sound of thunder is the effect of the lightning strike on the air.

is usually measured by collecting what falls in rain gauges and is expressed as a depth of water that has fallen, in millimeters. Wind can be observed with a weather vane, but to measure its speed, more technical equipment is needed. Alternatively, the Beaufort scale can be used to make a judgment of the strength of the wind by observing how it affects objects outdoors, such as trees. The relative humidity and dew point temperature of the air can be determined by making measurements with a hygrometer and reading a table of numbers.

The purpose of a weather map is to give a graphical or pictorial image of weather to a meteorologist. As a forecasting tool, weather maps allow a meteorologist to see what is happening in the atmosphere at virtually any location on earth. Complex three-dimensional models of weather systems can be made by collecting weather data at multiple levels in the atmosphere. Computers then compile that information to produce the pictures that weather scientists analyze. In the early days of meteorology, these pictures were all drawn by hand.

WEATHER PREDICTION AND FORECASTING

Weather affects virtually everyone daily. Human beings live largely at the mercy of the weather. It influences our daily lives and choices and has an enormous effect on corporate revenues and earnings. Weather can be predicted to some degree by observing the state of the sky and the wind. Weather is measured, and forecasts are usually released and used to make important decisions about travels, timing, and so on. Weather forecasts can save lives, reduce damages to property, reduce damages to crops, and tell the public and the global community about expected weather conditions. A forecast is basically predicting how the present state of the atmosphere will change with time. This involves plotting weather information on special charts. Weather radar and satellites are now also used to help predict the weather. Weather forecasters measure the weather so they can forecast it. Temperature, rainfall, wind, clouds, sunshine, and air pressure are measured all over the country, and the information is plotted on special charts. These weather charts have been used by forecasters for many years to predict what the weather will do over the next few days. Weather presenters often show simplified charts on television. Sophisticated equipment is used to help forecast the weather: weather radar can help to show where it is raining over a country, whereas satellites are used to reveal cloud cover and the development of large weather systems. Procedures for collecting and taking the observations are determined by the World Meteorological Organization.

There are a variety of forecasting techniques. The easiest of the techniques is called persistence. In this technique, tomorrow's weather is said to be same as today's weather. Local factors that should be considered when forecasting include clouds and snow. Clouds during the day will decrease the maximum temperature expected. Without the clouds, higher maximum temperatures would be obtained. With snow, the surface stays colder during the day, as less short-wave radiation is absorbed. During the night, radiational cooling effectively cools the surface. If there is some wind, the wind could create mechanical turbulence, which will mix down warmer air to the surface. Hence, winds keep the minimum nighttime temperature warmer than in calm conditions. By looking at cloud movement at different levels, one can infer the type of temperature advection that may be occurring, and therefore atmospheric stability.

Synoptic weather analysis and forecasting began after the telegraph made instantaneous long-distance communications possible after 1850. The invention of radio allowed the extension of the weather observation net over the oceans, and this was one of its first important uses. Every ship became a weather station, radioing reports at regular intervals to a central office. This great advance occurred by 1915, and weather prediction was of great service in Would War I. Significant theoretical advances were made during the middle of the 20th century, especially in the properties of the upper atmosphere, elucidated by such indirect methods as sound propagation and meteor trails.

THE SUN, THE AIR, AND THE WEATHER

The state of the air is important in weather studies. The elements of weather are air temperature, precipitation, cloud cover and sunshine, wind speed and direction, and air pressure. The air in the atmosphere is a mixture of gases consisting of nitrogen, oxygen, water vapor, carbon (IV) oxide, and some rare gases. The amount of water vapor is very important, as it gives us clouds and rain. Clouds are seen in the sky every day. They come in all shapes and sizes and bring with them all sorts of weather. A cloud is simply a visible mass of tiny water droplets that have formed because the air has become too cold at that height to store all its water as invisible vapor. This usually happens when warmer air near the ground is cooled down by rising higher in the atmosphere.

Different types of clouds can be described as they are viewed from the ground, using different terms. A cloud's name generally reflects the height at which it forms, as well as its general shape. The three main types of clouds are cirrus, cumulus, and stratus. Cirrus clouds are wispy in appearance and resemble horsetails. They are formed almost entirely of tiny ice crystals. Cumulus clouds look like fluffy balls of cotton wool. These can sometimes grow much larger, becoming cumulonimbus clouds, which bring heavy bursts of rain during thunderstorms. Cumulus clouds are clouds of vertical development and may grow upward dramatically under certain circumstances. Another type of cumulus cloud is the altocumulus cloud, which sometimes resembles fish scales. They sometimes have dark, shadowed undersides. Stratus clouds are layer clouds that form near the ground and make the weather very grey and dreary, and sometimes rainy. Stratus clouds form flat layers or uniform sheets. Only a fine drizzle can form from stratus clouds because there is no vertical development.

Air usually contains some water in the form of moisture called dew. The water is hardly seen, as it is like a gas. Humid air contains more moisture than dry air, but when the temperature of air falls, its ability to hold moisture decreases. If the temperature drops low enough, air can become saturated, even if it was originally much drier at the warmer temperature. At this point, excess moisture begins to condense, forming small water droplets on the ground called dew. As an air mass cools, it can hold less and less water vapor. If it cools down enough, it reaches a point at which the water vapor present in the air mass represents the amount needed to saturate an air mass at the lower temperature. The temperature at which saturation occurs is the dew point. The dew point depends on the amount of water vapor in the air. In winter, the temperature may fall below freezing. If dew has formed on the ground, it will freeze, forming white crystals called frost.

When the temperature of air close to the ground falls low enough, dew will form. If a larger layer of air is cooled, the condensation of excess moisture in the air forms a mist of tiny water droplets known as fog. Fog is common in the autumn and winter and usually forms when there is little or no wind to disturb it. It is also more common in hollows and valleys, where the air tends to be a little colder because it is heavier and sinks down into these places. Fog is least likely on hilltops, unless low clouds have descended to cover them.

The major driving force behind the weather is the sun. Energy from the sun is stored in the atmosphere as heat. When this heat is moved around, it makes the weather. The equator is much hotter than the poles because it receives much stronger sunlight. There is more heat stored in the atmosphere nearer the equator. Heat, however, likes to flow from warm to cold temperatures. More heat is also stored nearer the ground. This makes the air lighter than that above it, and it rises. When air rises, its temperature falls, which makes weather features such as clouds and rain.

SEVERE WEATHER

The greater part of Europe often experiences bad weather, particularly in winter. Bad weather usually comes in from the Atlantic Ocean with weather systems called depressions—regions of low pressure, strong winds, and rain. In the tropics, bad weather is much less common, but when it strikes, it can be devastating. Large tropical storms, which usually develop toward the end of summer, are called hurricanes. The most common place for hurricanes to form is in the Caribbean. Here, seawater temperature is high because the sunlight is strong, and a lot of heat is stored there. Under the right conditions, a storm will develop, which, with sufficient energy, will become a hurricane. Viewed from a satellite, a hurricane appears almost circular, with clouds spiralling out from a small center. On the ground, the weather in the center may be fairly calm, with clear skies, but as the hurricane moves over, the weather can become very nasty, with winds of over 100 mi. (161 km.) per hour that are strong enough to tear roofs off houses.

Heavy rain, dark black clouds, and lightning are evidence of a thunderstorm. Thunderstorms are not nearly as strong as hurricanes, but they can be damaging, particularly if large hailstones fall out from their clouds. Thunderclouds are known scientifically as cumulonimbus clouds. Thunderstorms are more common in summer because they need a lot of energy to form. The energy comes from the heating of the ground and the surface air by the sun. If this heating is strong enough, air heated near the ground will rise up a long way into the atmosphere because it is lighter than the air around it. Warmer air is lighter than colder air. As the air rises up, it becomes colder. Moisture in the air begins to condense out as clouds, in the same way as fog forms on a calm, cool night. In thunderclouds, however, the energy is much greater, and the currents of air are strong enough to split apart the raindrops that are forming. This builds up an electric charge, which, when released, is seen as lightning. The sound of thunder is the effect of the lightning strike on the surrounding air. When rain or hail begins to fall from a thundercloud, it is usually very heavy, but it generally lasts no more than 30 minutes. Sometimes, however, the death of one thunderstorm may lead to the development of another, and the bad weather may continue for several hours.

A rapidly spiralling column of air is called a tornado. Large thunderstorms develop because there is an awful lot of energy stored in the atmosphere. Some large thunderstorms give birth to tornadoes. The tornado is usually very small in comparison to the thunderstorm, but it can wreak terrible havoc across the small area over which it moves. At a distance, a tornado is seen as a rapidly rotating funnel or spout of air, usually colored grey because of clouds and earth debris caught up inside it. The strongest tornadoes can have wind speeds of over 250 mi. (402 km.) per hour—and sometimes over 300 mi. (483 km.) per hour.

Most water on earth is in the oceans. A little, however, is contained by air in the atmosphere. The water in the atmosphere is usually not seen except when it rains, as it is in the form of moisture or vapor. Water enters the atmosphere by evaporating from the surface of the oceans, lakes, and other liquid water bodies. At higher levels in the atmosphere, the air is colder, and moisture begins to condense out as fine droplets, which we see as clouds. When conditions are right on the ground, the same process forms fog. Eventually, water in clouds forms rain, hail, sleet, or snow, which falls back to the ground. This movement of water from the earth to the atmosphere and back again is called the water cycle. The water cycle is responsible for much of the world's weather.

Weather World 2010 Project

DEVELOPED BY THE Department of Atmospheric Sciences (DAS) at the University of Illinois Urbana-Champaign (UIUC), the Weather World 2010 project (WW2010) is a WWW framework for integrating current and archived weather data with multimedia instructional resources, using new and innovative technologies. The project focuses on many different manifestations of global warming such as hurricanes, clouds and precipitation, and El Niño. The accuracy of the instructional resources on the website has been reviewed by professors and scientists from the DAS at the UIUC and at the Illinois State Water Survey.

Weather World 2010 is the result of a long process dating back to January 1993, when Dr. Mohan Ramamurthy and programmer John Kemp created the Weather Machine. This resource allowed users to view weather images through a gopher server. At the same time, Steve Hall started to devise instructional modules in HyperCard for use by the educationally motivated Collaborative Visualization (CoVis) Project, a project that strives to promote project-based science learning. The advent of the first Web browser Mosaic marked the birth of a new medium for the exchange of information on the internet. As a result, efforts were made to place both weather and educational resources into HTML format. This conversion transformed the original Weather Machine products into the Daily Planet, which was created in 1994. This first attempt to realize a World Wide Web product was a success, and it soon became a popular site for many to browse.

Meanwhile, Mythili Sridhar and Steve Hall converted the HyperCard-based educational modules to HTML so that they could be used on the Web. The people working on the project soon became aware of the necessity of integrating weather data with explanatory and educational material. This led to the creation of the CoVis-sponsored Electronic Textbook, later named the Online Guide to Meteorology, in 1995. This server became an extremely useful location for users to learn about weather with archived data for examples. The CoVis also provided the Geosciences Web Server, a useful resource allowing users large collections of links to all sorts of weather information, as well as educational material.

In the summer of 1995, the team of researchers released the Weather Visualizer, which became one of the most successful attempts to integrate real-time weather and instructional material. It allowed users to customize their own weather maps and to get explanations about difficult or technical terms. Seeing the rising popularity of HTML and newer technologies such as Java, fall 1995 witnessed the creation of the Image Animator and the Interactive Weather Report—a couple of the first Java weather tools on the Web. Thanks to real-time instant access to weather data using Java applets, these tools allowed an increased level of educational interactivity.

The first discussions of a dynamic framework for hypermedia and CD-Web interactivity started to take place in the early months of 1996. Such discussion was prompted by the difficulties experienced by CoVis teachers in accessing the large volume of information within the educational modules. Often, their connections were too slow to effectively use the resources in their classrooms. The desire to improve and redesign the existing resources, including developing better graphical interfaces and navigation systems, prompted Steve Hall and Dave Wojtowicz to begin the construction of the early form of Weather World 2010 in May 1996. This project soon grew into a much larger task than was initially conceived: rather than a simple improvement, this new project was to provide a new framework to support the preexisting modules and allow users access to weather data and information. In October 1996, the project was presented to the students, faculty, and staff of the Department of Atmospheric Sciences at the University of Illinois. The project drew on the different expertise of the many volunteers that it managed to involve, and in return, it provided them with a chance to learn HTML. Since October 1996, nearly 20 people have volunteered for a variety of tasks: writing scripts to generate image products, developing helper sections to describe images and fundamental concepts, creating instructional modules, and participating in design input and performance testing.

Initially, the team of WW2010 spent considerable time browsing the internet, finding the most appealing features of available websites, and incorporating some of these features into the server. Although Java and other new technologies are opening up exciting possibilities, the researchers of WW2010 remain concerned with allowing easy access to large sets of data and instructional materials and efficient navigation. WW2010 is an example of how new and innovative technologies can be used to visualize some of the effects of climate change and global warming on our lives.

Western Boundary Currents

WESTERN BOUNDARY CURRENTS are intense jet currents at the western periphery of large-scale oceanic gyres in the World Ocean. As was shown in the pioneer paper of Henry Stommel in 1948, they are the result of two causes: the so-called β-effect (this term has arisen from traditional representation of Coriolis force, f, in the following form: $f = f_0 + \beta y$, where f_0 is a Coriolis parameter at a definite latitude; in other words, the β-effect is to the result of the spherical form of the Earth turning around its axis), and low conservation of absolute vortex for the oceanic motions.

Oceanic gyres are forced by horizontally inhomogeneous large-scale wind fields (or wind vorticity). For instance, in the North Atlantic Ocean, anticyclonic subtropical gyre is situated under northeastern trade wind and midlatitude westerly wind as a result of clockwise wind vorticity, whereas north tropical cyclonic gyre is a result of anticlockwise wind vorticity between the Intertropical Convergence Zone and the northeastern trade wind. Currents in the western part of each gyre are more intense than in the eastern part because this is dictated by low conservation of absolute (relative plus planetary) vortex.

Each particle moving northward (southward) gets an additional (loses) planetary vorticity as a result of the spherical form of the Earth. In the clockwise gyre, this should be compensated for by the increasing relative negative vorticity, that is, by the intensification of clockwise rotating. In the anticlockwise gyre, this should be compensated by the increasing of relative positive vorticity, that is, by the intensification of anticlockwise rotating. In both cases, this leads to intensification of currents in the western periphery of the basin. In the eastern part of gyres, all particles move in the opposite direction, in comparison with the western part. It leads to the weakening of circulation in the eastern gyres' end.

The β-effect may be also understood in terms of Rossby waves. Actually, long, nondispersive Rossby waves carry (kinetic) energy from the east to the west within each gyre. After their reflection from the western boundary of the basin, the short dispersive Rossby waves are generated and move to the east. However, the short Rossby waves are dissipated in the relatively narrow vicinity of the near-coastal zone as a result of their shortness and dispersive properties, which lead to more affective realization of dissipative processes. Thus, the kinetic energy of the planetary Rossby waves is accumulated in the vicinity of the western periphery of the gyres.

In fact, western boundary currents (especially in the Atlantic Ocean) are also controlled by thermohaline factors. The β-effect affects thermohaline circulation and causes the intensification of the thermohaline currents in the western part of the basin. Deep thermohaline currents in the North Atlantic Ocean (generating in the region of sinking of Deep Atlantic Ocean Water and spreading at the depths between 1.5 and 2.5 mi., or 2.5 and 4 km.) are southward, whereas compensative thermohaline currents in the upper baroclinic layer (between the surface and 0.6 and 1.2 mi., or 1 to 2 km.) are northward. As a result, the wind-driven northward Western Boundary Currents in the clockwise gyres intensify, and southward ones in the anticlockwise gyres weaken as a result of meridional thermohaline circulation.

The most intense Western Boundary Currents in the Northern Hemisphere are the Gulf Stream, Labrador Current, North Brazil Current (Atlantic Ocean), Kuroshio (Pacific Ocean), and Somali Current (Indian Ocean). The velocity in these currents' axes reaches or even exceeds 6.5 ft. (2 m.) per second. Detailed analysis of the structure and origins of Western Boundary Currents (e.g., the Gulf Stream) was done by Henry Stommel in 1958 and 1966.

Western boundary currents in the North Atlantic Ocean carry up to about 100 Sv (1 Sverdrup = 10^6 cu. m. per second) of water in the upper baroclinic layer. The wind vorticity accounts for about 30 to 60 Sv (30–60 multiplied by 10^6 cu. m. per second). The average power of source of Deep Atlantic Ocean Water is about 20 Sv (20 multiplied by 10^6 cu. m. per second). So, the joint effect of wind vorticity and meridional thermohaline circulation can explain up to 80 percent of observed transport of the western boundary currents in the North Atlantic Ocean.

Western boundary currents are meandered jets that generate the intense mesoscale eddies, the so-called rings. The typical horizontal size of rings is about 62 mi. (100 km.), and orbital velocity is 3.3 to 6.5 ft. (1 to 2 m.) per second. Rings trap the water in their central part and carry it with a typical speed of about a few centimeters per second. The lifetime of the rings may reach 4 years. Thus, mesoscale eddies account for a significant portion of volume transport in the vicinity of Western Boundary Currents. Recirculation of the Gulf Stream is one of the integral manifestations of mesoscale effects.

Western Regional Climate Center

THE WESTERN REGIONAL Climate Center (WRCC), based in Reno, Nevada, and inaugurated in 1986, is one of six regional climate centers in the United States. The regional climate center program is administered by the National Oceanic and Atmospheric Administration. Specific supervision is provided by the National Climatic Data Center of the National Environmental Satellite, Data, and Information Service.

The mission of the Western Regional Climate Center is to disseminate climate data and information of the highest standards pertaining to the western United States; promote better use of this information in policymaking; carry out applied research related to climate issues; and improve the coordination of climate-related activities at the state, regional, and national levels. The center receives queries from lawyers, media, insurance companies, different businesses, teachers and students, contractors, the Forest Service, state and local government, and individuals interested in weather observation.

The data collected by the center include daily climate observations for a digital period of record (6,781 stations, about 2,608 now active), summarized monthly climate data (5,240 stations), hourly precipitation data (1,937 stations), upper air soundings recorded twice a day (about 50 stations), surface airway hourly observations (over 1,800 stations nationwide). In addition, the center provides access to these databases: remote automatic weather station, historic lightning data though 1996, access to Natural

Resources Conservation Service SNOTEL (SNOwpack TELemetry), and other western databases.

The WRCC coordinates the work of federal resource management agencies and western committees and commissions. It liaises with other centers and programs such as the National Climate Data Center in Asheville, North Carolina; regional climate centers; state climatologists and state climate programs; the Climate Analysis Center, Washington D.C.; and the National Weather Service. Its main areas of research include the effects of climate variability in the western United States, the quality control of western databases, the relation of El Niño/Southern Oscillation to western climate, the climatic trends and fluctuations in the West, geographic information systems, and remote sensing. It is also the home of the regional climatologist.

Although the WRCC is concerned with some of the most evident phenomena of global warming, such as the effect of El Niño on western climate, the climatologists at the center do not agree on a single definition of global warming. For example, in July 2007, Jim Ashby, one of the WRCC climatologists, challenged the credibility of weather data collected by weather stations, as they are often moved. Even moving the weather station just few hundred yards could make a difference in temperature and moisture, Ashby maintained, creating a situation in which data belonging to different areas are compared. This comparison of inhomogeneous data would be, according to Ashby, the same as comparing apples and oranges. Ashby has also stressed that even stations that remain in the same place can have changing circumstances that alter weather readings.

Atmospheric readings can be altered by the surroundings (the presence of trees favors cooler temperatures, whereas new buildings and more roads and rooftops retain more heat). Ashby takes Reno, where the Western Regional Climate Center is situated, as a classic example of a place where weather is being changed by urbanization. Average low temperatures in town have risen about 10 degrees (5 degrees C) in the last 20 years. "Most of the warming is due to the fact Reno is growing like a weed," Ashby argued. "The weather station used to be out in a field somewhere. Now it's surrounded by asphalt." This line of reasoning comes dangerously close to that of global warming contrarians, who say that all the moves and changes at weather stations have affected the validity of the climate record.

Another climatologist at the center, Kelly Redmond, has instead pointed out the visible effects of global warming on the vegetation of the region. Western states are heavily dependent on snowpack for their flora. Melting snow provides three-fourths of the water in streams. Over the past 35 years, temperatures across the region have risen from 1–3 degrees F (0.5–1.6 degrees C), causing the snow to melt as much as three weeks earlier and leading to widespread droughts.

West Virginia

WEST VIRGINIA HAS the 37th largest population of America's 48 contiguous states and is the 20th largest emitter of carbon dioxide. The past century has seen an average temperature increase of 1.1 degrees F (degrees C) in Charleston, the state's capital, and an average precipitation increase of 10 percent across the state. Scientists predict that if the climate continues to rise, there could be an increase in the number of thunderstorms and extremely hot days. By 2100, average temperatures in winter, spring, and summer could be 3 degrees F (1.6 degrees C) warmer than at present, and autumn temperatures could be 4 degrees F (2.2 degrees C) higher. Precipitation could also be significantly higher.

Rising temperatures have the potential to alter the state's natural environment, particularly the topography of its forests. The exact effect of a warmer climate on forests, which constitute 97 percent of the state's land mass, is unknown. If average rainfall decreases in the coming years, forests could shrink by as much as 10 percent, and grassland will appear where trees once stood. In contrast, a combination of warmer temperatures and increased rainfall could support the growth of tree species that thrive in such conditions, such as oaks and pines, and create much denser forests. Changes to the state's forests would have significant implications for the plant and animal species that rely on forests for their survival. Hares, red squirrels, and the northern flying squirrel are particularly at risk, as their habitats are concentrated in mountain forests, thus making it impossible for them to move to higher altitudes. Significant climate change over the next century could potentially eradicate some or all of West Virginia's high-altitude forests. The state's most expansive forest, the Monongahela Forest, is one such example.

The state's water supply, much of which originates from groundwater such as lakes and rivers, could also be affected by hotter weather. Much of the state lies at a high altitude, and an earlier spring would cause water levels to rise as a result of melting snow. Higher water levels may cause problems such as flooding, property damage, and erosion. Summer droughts, which already have an effect on water supplies, could cause rivers and lakes to dry up entirely, cutting off water to a substantial portion of the state's population. At present, nearly all the rural population and around half the urban population are supplied by groundwater. Receding water reserves could exacerbate problems such as acid and sludge drainage from abandoned coal mines and increase concentrations of bacteria and feces in the water supplied to homes and businesses. Low water supplies would also affect the tourist industry by limiting the opportunities for sports such as white-water rafting.

A warmer climate in West Virginia could also change patterns of farming and agriculture. Less rainfall would reduce soil moisture and create the need for irrigation—a practice that would divert water from homes and communities. Alternatively, it could push agriculture to the northern reaches of the state. More sun and less rain could increase yields of hay, the state's main crop, by as much as 30 percent, but at the same time it would destroy arable pasture used for livestock grazing. In turn, livestock farming would be less profitable, because animals would not yield as much meat.

If climate change continues, it will create health risks for the inhabitants of West Virginia. Heat-related deaths and illnesses would likely increase, particularly among elderly people living alone. The increase in ground-level ozone that would result from warmer temperatures could potentially lead to more incidences of respiratory illnesses such as asthma and impaired lung function. Ticks and certain species of insect would be more able to thrive and spread diseases such as dengue fever in a warmer climate. Mosquitoes would be especially adept at surviving and would likely spread malaria, a disease that does not naturally exist in the state, and California encephalitis, a lethal disease that causes neurological damage. Higher rainfall, another possible consequence of climate change, could facilitate the transmission of water-borne illnesses such as giardia, crypto-sporidia, and bacterial gastroenteritides.

The state faces specific policymaking challenges to address the possible consequences of climate change.

Wind-Driven Circulation

WIND-DRIVEN CIRCULATION (WDC) refers to ocean currents initiated and propelled by winds blowing across the surface of the ocean. Wind-driven circulation is part of the complex system of energy and heat redistribution that helps to draw tropical heat away from equatorial regions to moderate the earth's climate.

WIND GENERATION

Wind is caused by the uneven solar heating of the Earth's surface, which creates areas of high and low atmospheric pressure. Pressure differentials cause air to circulate from areas of high to low pressure. Solar heating is greatest near the equator, causing a region of low pressure. Rising air moves northward as cooler air from high pressure, mid-latitude regions moves towards the equator. The Coriolis Effect, the rotational action of the earth spinning on its access, deflects the winds towards the east north of the equator and to the west south of the equator. This explains why prevailing winds in the midlatitude northern hemisphere come from the west.

OCEANIC CIRCULATION

An understanding of wind generation helps to explain the operation of ocean currents. There are two general types of ocean circulation and both result from solar heating: (1) WDC, and (2) thermohaline circulation (THC). Differential solar heating generates wind. Wind blowing across the surface of the ocean causes the water to move. The direction of the ocean current is determined in part by the direction of the prevailing winds at a given latitude. WDC is responsible for currents near the ocean's surface.

THC drives deep-water ocean currents and vertical movement of water. THCs occur as water density increases, either through cooling as water moves towards the poles, or because of increased salinity. In both cases, the THC is responsible for carrying warmer surface water to the ocean depths.

There is an interplay, then, between the WDCs and THCs that is exemplified in the Gulf Stream that moves warm water from the Caribbean in a northeasterly direction, along the eastern seaboard of North America, towards northern Europe. As WDCs carry water away from the tropics, the water cools and becomes more saline. It consequently becomes more dense, which causes it to sink along a THC. This mechanism whereby warm surface water is transported towards the poles, descends as it becomes cooler, to be re-circulated southward as cool deepwater currents is sometimes referred to as the North Atlantic conveyor.

GLOBAL WARMING AND THE INTERPLAY OF WDCS AND THCS

The Gulf Stream starts as a WDC because it gets its initial energy from the trade winds. Global warming could affect the Gulf Stream in two ways. The first, and more widely reported mechanism occurs because global warming could melt arctic ice, decreasing sea salinity. This will in turn hinder the ability of the water to descend as part of the THC. The end result is the cooling of northern latitudes.

Global warming could also affect the initial forcing of the Gulf Stream. Some researchers suggest that global warming will disrupt and weaken the trade winds. Diminished trade winds means less energy driving the Gulf Stream northward, also contributing to a cooler climate at high latitudes. This could cause dramatic cooling in northern Europe which needs the North Atlantic Conveyor to moderate its climate. The paradox is that global warming could ultimately cause regional cooling in some parts of the world by affecting both the THCs and WDCs.

Winds, Easterlies

WINDS ARE DEFINED by their origins. The "easterly" descriptor refers to winds with an easterly zonal component (coming from the east). These include northeasterly and southeasterly winds. Easterly winds occur at all atmospheric scales, including local and synoptic. However, the term "easterly winds" generally refers to large-scale belts of winds operating within the global circulation of the atmosphere.

In the atmosphere's general circulation, two distinct bands of easterly winds exist: the trade winds and the polar easterlies. They are found at low and high latitudes, respectively, and arise from the dynamics of air flow among pressure systems.

Among the most consistent winds on earth, the trade winds (or trades) are part of the Hadley cell circulation found from approximately 0 degrees to 30 degrees north and south of the equator. Air rises near the equator as a result of a combination of convection spurred by intense solar radiation and the low-level convergence of wind in a circumpolar zone called the Intertropical Convergence Zone. As the rising air approaches the tropopause, it turns. At approximately 30 degrees, the air subsides, or sinks, resulting in the belt of persistent subtropical highs. Air diverges out of these anticyclones and flows toward the equatorial low. This outflow of air gives rise to the trades. As the air moves toward the equatorial low, it is deflected as a consequence of the Coriolis force (or effect). This deflection results in northeasterly trade winds in the Northern Hemisphere and southeasterly trades in the Southern Hemisphere. The trade winds are also referred to as tropical easterlies, particularly when the associated vertical wind shear is large.

The polar easterlies, a belt of winds found from approximately 60–90 degrees in each hemisphere, constitute another component of the general circulation. These winds originate from dynamics similar to those of the Hadley cell. Thermally driven high pressure exists at the poles; similarly, a circumpolar zone of low pressure is found near 60 degrees. As air flows from the polar high to the subpolar low (as a result of the presence of a pressure gradient), it is deflected. This deflection leads to a belt of easterly winds in both Northern and Southern hemispheres.

Rising air over the western tropical Pacific, with sinking air over the eastern tropical Pacific, comprises the Walker air current. The trades, as part of the Walker circulation, push warm surface waters toward the west.

Any weakening of the trades, then, would disrupt this oceanic transport of water. This dynamic is similar to an El Niño, in which the trade winds slow and even break down. Recent research suggests that climate changes, specifically global warming, would weaken or slow the trade winds. Indeed, the Walker circulation has already diminished by 3.5 percent since the 1800s. This slowing is projected to continue, and much of this change is attributed to anthropogenic activity.

The culprit in the slowing trade winds is the balance between evaporation and precipitation. To maintain a balance, the atmospheric absorption of moisture must be balanced by its release by precipitation. Water vapor, transported west by the trade winds, is precipitated out over the western Pacific. Warmer temperatures, then, spur the absorption of additional water vapor by enhancing evaporation rates. However, precipitation rates increase more slowly. To balance these processes, wind flow must decrease.

Weakened trade winds would result in numerous consequences, including the disruption of normal weather and climate patterns, as well as suppressed oceanic upwelling and potentially reduced biological productivity. The latter would have important economic ramifications, particularly for the Pacific fishing industries.

Winds, Westerlies

THE WESTERLIES ARE the prevailing winds in the middle latitudes blowing from the subtropical high pressure toward the poles. The westerlies originate as a result of pressure differences between the subtropical high-pressure zone and the subpolar low-pressure zone. The westerlies curve to the east because of the Coriolis effect, caused by the Earth's rotation. In the Northern Hemisphere, the westerlies blow predominantly from the southwest, whereas in the Southern Hemisphere, they blow predominantly from the northwest. The equatorward boundary is fairly well defined by the subtropical high-pressure belts, whereas the poleward boundary is more variable. The westerlies can be quite strong, particularly in the Southern Hemisphere, where less land causes friction to slow them down. The strongest westerly winds typically occur between 40 degrees and 50 degrees latitude.

Winds transport heat from warmer areas to cooler areas and help the Earth to maintain equilibrium of its thermal environment. In the midlatitude, the westerlies play a big role in the weather and atmospheric circulation in the middle latitudes. They transport warm, moist air to polar fronts and are also responsible for the formation of extratropical cyclones. In winter, they collect warm, moist air from over the oceans, move it to the cooler continents, and bring heavy rainfall to the areas like the northwest coast of the United States. In summer, they collect hot, drier air from over the continents and move it to the oceans.

Does global warming influence westerlies? A recent study of westerlies in the Southern Hemisphere shows that the westerlies are shifting southward, toward Antarctica. No conclusion has been made yet, however. Some scientists believe that recent observations are related to global warming, but others think of them as a part of natural variations. North Atlantic Oscillation (NAO) is one indicator that shows the relationship between global warming and westerlies. NAO is calculated by the difference in pressure between the permanent low-pressure system located over Iceland (Icelandic Low) and the permanent high-pressure system located over the Azores (Azores High). Global warming can reduce the difference in pressure between the two places. At a high NAO index, a large pressure difference between the two places induces stronger westerlies flow. Storm tracks advance northward, and Europe experiences milder winters but more frequent rainfall in central Europe and nearby. At a low NAO index, with suppressed westerlies, storm tracks move more toward the Mediterranean, which results in colder winters in Europe and southern Europe and in North Africa receiving more storms and higher rainfall.

El Niño–Southern Oscillation (ENSO) is another indicator. In winters of El Niño years, the polar jet stream in the Northern Hemisphere moves farther poleward and brings warmer winter weather to the northeastern part of the United States. In the winter of 2006 to 2007, the warming induced was about 9 degrees F (5 degrees C), which was as much as five times the typical air temperature increase compared with a warming in a typical El Niño year. Changes in both surface and upper-level westerlies resulting from El Niño patterns can also influence the development, intensity, and track of hurricane over the tropical Atlantic Ocean. In fall 2006, El Niño strengthened the upper-level westerlies, increased wind shear, and discouraged tropical cyclogenesis over the tropical Atlantic. Whether or not global warming is behind these stronger El Niño patterns is still being researched. A recent climate model (Joellen L. Russell et al., 2007) indicates that westerlies influence the temperature of the Southern Ocean. According to the model, the southward movement of the Southern Hemisphere westerlies in recent years transfers more heat and carbon dioxide into the deeper waters of the Southern Ocean. This poleward shift of the westerlies has intensified the strength of the westerlies near Antarctica. The pattern could slow down global warming somewhat but also induce ocean levels to rise in Antarctica.

How global warming influences the westerlies still remains in question. The recent observation, however, suggests that global warming brings noticeable change in the westerlies.

Wisconsin

WISCONSIN IS 65,498 sq. mi. (169,639 sq. km.) in size, with inland water making up 1,830 sq. mi., (4,740 sq. km.), and Great Lakes Coast water of 9,358 sq. mi., (24,237 sq. km.). Wisconsin's average elevation is 1,050 ft., (320 m.) above sea level, with a range in elevation from 579 ft., (176 m.) above sea level on Lake Michigan to 1,951 ft., (595 m.) at Timms Hill. Wisconsin is customarily divided into two major natural regions: the Central Lowland (low-lying area and swings in a broad belt across the southern two-thirds of Wisconsin) and the Superior Upland (higher elevation, forest cover, and numerous small glacial lakes). A low-lying and partially swampy plain, known as the Lake Superior Lowland, occupies the areas along the southern shore of Lake Superior. Wisconsin's rivers drain into either the Mississippi River system or the Great Lakes–St. Lawrence system. The Mississippi River forms part of the border with Minnesota and the entire border with Iowa. Wisconsin has many lakes and a few reservoirs.

Weather in Wisconsin varies greatly from winter to summer, with bitter cold and lots of snow in winter and warm and humid summers. This type of climate is called temperate continental. Three different types of air masses affect Wisconsin. The continental polar air masses from the northwest bring bitter cold, dry weather in winter. The maritime tropical gulf air mass from the Gulf of Mexico brings high humidity and heat in summer. The maritime polar Pacific air mass can bring more moderate weather straight from the west any time during the year. Wisconsin's weather is also affected by the Great Lakes on its northern and eastern sides by their moderating of the weather in the coastal areas, which are warmer in winter and cooler in summer than the rest of the state. Residents of shoreline cities get lake-effect snow (perhaps several inches, while 30 mi. (48 km.) inland, the sky is sunny and nobody needs to shovel). The annual precipitation is 31 in (79 cm.). The southern counties get about 30 in. (76 cm.) of snow each winter, and the annual snowfall in Iron County to the north can be as much as 100 in. (254 cm.). The highest temperature recorded in the state is 114 degrees F (45.5 degrees C) on July 13, 1936, and minus 55 degrees F (13 degrees C), on February 4, 1996, is the lowest temperature recorded in the state.

Wisconsin is a Corn Belt state, and corn is its major crop. Other leading crops are soybeans, hay, sweet corn, potatoes, cranberries, and oats. Major industries include dairy products, corn, hay, and beef. Wisconsin takes advantage of Lake Michigan for commercial fishing, though it is only a small industry in the state. Important species are whitefish, lake trout, perch, chub, alewife, and carp. Forestry is a minor industry, with most hardwood cut going to plywood and veneer manufacture; the pulp and paper industry consumes much of the softwood harvest. Wisconsin's mineral output is limited to stone, sand and gravel, copper, lime, lead, and talc.

Canadian geese seeking refuge in the comparatively warm water temperature during -20°F weather in Mequon, Wisconsin.

Wisconsin experienced a sample of possible effects of climate change with the Great Flood of 1993, when rain and snow runoff raised the Mississippi River along with other rivers and small streams. Madison reported 21.49 in. (54.5 cm.) of rain. Signs of global warming are apparent throughout the Great Lakes. Over the past 150 years, the average extent of ice cover on many of Wisconsin's lakes has continuously declined.

Although climate models vary on the amount of temperature increase during the 21st century, ranging from 8–7 degrees F (4.4–3.8 degrees C), the average summer water level in the Great Lakes could drop 1.5–8 ft. (0.4–2.4 m.) by the end of the century, and extreme 100-year floods (named because they happen once every 100–200 years) could begin to occur on a much more frequent basis. With extreme floods and higher temperatures, Wisconsin could experience more drought conditions as a result of increased evaporation, and reduced soil moisture may force farmers to rely more on irrigation.

Possible effects from increased temperatures include decreased water supplies; changes in food production, with agriculture improving in cooler climates and decreasing in warmer climates (Wisconsin farmers could see an increase in demand for corn-based ethanol); changes in rain pattern to downpours, with the potential for flash flooding and health risks of certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents; warmer temperatures can cause heat-related illnesses and lead to higher concentrations of ground-level ozone pollution causing respiratory illnesses, especially in cities with smog, like Milwaukee.

On the basis of energy consumption data from EIA's State Energy Consumption, Price, and Expenditure Estimates, released June 1, 2007, Wisconsin's total CO_2 emissions from fossil fuel combustion in 2004 were 107.05 million metric tons, made up of contributions from commercial (5.67 million metric tons), industrial (16.67 million metric tons), residential (10.02 million metric tons), transportation (30.57 million metric tons), and electric power (44.13 million metric tons).

Wisconsin established the Task Force on Global Warming in April 2007 to understand emissions impacts, determine modeling scenarios, and define the sensitivities that will need to be run to establish reasonable ranges of outcomes for confident decision making by Wisconsin legislators. Wisconsin joined the Climate Registry, a voluntary national initiative to track, verify, and report greenhouse gas emissions, with acceptance of data from state agencies, corporations, and educational institutions beginning in January 2008.

Wisconsin lawmakers have enacted a minimum renewable electricity standard that requires utilities to provide 22 percent of the state's power from renewable sources by 2011. To meet this goal, the Wisconsin Public Service Corporation installed 14 wind turbines in Kewanee County that are expected to provide enough electricity for 3,600 homes and generate tax revenue. The National Renewable Energy Laboratory also estimates Wisconsin as having the solar potential to provide electricity generation.

The Wisconsin Department of Natural Resources is the agency responsible for carrying out state conservation programs. Reforestation, soil erosion, and wildlife management are the principal concerns of conservationists in Wisconsin.

Woods Hole Oceanographic Institution

THE WOODS HOLE Oceanographic Institution (WHOI), a world-renowned private, not-for-profit organization founded in 1930, is the largest independent oceanographic research institution in the United States. WHOI is committed to higher education and scientific research that furthers the understanding of the world's oceans and their role within the Earth's ecosystem as a whole. In addition, WHOI disseminates its research findings and information to the public and policymakers to foster understanding and decisionmaking for the greater good of society. At any given moment, more than 350 projects are in progress around the world, representing a wide range of scientific inquiries, in which collaboration and creativity are highly valued and encouraged.

WHOI recruits distinctly qualified scientists, engineers, staff, and students and provides an interdisciplinary and flexible setting in which students, as future scientists and engineers, can thrive. The research activities of the WHOI are centered in five departments: applied ocean physics and engineering, encompassing ocean acoustics, observation systems, and immersible vehicles; biology, with specialties in biooptical studies, pollution effects in the sea, and the behavior of marine animals; marine chemistry and geochemistry, focusing on chemical analyses and modeling of ocean processes; physical oceanography, including the examination of the geography and physics of the ocean currents; and geology and geophysics, including the study of the oceans' role in past climate change.

WHOI's research efforts are enhanced by four ocean institutes, established in 2000, which address the concerns of members of the general public and policymaking bodies and make research findings available as expeditiously as possible. The Coastal Ocean Institute encourages pioneering, interdisciplinary experiments, and field missions to increase knowledge and understanding about basic ocean processes. The Ocean Life Institute sponsors studies of the oceans' organisms and processes to understand the evolution of life and adaptability of species to their natural surroundings.

The Ocean and Climate Change Institute, among other undertakings, supports research about the effect of greenhouse gases on the ocean and the effect of ocean dynamics that may cause large, sudden climate shifts. WHOI's interest in research and technology that focus on the possible regional and global effects of changes in the Arctic on circulation and climate, including the effects on fisheries and ecosystems beyond the Arctic, was advanced in 2006 with the receipt of a grant to establish the Clark Arctic Research Initiative. The initiative is intended to make resources available to support individual and collaborative focused research based in the Arctic region through 2007.

The WHOI's fourth institute, the Deep Ocean Exploration Institute, encourages multidisciplinary research endeavors throughout WHOI and advocates the development of deep-sea technology, including vehicles such as *Alvin*, the Deep Submergence Vehicle owned by the U.S. Navy and operated by WHOI. In addition to *Alvin,* the National Deep Submergence Facility, funded by the federal government and located at WHOI, oversees the operation of the remotely operated vehicle *Jason/Medea* and the robotic underwater vehicle *ABE.* The year 2008 will be one of significant change as the *ABE* is replaced by the *Sentry,* which can dive to greater depths and has longer deployment capability than its predecessor.

Of even greater note is the anticipated retirement in 2008 of *Alvin*, which carries two scientists and a pilot as deep as 3 mi. (4.8 km.) for 6- to 10-hour dives. The submersible vehicle, which has made more than 4,000 dives since 1964, can reach almost two-thirds of the ocean's floor, moving at speeds up to 1.5 m.p.h. *Alvin* has remained a state-of-the-art vehicle because it has been disassembled, inspected, and reassembled every 3 to 5 years. Every part of *Alvin* has been replaced at least once in the vehicle's lifetime, but additional refurbishing will unlikely enable the sub to do more than it does now. *Alvin's* replacement vehicle will be funded by the National Science Foundation and will reach greater depths than *Alvin*, reaching almost the complete ocean floor. WHOI has indicated that operating both submergence vehicles is cost-prohibitive. *Alvin* leaves behind a rich history that has included locating a lost hydrogen bomb in the Mediterranean Sea, photographing the Titanic, and exploring deep-sea hydrothermal vents, where it gathered information about 300 life-forms that were previously unknown.

The WHOI's research fleet, which in addition to its submergence vehicles includes one of the United States' newest research vessels, the Navy-owned *Atlantis*, among its ships, provides students in the joint program offered by WHOI and the Massachusetts Institute of Technology (MIT) incomparable opportunities at research and learning. The MIT/WHOI Joint Program ranks among the leading graduate marine science programs in the world. In addition, WHOI 's Geophysical Fluids Dynamic (GFD) Program offers eight to 10 new graduate fellows each year the unique experience of participating in an intensive 10-week interdisciplinary research program. The students present a lecture and prepare a written report for inclusion in the GFD Proceedings Volumes.

Students who have fulfilled the requirements of a Ph.D. program may be awarded one of several postdoctoral appointments: the scholar, fellow, or investigator. Postdoctoral scholarships are awarded for 18 months in the fields of oceanography, biology, chemistry, engineering, geology, geophysics, mathematics, meteorology, physics, and biology. In addition, professionals in law, social sciences, or natural sciences may apply for Marine Policy Fellowships, which focus on the examination of maritime conflicts. The WHOI also appoints postdoctoral investigators to positions that fall within the parameters of existing research contracts or grants.

In addition to its premier graduate and postdoctoral programs, WHOI provides opportunities for undergraduate students to gain experience through its Summer Student and Minority Fellowship programs, working in partnership with scientists and engineers on a wide range of scientific topics.

WHOI also grants a limited number of undergraduate students and certain advanced high school students the chance to participate in WHOI's education programs as Guest Students for up to 1 year. Middle school teachers benefit from participation in profession development workshops presented by WHOI scientists and engineers at the WHOI Exhibit Center, which highlights the institution's research programs and vessels.

The WHOI, in partnership with the Marine Biological Laboratory (MBL), an international research center for biology, biomedicine, and ecology, makes a critical contribution to the everyday operation of the MBLWHOI Library. The library, acclaimed for having one of the world's largest collections, both print and electronic, in biomedicine, oceanography, marine biology, and ecology, meets the daily needs of WHOI and MBL scientists and associated researchers. Researchers and students affiliated with the MIT/WHOI Joint Program, the Boston University Marine Program, the Sea Education Association, the National Marine Fisheries Service, the National Ocean and Atmospheric Administration, and the United States Geological Survey also make use of the library's services and resources.

The MBLWHOI Library houses the Data Library and Archives, which, through a wide-ranging collection of administrative records, oral papers and histories, personal papers and diaries, photographs, film, video, instruments, and other documents, makes the history of the WHOI accessible to WHOI's scientific community. The library encourages access to the collection by other institutions and researchers, but its services are restricted to those compatible with the needs of WHOI and MBL. The MBLWHOI Library offers an impressive collection of online resources including the *Alvin* dive log database, the *Alvin* ocean floor photos, digital photos from the WHOI archives, a searchable database of nearly 4,000 films and videotapes in the library's collection, WHOI oral history project, a database providing links to data files from research cruises, and images and descriptions about WHOI ships.

The WHOI receives funding from private contributions and endowment income, but the majority of its funding is generated by peer-reviewed grants and contracts from government agencies, including the National Science Foundation.

In August 2007, a joint venture led by WHOI and including the Scripps Institution of Oceanography at the University of California, San Diego, and Oregon State University's College of Oceanic and Atmospheric Sciences, was awarded a $97.7 million contract by the Joint Oceanographic Institutions in support of the National Science Foundation's Ocean Observatories Initiative. Charity Navigator, an independent evaluator of charities in the United States, assigned its highest ranking of four stars to WHOI—one of 1,300 charities to be recognized as outperforming most charities in its cause. Evaluations are based on annual financial information each charity provides to the U.S. Internal Revenue Service.

World Bank

THE WORLD BANK (or the Bank) was established on December 27, 1945, following the ratification of the Bretton Woods agreement. The World Bank was conceived of in July 1944 at the United Nations Monetary and Financial Conference to provide development assistance to facilitate the reconstruction of Europe following World War II. Since then, the Bank has provided financial assistance to developing countries following natural disasters and humanitarian emergencies to facilitate postconflict rehabilitation and economic liberalization and development.

The organization of the World Bank consists of two agencies of the five that make up the World Bank Group (WBG): the International Bank for Reconstruction and Development (IBRD) and the International Development Association (IDA). The Bank consists of 185 member countries, all of whom are shareholders, represented by a board of governors—the ultimate policymakers of the Bank. The board of governors consists of member countries' ministers of finance or development, and it meets annually. The governors delegate specific duties to 24 on-site executive directors.

The five largest shareholders—France, Germany, Japan, the United Kingdom, and the United States—each appoint one executive director, and the remaining member countries are represented by 19 other executive directors, thus making up the 24. The president of the Bank, currently Robert B. Zoellick, is responsible for chairing the meetings of the board of directors and for overall management of the Bank. The president of the Bank serves a renewable five-year term. The president is, by tradition, a U.S. citizen nominated by the president of the United States—the bank's largest shareholder. The presidential nominee is confirmed by the board of governors.

The World Bank's activities are focused on the reduction of global poverty, especially on the achievement of the Millennium Development Goals (MDGs), goals calling for the elimination of poverty and the implementation of sustainable development. The constituent parts of the Bank, the IBRD and the IDA, achieve their aims through the provision of low- or no-interest loans and grants to countries with little or no access to international credit markets. The Bank is a market-based, nonprofit organization, using its high credit rating to make up for the low interest rate of loans.

MISSION AND FUNDING

The Bank's mission is to aid developing countries and their inhabitants achieve the MDGs through the alleviation of poverty by developing an environment for investment, jobs, and sustainable growth, thus promoting economic growth, and through investment in and empowerment of the poor to enable them to participate in development. The World Bank focuses on four key factors necessary for economic growth and the creation of a business environment: capacity building (strengthening governments and educating government officials), infrastructure creation (implementation of legal and judicial systems for the encouragement of business, the protection of individual and property rights and the honoring of contracts), development of financial systems (the establishment of strong systems capable of supporting endeavors from micro credit to the financing of larger corporate ventures), and combating corruption (eradicating corruption to ensure optimal effect of actions).

The Bank obtains funding for its operations primarily through the IBRD's sale of AAA-rated bonds in the world's financial markets. Although this does generate some profit, the majority of the IBRD's income is generated from lending its own capital. The IDA obtains the majority of its funds from 40 donor countries, who replenish the bank's funds every 3 years, and from loan repayments, which then become available for relending.

The Bank offers two basic types of loans: investment loans and development policy loans. The former are made for the support of economic and social development projects, whereas the latter provide quick disbursing finance to support countries' policy and institutional reforms. Although the IBRD provides loans with a low interest rate (between 0.5 and 1 percent for a standard Bank loan), the IDA's loans are interest free. The project proposals of borrowers are evaluated for their economical, financial, social, and environmental aspects to ensure that they are viable before any amount of money is distributed.

The Bank also distributes grants for the facilitation of development projects through the encouragement of innovation, cooperation between organizations, and participation of local stakeholders in projects. IDA grants are predominantly used for debt burden relief in the most indebted and poverty-struck countries, amelioration of sanitation and water supply, support of vaccination and immunization programs for the reduction of communicable diseases such as HIV/AIDS and malaria, support to civil society organizations, and the creation of initiatives for the reduction of greenhouse gases.

THE WORLD BANK AND CLIMATE ISSUES

With respect to its work addressing issues of global warming, the World Bank has created and funded a number of climate-related partnerships and programs with other agencies and national governments, including the United Nations Framework Convention on Climate Change (UNFCCC), the Global Environment Facility (GEF), Carbon Finance, the Energy Sector Management Assistance Program (ESMAP), the Asia Alternative Energy Program (ASTAE), the Global Facility for Disaster Reduction and Recovery (GFDRR), the Vulnerability and Adaptation Resources Group (VARG), and the Global Gas Flaring Reduction partnership (GGFR).

The UNFCCC is an international treaty through which countries consider ways to reduce global warming and cope with inevitable temperature increases. The World Bank is an observer to the UNFCCC and also takes part in a number of technical discussions conducted by the UNFCCC Secretariat, such as by the Subsidiary Body for Implementation and the Subsidiary Body for Scientific and Technological Advice.

The GEF is the financing mechanism for the UNFCCC, as well as other key international environmental agreements. As a GEF-implementing agency, the World Bank helps identify, prepare, and implement projects that reduce poverty and benefit the local and global environment. Climate change was the second most active focal area of the GEF active portfolio at the end of fiscal year 2006.

The World Bank's Carbon Finance Unit offers a means of leveraging new private and public investment into projects that serve to mitigate climate change by reducing greenhouse gas emissions, while promoting sustainable development. Projects relate to rural electrification, renewable energy, energy efficiency, urban infrastructure, waste management, pollution abatement, forestry, and water resource management.

The atrium of the World Bank in Washington, D.C. It has funded a number of climate-related partnerships and programs.

ESMAP, cosponsored by the World Bank and the United Nations Development Programme, is a global technical assistance program that provides policy advice on sustainable development issues to the governments of developing countries and economies in transition. ESMAP also contributes to technology and knowledge transfer in energy sector management and, since its creation in 1983, has operated in 100 different countries through some 450 different activities. Recently, a new window in ESMAP has opened to support the goals of the Clean Energy Investment Framework.

The ASTAE program, established in 1992, aims at mainstreaming renewable energy and energy efficiency in the World Bank's lending operations in the power sector in Asia. The World Bank is cooperating actively with the GFDRR, which aims at integrating hazard risk reduction strategies in development processes at local and national levels. The potential exacerbation of extreme climatic events as climate changes suggests significant overlap between the areas of adaptation to climate change and disaster risk reduction.

The VARG is an informal network of multi- and bilateral development institutions that aim to facilitate the integration of adaptation to climate change in the development process. The World Bank is one of 19 organizations that are partnering in this open-knowledge network.

The GGFR partnership, a World Bank–led initiative, facilitates and supports national efforts to use currently flared gas by promoting effective regulatory frameworks and tackling the constraints on gas utilization, such as insufficient infrastructure and poor access to local and international energy markets, particularly in developing countries. Launched at the World Summit on Sustainable Development in August 2002, GGFR brings around the table representatives of governments of oil-producing countries, state-owned companies, and major international oil companies, so that together they can overcome the barriers to reducing gas flaring by sharing global best practices and implementing country-specific programs.

THE SUSTAINABLE DEVELOPMENT NETWORK

Another World Bank initiative is the Sustainable Development Network, a part of which includes a Climate Change Team within the Environment Department of the Bank. The Climate Change Team provides resources and expertise for the World Bank's participation in international climate change negotiations under the UNFCCC and provides technical advice to the World Bank's GEF Program on the preparation of GEF climate change mitigation projects in energy efficiency and renewable energy and on the development of strategic initiatives with the GEF. The team also is leading the Bank's efforts related to climate change vulnerability and adaptation issues for its client countries.

The Bank recognizes that achieving objectives related to climate change is a long-term process requiring the integration of the greenhouse gas (GHG) mitigation and the vulnerability and adaptation agendas into mainstream operational work. These instruments include planning, policy dialogue, generation and dissemination of knowledge, and investment lending, all of which are primarily aimed at promoting national development priorities. Bank support to clients for better managing climate change occurs in three key areas: mitigation of GHG emissions, reduction of vulnerability and adaptation to climate change, and capacity building. In the area of GHG mitigation, the bank promotes policy and regulations, as these tend to have large and sustainable effects on improving the efficiency of resource use and, consequently, reduction of GHG emissions. In the context of these reforms, the Bank mobilizes resources from the GEF and the Prototype Carbon Fund to support GHG abatement measures that simultaneously address poverty reduction and sustainable development goals.

In areas of vulnerability and adaptation, where the decision on UNFCCC support is pending, the Bank will mobilize donor financing for a Vulnerability and Adaptation Facility to better prepare for climate change. Over the medium term, the Bank will focus on improving the understanding of the potential effects of climate change and on identifying and implementing no-regrets measures to reduce vulnerability to current climate and to climate change. Finally, the Bank will assist clients in building the capacity needed to deal with GHG abatement and with vulnerability and adaptation.

As part of its work in climate change, the World Bank has developed a variety of resource and training materials addressing the fundamental issues underlying climate change, examples of successful mainstreaming of climate change concerns into project work or underlying analysis, and basic tools for accurately identifying the climate change effects of projects, baselines, and alternatives. The climate risk screening toolkit is referred to as ADAPT (Assessment and Design for Adaptation to Climate Change), which is a prototype tool that will screen proposed development projects for potential risks posed by climate change and variability. The Bank has also developed a variety of tools and examples to help its staff and clients more readily address the methodological, technical, and economic issues underlying the incorporation of GHG issues in project development and economic analysis. In the area of renewable energy, the Renewable Energy Toolkit comprises a range of tools to help Bank staff and country counterparts improve the design and implementation of renewable energy projects. It aims at providing practical implementation needs at each stage of the project cycle and also helps project staff determine sustainable business models, financing mechanisms, and regulatory approaches.

World Business Council for Sustainable Development

THE WORLD BUSINESS Council for Sustainable Development (WBCSD), based in Geneva, Switzerland, is a global association of businesses focused on market-oriented solutions to sustainable development and is appropriately structured along the lines of a chief executive officer (CEO)–led business. The WBCSD's mission statement asserts its purpose: "Our mission is to provide business leadership as a catalyst for change toward sustainable development, and to support the business license to operate, innovate and grow in a world increasingly shaped by sustainable development issues." The WBCSD arose from ideas forwarded at the United Nations Conference on Environment and Development (UNCED), also known as the Rio de Janeiro Earth Summit of 1992, where Swiss businessman Stephan Schmidheiny was appointed chief adviser for business and industry to the secretary general of the UNCED. Schmidheiny created a forum called Business Council for Sustainable Development that eventually published the book *Changing Course*, in which the phrase eco-efficiency—doing more with less—was first used. The WBCSD was constituted in its current form when it merged (1995) with the World Industry Council for the Environment.

The WBCSD has approximately 60 national and regional business councils and has its North America office in Washington, D.C. Only companies committed to sustainable development are invited, by the executive council, to join the association.

General Motors, DuPont, 3M, Deutsche Bank, Coca-Cola, Sony, Oracle, BP, and Royal Dutch/Shell are among approximately 200 member companies from 35 countries representing 20 industrial sectors. Members make their knowledge, experience, and some limited human resources available to the WBCSD and are asked to base their business development within the parameters of economic, social, and environmental sustainability. Member company CEOs act as executive council members, cochair working groups, and promote the objectives of the WBCSD within their companies.

OBJECTIVES OF THE COUNCIL

The council's objectives are to be a leading business advocate on sustainable development, participate in policy development to create the right framework conditions for business to make an effective contribution to sustainable human progress, develop and promote the business case for sustainable development, demonstrate the business contribution to sustainable development solutions and share leading-edge practices among members, and contribute to a sustainable future for developing nations and nations in transition. To achieve these objectives the WBCSD has four focus areas (FAs): energy and climate, development, the business role, and ecosystems.

The WBCSD initiated its Energy and Climate FA in 1999 by creating and promoting ways for business to prosper while being socially and environmentally conscious within a sustainable development framework that prepares business for the carbon-constrained future necessary for the planet to counter anthropogenic (human-induced) global warming and climate change. This required innovation, education, and dialogue seeks to create an efficient approach to energy sustainability and climate change through changing and adapting policy frameworks, business plans and markets, advancing technologies, and the interaction between business, government, and economies regionally, nationally, and globally. One focus of this initiative was/is the large greenhouse gas (GHG) emitters (United States, China, India, and Russia). The WBCSD interacts with the UN Environment Programme (UNEP), the UNEPs Intergovernmental Panel on Climate Change (IPCC), and the UN Framework Convention on Climate Change, and also focuses on the development of a post-2012 flexible Kyoto mechanism. Energy and climate became the primary WBCSD FA in 2005.

WBSCDs *Facts and Trends to 2050* (2004) and *Pathways to 2050* (2005) proposed potential pathways to GHG stabilization and to creating a low GHG economy. Its *Policy Directions to 2050: A Business Contribution to the Dialogues on Cooperative Action* (2007) promotes these goals and the averting of a climate change catastrophe through the coordinated and sustained actions of governments, businesses, and consumers. The WBCSD's Greenhouse Gas Protocol Initiative joint initiative with the World Resources Institute attempts to standardize all GHG accounting.

The WBCSD contends that stable and sustainable societies cannot and must not tolerate poverty among their citizens and that businesses, economies, governments, and societies must work together to ensure open and fair access to all markets and opportunities. The WBCSD supports this focus through its Sustainable Livelihoods project, which advocates the changes in societal, policy, and business frameworks necessary to achieve this focus while promoting business-led development targeting the long-term alleviation of poverty.

The WBCSD Business Role FA began in 1992 with the publication of the book *Changing Course*, the basic premise of which was that the only solution to the challenges of environmental deterioration and climate change is the active participation of business. The WBCSD tried to ignite a discussion on the role that business should or might play in any future economic, social, and environmental sustainable society with its

2006 publication of *From Challenge to Opportunity: The Role of Business in Tomorrow's Society*. The WBCSD secretariat and its FA Core Team (FACT), composed of 11 member companies led by two cochairs, creates and implements the WBCSD Action Plan seeking to provide platforms for discussion and debate among business leaders, facilitate future thinking on how business might support sustainable development, use the available WBCSD resources more appropriately, and shape the message of the WBCSD to the business world.

Ecosystems became a WBCSD FA in March 2007 and, as a FA, is built on the WBCSD's Sustaining Ecosystems Initiative created in November 2005 to rally and direct business to address the ecosystem opportunities and challenges outlined in the July 2005 *Millennium Ecosystem Assessment* that the WBCSD partially authored. The goal is to encourage business to address the risks inherent in the accelerating degradation of the ecosystem and the loss of ecosystem services and to adopt mitigation and market-based strategies for enhancing sustainable management and ecosystems use. The WBCSD began addressing these issues by demonstrating how business could integrate these strategies into management systems when the WBCSD and the World Conservation Union (IUCN) jointly produced (1997) two reports on business and biodiversity: *A Guide for the Private Sector* and *A Handbook for Corporate Action*. The WBCSD and the IUCN continued to promote the benefits of integrating biodiversity into business after they partnered with the World Conservation Union to host a workshop on the subject in Bangkok, Thailand, in November 2004.

World Climate Research Program

THE WORLD CLIMATE Research Program (WCRP) is sponsored by the International Council for Science (ICSU), the World Meteorological Organization (WMO), and the Intergovernmental Oceanographic Commission (IOC) of the United Nations Educational, Scientific and Cultural Organization (UNESCO). The program brings together the intellectual and structural potentialities related to climate and climate change of more than 185 countries. The program thus aims to work as an international forum to share scientific discoveries and facilities to advance the understanding of the phenomena that influence climate. The two underlying objectives of the WCRP are to determine the predictability of climate and to assess the effect of human activities on it.

These two objectives stem from the needs identified by the UN Framework Convention on Climate Change. To achieve its objectives, the WCRP adopts a multidisciplinary approach, organizes extensive observational and modeling projects, and encourages researches on aspects of climate too large and complex to be addressed by any one nation or single scientific discipline. The WCRP is not open exclusively to scientists. On the contrary, it aims to involve different subjects such as policymakers, information end-users, and sponsors in a scientifically accurate debate on climate change and variability.

The WCRP was established in 1980. It was initially joint-sponsored by the ICSU and the WMO. Since 1993, the IOC of UNESCO has also become a sponsor of the program. Since its establishment, the WCRP has contributed to the advancement of climate science. Thanks to WCRP researchers, climate scientists can monitor, simulate, and project global climate with improved accuracy so that climate information can be used for governance, in decision making, and in support of a wide range of practical applications. In 2005, after 25 years of serving science and society, the WCRP launched its Strategy Framework 2005–2015, which expresses the program's commitment to working efficiently and effectively toward strengthening knowledge and increasing capabilities with regard to climate variability and change. Titled the Coordinated Observation and Prediction of the Earth System, the framework aims "to facilitate analysis and prediction of Earth system variability and change for use in an increasing range of practical applications of direct relevance, benefit and value to society." The WCRP is thus devoted to provide a larger series of products and services to an ever-increasing group of users. The WCRP intends to reach this goal through the integration of observations and models to generate new understanding and improve climate predictions.

Today, the WCRP covers studies of the different parts of the Earth's climate system: global atmosphere, oceans, sea and land ice, the biosphere, and the land surface. The major core projects, diverse working groups, various cross-cutting activities, and many cosponsored activities of the WCRP all aim to improve scientific understanding of processes that can enable better forecasts.

The Global Energy and Water Cycle Experiment (GEWEX) project studies the dynamics and thermodynamics of the atmosphere, the atmosphere's interactions with the Earth's surface (especially over land), and the global water cycle. GEWEX uses suitable models to represent and forecast the variations of the global hydrological regime and its effect on atmospheric and surface dynamics. GEWEX also focuses on variations in regional hydrological processes and water resources and their response to changes in the environment, such as the increase in greenhouse gases. GEWEX projects are divided into three focus areas corresponding to the key elements in the global energy and water cycle: radiation, hydrometeorology, and modeling and prediction.

The Climate Variability and Predictability (CLIVAR) project, set up in 1995, specifically targets climate variability. Its mission is to observe, simulate, and predict the Earth's climate system, with a focus on ocean-atmosphere interactions. CLIVAR seeks to develop predictions of climate variations on seasonal to centennial timescales and to refine the estimates of anthropogenic climate change. CLIVAR also includes a Working Group on Seasonal to Interannual Prediction, which oversees development of improved models, assimilation systems, and observing system requirements for seasonal prediction.

The section of WCRP dealing with the Stratospheric Processes and Their Role in Climate (SPARC), founded in 1993, carries out research on the chemistry of the climate system. In particular, it focuses on the interaction of dynamic, radiative, and chemical processes. SPARC's projects include the construction of stratospheric reference climatology and the improvement of understanding of trends in temperature, ozone, and water vapor in the stratosphere. SPARC also studies gravity wave processes, their role in stratospheric dynamics, and how these may be represented in models.

The Climate and Cryosphere (CliC) project, founded in 2000, measures the effects of climatic variability and change on components of the cryosphere and their consequences for the climate system. CliC is also charged with the task of improving the management of data and information relating to the cryosphere and climate, and with making data more readily available for use by the broader scientific community. To this end, CliC has established a Web-based Data and Information Service for CliC.

The Surface Ocean–Lower Atmosphere Study aims to quantify the key biogeochemical-physical interactions and feedbacks between the ocean and the atmosphere. WCRP cosponsors the project jointly with the Commission on Atmospheric Chemistry and Global Pollution, the International Geosphere-Biosphere Programme and the Scientific Committee on Oceanic Research. The project investigates biogeochemical interactions and feedbacks between ocean and atmosphere, exchange processes at the air-sea interface and the role of transport and transformation in the atmospheric and oceanic boundary layers, and air-sea fluxes of carbon dioxide and other long-lived radiatively active gases.

The Working Group on Surface Fluxes was established in 2007 to review the requirements of the different WCRP schemes for surface sea fluxes including biogeochemical fluxes, to coordinate the various related research initiatives, and to encourage research and facilitate operational activities on surface fluxes.

World Health Organization

THE WORLD HEALTH Organization (WHO), established in 1948 by the United Nations (UN), has a mission to promote international cooperation for improved health conditions of all peoples. The headquarters for WHO are in Geneva, Switzerland. Operations fall under the World Health Assembly (the policymaking body holds annual meetings), an executive board of health (specialists elected for three-year terms by the assembly) and a secretariat with regional offices and staff throughout the world. Financing for the services provided by WHO comes from member governments based on ability to pay and, since 1951, from an allocation from the technical assistance program of the UN.

The auspices of the WHO include providing a central clearinghouse for information and research as relates to health, sponsoring measures for the control of disease, and strengthening and expanding the public health administrations of member nations.

Overall health depends on potable water for drinking and washing, sufficient nutrition, and shelter and protection from weather extremes. Increased temperatures, rising sea levels, and changing weather patterns are factors affecting food, water, and shelter. Excellent health services and living conditions would have a protective or palliative effect on those populations. Substandard health services and living conditions would have a negative effect on populations in poverty or in disaster situations.

For prevention and preparedness, the WHO coordinates review of scientific evidence on the links between climate, climate change, and health. On the basis of the information available, WHO established a list of possible health effects resulting from rapid climate change, especially in vulnerable populations. The effect of warmer temperatures would increase the incidence of heat-related illnesses and lead to higher concentrations of ground-level ozone pollution, causing respiratory illnesses (diminished lung function, asthma, and respiratory inflammation). Flooding associated with storms and rising sea levels could increase the risk of contracting certain infectious diseases from water contamination or disease-carrying vectors, especially for the malnourished.

WORLD HEALTH PROGRAMS AND ACTIVITIES

WHO supports actions to reduce human influence on the global climate while still recognizing the effect past emissions and human action have on the likelihood of warming and more variable climate for at least several decades. To alleviate this issue as well as reduce health vulnerability to future climate change, WHO supports programs for combating infectious diseases, improving water and sanitation, and ensuring response to natural disasters. In addition, research and effort are being put into building the capacity of health services and information to help adapt to climate changes.

Primary prevention includes actions to prevent the onset of disease from environmental disturbances in an otherwise unaffected population (mosquito nets, vector control, early weather-watch warning systems). Secondary prevention includes early-response action (disease surveillance). Tertiary prevention includes diagnosis and treatment to lessen the morbidity or mortality caused by disease.

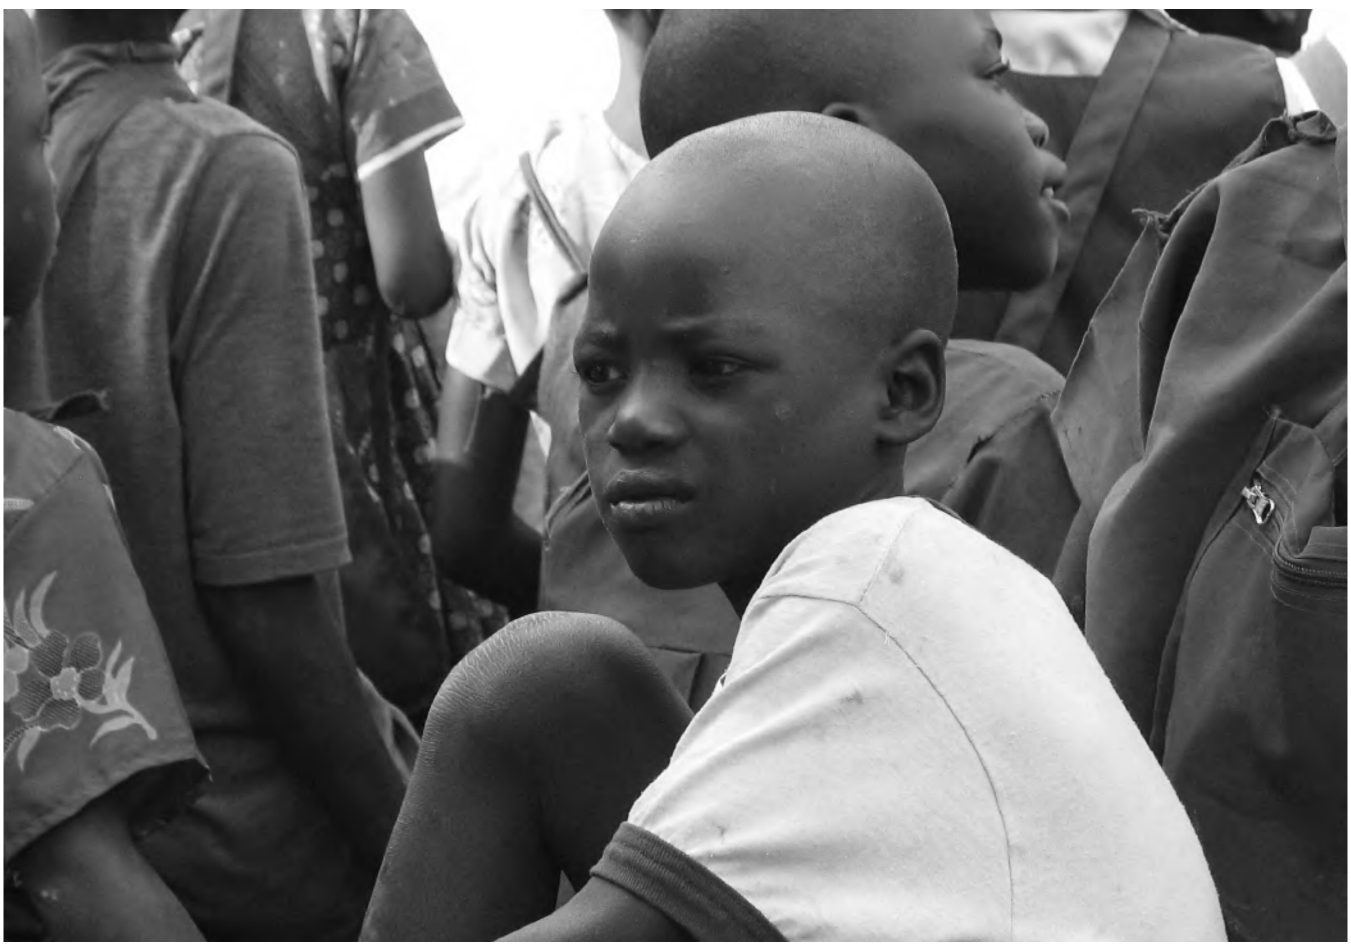
Adaptation refers to actions taken to lessen the effects of the anticipated changes in climate. The ultimate goal of adaptation interventions is the reduction, with the least cost, of diseases, injuries, disabilities, suffering, and death from climate change. Public health programs should anticipate the health effects of climate change such as, for instance, those on infectious diseases. For example, surveillance systems could be improved in sensitive geographic areas. Such regions include those bordering areas of current distribution of vector-borne diseases that could themselves experience epidemics under certain climatic conditions. Vaccination programs could be intensified, and pesticides for vector control and drugs for prophylaxis and treatment could be stockpiled.

To prepare for climate change, the WHO encourages and fosters international cooperation through collaborating with partners (UN agencies and other international organizations, donors, civil society, and the private sector). WHO provides support to countries to implement programs using best technical guidelines and practices and helping to establish health priorities and strategy.

To prepare appropriately for climate change, climate and environmental monitoring are essential. To be most effective, health professionals must interact with the environmental sectors to evaluate the changing climate and assess risks. Researchers and monitoring organizations interested in health impact assessment have requested assistance from health researchers to ensure an accurate risk assessment. Health researchers must also be encouraged to access environmental data or be given the tools necessary to find the information on air and water pollution levels. Additional monitoring should include food contamination and identification of emission sources or contamination sites. The WHO/ECEH (European Centre for Environment and Health) is developing a Health and Environment Geographic Information System (HEGIS) to identify areas and issues of priority for the environment and health. With an initial focus on demographics and air quality, the information system has the potential for expansion to include climate change data and health effects.

The agenda of WHO includes promoting development of health-promoting activities, fostering health security, strengthening health systems, and collecting and disseminating research information.

Health development is directed by the ethical principle of equity: access to lifesaving or health-promoting interventions should not be denied for unfair (economic or social) reasons. Despite how health has become a



Children in Uganda: The World Health Organization coordinates review of scientific evidence on the links between climate change and health. Increased temperatures, rising sea levels, and changing weather patterns would affect food, water, and shelter.

standard factor in perception of social and economic progress, as well as receiving additional resources and funding, poverty and poor health are still widespread around the world. WHO activities are aimed at health development and at making health outcomes in poor, disadvantaged, or vulnerable groups a priority. The organization's agenda is to focus on the prevention and treatment of chronic disease in all populations and to research and address tropical diseases as part of their Millennium Development goals.

WHO intends to foster health security even for vulnerable populations by demanding action from the international community in addressing preventable diseases. Forty percent of the global population is very poor, many suffer from water shortages, more than a billion lack safe drinking water, and water-related diseases cause between 2 and 5 million deaths each year. Public health and preventive measures are available, and action is justified, including vaccination or control measures such as improved sanitation and temperature control of foods. In addition there is the risk of outbreaks from emerging and epidemic-prone disease.

Such outbreaks are occurring in increasing numbers, fuelled by such factors as rapid urbanization, environmental mismanagement, the way food is produced and traded, and the way antibiotics are used and misused. The threat of climate change also demands action for building capacity and adaptabilities to climate change. WHO provides workshops in vulnerable countries and works with policymakers to ensure adequate healthcare is available for treatment. These activities have a twofold benefit: action taken now both improves current health conditions and provides a foundation for additional adaptation measures in the future to address climate changes.

As an ultimate measure for ensuring adequate health care not only in the future but in the present as well, health systems around the world must be strengthened. To function as a method for reducing poverty, health services must be available to all populations, including those that are now underserved because of economic reasons. WHO works with countries to ensure an adequate number of trained professional and additional staff to meet the healthcare needs, funding to provide services, and access to medication and supplies as well as the technology to provide appropriate care.

For collecting and disseminating research information, the WHO maintains a searchable database on the Web on a broad range of health subjects including links to journal articles, research undertaken, and recommendations. As mentioned before, the WHO/ECEH also is developing a HEGIS to identify areas and issues of priority for environment and health. With an initial focus on demographics and air quality, the information system has the potential for expansion to include climate change data and health effects.

World Meteorological Organization

THE WORLD Meteorological Organization (WMO) is a specialized agency of the United Nations (UN). It is the UN voice on the state and behavior of the Earth's atmosphere, its interaction with the oceans, the climate it produces, and the resulting distribution of water resources. The WMO has a membership of 188 member states and territories. It originated from the International Meteorological Organization, which was founded in 1873. Established in 1950, WMO became the specialized agency of the United Nations in 1951 for meteorology (weather and climate), operational hydrology, and related geophysical sciences. It is based in Geneva, Switzerland.

The WMO seeks to provide the framework for an international cooperation regarding climate matters. The organization points out that weather, climate, and the water cycle know no national boundaries, so international cooperation at a global scale is essential for the development of meteorology and operational hydrology. Since its establishment, the WMO has devised programs and services attempting to contribute to the preservation of the environment and the welfare of humanity. The National Meteorological and Hydrological Services have sought to protect life and property against natural disasters, to preserve the environment, and to encourage the economic and social well-being of all sectors of society in areas such as food security, water resources, and transport.

The WMO supports cooperation to establish networks for meteorological, climatological, hydrological, and geophysical observations, as well as for the exchange, processing, and standardization of related data. It also provides technology transfer, training, and research and fosters collaboration between the National Meteorological and Hydrological Services and its members. The organization sponsors the application of meteorology to public weather services, agriculture, aviation, shipping, the environment, water issues, and the mitigation of the effects of natural disasters.

WMO aids the free exchange of data and information, products, and services in real- or near-real-time on topics relating to safety and security of society, economic welfare, and the protection of the environment. It contributes to policymaking in these areas at national and international levels. In the specific case of disasters related to weather, climate, and water, which represent nearly 90 percent of all natural catastrophes, WMO's programs try to provide advance warnings that save lives and reduce damage to property and the environment. The organization is also committed to reducing the effects of human-induced disasters, such as those associated with chemical and nuclear accidents, forest fires, and volcanic ash. Thus, the WMO is central in international efforts to monitor and protect the environment. In collaboration with other UN agencies and the National Meteorological and Hydrological Services, the WMO supports the implementation of a number of environmental conventions and is instrumental in providing advice and assessments to governments on related issues. The organization claims that its activities contribute toward ensuring the sustainable development and well-being of nations.

Global warming is a major WMO concern. The organization supports intergovernmental legal agreements on major global environmental concerns such as ozone-layer depletion, climate change, desertification, and biodiversity. WMO also coordinates the observing systems that provide the necessary data to assess atmospheric-ocean processes and interactions, such as El Niño/La Niña, and water-resources availability. Most significantly for global warming, the WMO lists, among its programs, the Global Atmosphere Watch (GAW). The WMO's interest in a program of atmospheric chemistry and the meteorological aspects of air pollution dates back to the 1950s. This included assuming responsibility for standard procedures for uniform ozone observations and establishing the Global Ozone Observing System during the 1957 International Geophysical Year.

In the late 1960s, the Background Air Pollution Monitoring Network was set up and was subsequently consolidated with the Global Ozone Observing System into the current GAW in 1989. The GAW monitoring scheme includes a coordinated global network of observing stations along with supporting facilities. GAW provides data for scientific measurements of changes in the chemical composition and related physical characteristics of the atmosphere that may negatively affect our environment. The priorities of the scheme have been identified in greenhouse gases for possible climate change, ozone and ultraviolet radiation for both climate and biological concerns, and certain reactive gases and the chemistry of precipitation.

GAW is intended to provide accessible, high-quality atmospheric data to the scientific community. These components include measurement stations, calibration and data-quality centers, data centers, and external scientific groups for program guidance. Support for these components is obtained, largely, by individual WMO member countries that directly participate in the program. Additional resources come from international funding and the WMO secretariat's internal budget.

World Resources Institute

THE WORLD RESOURCES Institute (WRI) is a nonpartisan and nonprofit environmental organization that tries to find practical applications for theoretical research on the protection of the Earth and the improvement of people's lives. WRI supplies information and proposals for policies that promote a sustainable development both in environmental and social terms. WRI is based in Washington, D.C., and has a staff of more than 100 scientists, economists, policy experts, business analysts, statistical analysts, mapmakers, and communicators.

The institute takes as its point of departure for action the fact that the shift to low-carbon technology will only occur by persuading owners and shareholders of its profitability. To WRI, business investors are instrumental in solving the climate crisis. WRI produces a highly respected biennial publication, the *World Resources* report, which supplies data and in-depth analysis on current environmental issues, including, for example, the importance of efficient ecosystem management for rural poverty relief. The report is a collaborative product of WRI with the World Bank, United Nations Environment Programme, and UN Development Programme. *World Resources* was launched in 1986 to bridge the gap in information about the conditions of the world's natural resources.

GOALS AND ACTIVITIES

The activities of the institute are structured around four key areas and goals. In the field of people and ecosystems, the institute aims to reverse the process of rapid degradation of ecosystems and guarantee their ability to provide humans with needed goods and services. Regarding access to information, WRI attempts to improve public knowledge about decisions on natural resources and the environment. In the area of climate protection, energy, and transport, WRI is active in the protection of the global climate system from further harm caused by emissions of greenhouse gases. The institute is also committed to help humanity and the natural world adapt to the climate change that is already taking place. As for markets and enterprise, WRI seeks to promote an economic development that will increase social opportunities and, at the same time, protect the environment. WRI has worked with the private sector to find profitable solutions that have both economic and environmental benefits. WRI also created the accounting system which companies all over the world use to account for their greenhouse gas emissions.

WRI was founded in June 1982 by American lawyer and environmental activist James Gustave Speth. Speth, a former chairman of the U.S. Council on Environmental Quality and later professor of law at Georgetown University, also acted as WRI's first director. He held this position until January 1993, when he became director of the UN Development Programme and was then succeeded by Jonathan Lash, senior staff attorney at the Natural Resources Defense Council from 1978 to 1985. The institute was created thanks to the John D. and Catherine T. MacArthur Foundation of Chicago, which provided $15 million to help finance the first five years of WRI. The institute was organized as a nonprofit Delaware corporation that could receive tax-deductible contributions under the U.S. Internal Revenue Code. WRI was founded not as an activist environmental membership organization but as an independent institution that should carry out scientifically sound research and suggest viable policies.

In 1985, WRI was one of the first research centers to organize an international meeting on the rising emissions of carbon dioxide and other greenhouse gases into the atmosphere. During its over two decades of activity, WRI has attracted other centers that have decided to merge with the institute, including the North American office of the International Office for Environment and Development and the Management Institute for Environment and Business. In 1990, the UN Development Programme commissioned WRI with a study that eventually resulted in the creation of the Global Environment Facility. Throughout the 1990s, WRI played a key role in initiatives aimed to contain the phenomenon of global warming. In 1992, the institute made important contributions to the development of the Convention on Biological Diversity, which was then signed at the Earth Summit in Rio de Janeiro.

In 1999, WRI committed to stopping its own emissions of carbon dioxide. The institute has also created several important networks such as the Global Forest Watch, which monitors the conditions of forests; the Access Initiative, a global forum of civil society organizations committed to improving citizen access to information and favor their participation in decisions that affect the environment;

and the Green Power Market Development Group, a partnership of Fortune 500 companies devoted to establishing corporate markets for renewable energy. WRI has also been responsible, in partnership with Mexico City, for the creation of the Bus Rapid Transit Corridor, a system of transport designed to reduce environmental damages. The institute is collaborating with metropolises such as Shanghai, Hanoi, and Istanbul for the creation of similar systems.

World Systems Theory

AN UNDEREXAMINED ASPECT of global warming is the geographic separation between the people who generate greenhouse gases and the people who are most likely to be hurt by global warming. This article explains how World Systems Theory (WST) can help us understand how climate change is both a cause and a consequence of existing social and regional inequalities. This essay begins by explaining the basic concepts of WST. It then uses WST to explain how geopolitical structures in the global economy ensure that the benefits and costs of burning fossil fuels are not shared equally.

WST evolved to counter free-market economists such as Walter Rostow, who argued that countries were poor because of deficiencies within those countries. Less developed countries could advance by emulating wealthy countries, which had moved through several stages of development.

DEPENDENCY THEORY

A chorus of critics challenged this view because, from their perspective, adherents to the stages of development view blamed the poor countries for their poverty. In response, critics argued that the lack of development in places such as South America was a result of the economic and political structures imposed by wealthy countries through colonial and lingering postcolonial relationships. Foremost among these scholars was Andre Gunder Frank.

His dependency theory argued that as capitalism diffused outward from the economic core of Western Europe over the past 500 years, it transformed the places at the periphery that were drawn into the growing capitalist world system. These new territories in Africa and Latin America were thrust into a subordinate role, and their economies were restructured to suit the needs of the colonial powers in Europe. Frank summarized this subordination as the "development of underdevelopment." Capitalist penetration into new regions underdevelops or undermines the economic potential of these places. Frank wanted to shift the blame for poverty away from the processes within poor countries and to place responsibility for poverty on the structural relationships imposed by colonial, and later, neocolonial, core powers.

Building on dependency theory, scholars such as Immanuel Wallerstein proposed WST to provide more historical context into the processes leading to the development of inequality. WST sorts the countries of the world into three broad categories according to the type of economic processes that predominate in those countries. Countries in the periphery are largely dependent on agriculture and other forms of natural resource extraction. Social inequality is high because most jobs are typically low skill and low wage. Core countries have diverse economies based on manufacturing, services, and information technology. An intermediate category called the semiperiphery includes countries that are more economically diverse than peripheral countries but that have invested less in manufacturing and other tertiary sectors. Hence the level of development is less than that of core countries.

WST improves on the rigid core-periphery dichotomy of dependency theory by adding the semiperipheral category. This modification helps to explain the historical reality of peripheral countries such as Korea ascending to core status, or how the global economy can relegate former colonial powers such as Portugal to semiperipheral status. WST tells us that the international division of labor creates a system of unequal exchange and income inequality between core, semiperipheral and peripheral countries. Peripheral countries extract raw materials and ship them largely unprocessed to the semiperipheral and core countries for processing. The finished goods are then shipped back to the peripheral countries at much higher prices. This system of unequal exchange is perpetuated by protectionist international trade agreements; copyright and patent laws, which limit the diffusion of processing technology to the periphery; the role of multinational corporations, which repatriate profits to the core that were earned by extracting resources in the periphery; and the role of wealthy local elites in poor countries, who benefit from the status quo relationships between the core and periphery.

The creation and perpetuation of global economic and political inequality has direct implications for understanding the effects of global climate change. As noted above, countries in the periphery are far more reliant on agriculture than are countries in the core. Countries in the core are much more invested in manufacturing. As a consequence, they produce disproportionately large amounts of greenhouse gases. That means that there is a geographic separation between the largest producers of greenhouse gases and the regions that will suffer the most harm from global warming. In short, climate changes will have a disproportionately negative impact on the economies and communities in the periphery. The fact that countries at the periphery have the fewest resources to adapt to climate change makes matters even worse. WST is a useful counterbalance to traditional neoclassical discussions of market-based solutions to greenhouse gas reductions because it brings a geopolitical perspective to our understanding of climate change.

Worldwatch Institute

THE WORLDWATCH INSTITUTE is "dedicated to fostering the evolution of an environmentally sustainable and socially just society, where human needs are met in ways that do not threaten the health of the natural environment or the prospects of future generations." It describes itself as "an independent, globally focused environmental and social policy research organization" with a "unique blend of interdisciplinary research and accessible writing." Worldwatch is essentially a think tank, with its closest environmental movement analogues being Resources for the Future, the World Resources Institute, and the Earth Policy Institute. The latter is headed by Lester Brown, who founded Worldwatch in 1974 and served as its president through 2000. Its current president is Christopher Flavin.

Worldwatch prides itself on its accessible writing style and its fact-based analysis of critical global issues. It focuses on the underlying causes of these issues and seeks, through education and dissemination of information, to inspire people to act in positive ways. A search of its website produces large numbers of publications regarding climate change, which it has addressed in its publications since at least 1984. *Worldwatch Papers*, one of its signature publications, has sought to educate the public regarding "pressing economic, environmental, and social issues" since 1975. Worldwatch has published *State of the World*, a widely read and widely influential annual report, beginning in 1984. Although Worldwatch does not lobby Congress directly, this comprehensive report is read by legislators as well as world leaders, students, and ordinary individuals and has been translated into

25 languages. In 1992, *Vital Signs: The Trends That Are Shaping Our Future* came into being—an annual series designed to be even more accessible, with its "brief, digestible glimpses into more than 50 issues affecting the world each year." The group publishes a bimonthly magazine, *World Watch,* and has moved to Web-based education recently with *Vital Signs Online*. It also produces an occasional series of books on specialized issues.

Worldwatch is not a one-issue organization, having written about a very wide range of environmental issues including energy, water pollution and availability, soil erosion and other agricultural concerns, population, biodiversity, materials recycling and conservation, forests, toxic materials, and so on. However, it seeks to foster recognition that these issues are inextricably tied to issues of social justice and peace. It began paying consistent attention to the relationship between social and environmental issues, particularly in international settings, much earlier than most environmental organizations. It began calling attention to the need for a sustainable society in at least 1982, five years before "sustainability" began to gain widespread attention with the publication of the Brundtland Commission report, *Our Common Future*. One of the features of its website is an item entitled "Natural Disasters and Peacemaking." A premise is that natural disasters can serve as a means of breaking down social and political barriers, leading to opportunities for peace.

A desire to inspire change in societal attitudes and actions from a grassroots perspective is a hallmark of this organization. It seeks to effect change not by force from the top but by educating the public and thereby inspiring them to demand change.

Worldwatch spends 78.4 percent of its overall budget to pay for the programs and services it exists to provide. Its administrative expenses use 6.7 percent of its budget, and fundraising accounts for another 14.7 percent. Worldwatch spends $0.19 to raise each dollar it earns. Christopher Flavin's compensation for fiscal year 2005 was $95,000, which amounted to 3.38 percent of the group's total budget—a larger percentage (though a smaller amount) than the leaders of many other environmental organizations such as World Resources Institute, Environmental Defense, or the Natural Resources Defense Council.

World Weather Watch

THE WORLD WEATHER Watch is the central program of the World Meteorological Organization (WMO), the United Nations' agency for cooperation among national weather bureaus, founded in 1950. The Fourth World Meteorological Congress approved the idea of the program in 1963, and the WMO, which has 188 member countries and territories, subsequently established the World Weather Watch to make available an integrated worldwide weather-forecasting system.

The World Weather Watch includes the Tropical Cyclone Program, the Antarctic Activities Program, an Emergency Response Activities Program for environmental emergencies, and the Instruments and Methods of Observation Program to ensure the quality of the observations that are vital for weather forecasting and climate monitoring.

Through the World Weather Watch, a system is in place for countries around the world to obtain daily weather forecasts. The core components of the World Weather Watch—the Global Observatory System (GOS), the Global Telecommunications System (GTS), and the Global Data-Processing and Forecasting System (GDPFS)—enable the World Weather Watch to provide basic meteorological data to the WMO and other related international organizations.

The GOS allows for observing, documenting, and communicating data about the weather and climate for the creation of forecast and warning services. Monitoring the climate and the environment is a priority of the WMO, and the GOS is critical to the effective and efficient operations of the WMO. Long-term objectives of the GOS include the standardization of observation practices and the optimization of global observation systems.

The GTS consists of land and satellite telecommunication links that connect meteorological telecommunication centers. The GTS provides efficient and reliable communication service among the three World Meteorological Centers in Melbourne, Moscow and Washington, and the 15 Regional Telecommunication Hubs that make up the Main Telecommunication Network. The six Regional Meteorological Telecommunication Networks, covering Africa, Asia, South America, North America, Central America and the Caribbean, South–West Pacific, and Europe, ensure the collection and distribution of data to members of the WMO. The National Meteorological Telecommunication Networks make it possible for the National Meteorological Centers to collect data and to receive and disseminate weather information on a national level.

The primary aim of the GDPFS is to prepare and provide meteorological analyses to members in the most cost-effective manner possible. The GDPFS is organized to implement functions at international, regional, and national levels through the World Meteorological Centers, the Regional Specialized Meteorological Centers, and the National Meteorological Centers. Real-time functions include preprocessing and postprocessing of data and the preparation of forecast products. Non-real-time functions include long-term storage of data and the preparation of products for climate-related analysis.

Increasingly, the World Weather Watch provides support for developing international programs related to global climate and other environmental issues and to sustainable development. The entire continent of Africa has only 1,150 World Weather Watch stations—one per 26,000 sq. km., (10,038 sq. mi.)—even though the continent's land mass is as large as North America, Europe, Australia, and Japan put together. This represents coverage eight times lower than the WMO's recommended minimum level. The changing climate of Africa necessitates greater capacity building on the part of institutions prepared to address the likely crises that lie ahead. The World Weather Watch is vital in developing that capacity.

The World Weather Watch and its parent organization, the WMO, through the development of a permanent global weather data network, have proven critical to defining global warming as a given. As a consequence, the political and policymaking debates about climate change and its very real consequences, such as those facing Africa, have moved to a new arena. Although the World Weather Watch cannot compel individual governments to act on its findings, it can and has framed the issue of climate change on a truly global scale.

World Wildlife Fund

ALTHOUGH THE WORLD Wildlife Fund around the world has changed its name to the World Wide Fund for Nature, the original name remains the official one in the United States and Canada. As an international nongovernmental organization, it was founded in 1961 in Switzerland to help with the conservation, research, and restoration of the natural environment, changing its name in 1986, although still keeping its initials (WWF) around the world.

Although over many years the WWF became famous for its protection of endangered fauna—its symbol remains a panda bear—it has also been keen to preserve natural environments, seeing its role as helping endangered flora as much as fauna, with the change in its name reflecting this. Indeed the WWF now recognizes that the single biggest threat to the environment today comes from global warming, and as a result it has campaigned for companies and individuals to reduce their greenhouse gas emissions.

In December 2007, the World Wildlife Fund issued a report titled "Antarctic Penguins and Climate Change."

The major area where the WWF initially concentrated its energies was in reducing deforestation, especially in Brazil, Central Africa, and the Russian Far East. This has seen U.S. experts from the WWF-U.S. taking part in projects in these regions, and also in other parts of the world. They have been involved in recording the level of deforestation, and in many cases illegal logging, and notifying the relevant governments as well as bringing extreme levels of deforestation to world attention.

Traditionally, the WWF has organized throughout the United States at a city, town, and village level, with the education of young people being at the forefront of its approach. This means that the WWF has devoted much of its time and energy to encouraging students to gain a greater interest in the environment and the threat of global warming through the provision of resource kits, booklets, and lectures. Many of these items have been available free of charge, or heavily subsidized, with many schoolchildren becoming interested in the world of the WWF through television documentaries and other media sources such as the internet.

This has seen the developing of educational problems to allow more students to plan ways of reducing carbon dioxide emissions. Among the children who have been involved in WWF projects have been some of those displaced by Hurricane Katrina, who have been better able to understand the problems leading to the hurricane. To that end, the WWF hosts the Southeast Climate Witness Program, which allows students to attend a Climate Camp in June 2008 and to take part in the Youth Summit in Washington, D.C., in the following month. Many schools around the United States also raise money for the WWF that is used for the campaign against climate change.

Although it has long been a community movement, the WWF has also started working heavily with businesses. This change has seen the WWF and some of its partners collaborating with 12 prominent companies including the Collins Companies, IBM, Johnson & Johnson, Nike, Polaroid, and Sony. These large corporations have agreed to work toward reducing their carbon dioxide emissions by over 10 million tons each year, which, as a result, has led to many smaller companies becoming aware of their effect on the generating of greenhouse gases and working to reduce their emissions. The WWF has also tried to get, with less success, the energy utility companies to reduce the emissions of their operations.

Wyoming

WYOMING IS 97,819 sq. mi. (253,350 sq. km.) with inland water making up 714 sq. mi. (1,849 sq. km.). The Continental Divide (the separation mark of the Pacific and Atlantic watersheds) passes through Wyoming, making Wyoming a source for the Missouri-Mississippi, the Great Basin, the Columbia, and the Colorado drainage systems.

The climate in Wyoming is relatively cool and depends on the elevation; for example, the summers are moderately warm at lower elevations. Early freezes and a late spring provide long winters and a short growing season (from approximately 80 days in the northwest to 120 days in the plains). Precipitation also varies with elevation. Snow falls from November to May—the yearly snowfall can be as little as 10 in. or less in the basins and 15 to 20 in. in the Plains to over 60 to 70 in. at the higher elevations.

Wyoming has 22 state parks, Grand Teton and Yellowstone national parks, and national forests set aside for preservation. The largest aquifer in the world, Ogallala Aquifer lies underground beneath eight states including Wyoming. Major industries include agriculture (most of the agricultural land is used for grazing, though dryland wheat and some irrigated crops are grown) and mining for coal, natural gas, and petroleum. Industries that are important to Wyoming's economy include petroleum refining, chemical industries, food processing, industrial machinery, and wood products.

Although climate models vary on the amount of temperature increase possible, potential risks include having decreased water supplies; increased risk for wildfires; changes in food production, with agriculture improving in cooler climates and decreasing in warmer climates; change in rain pattern to downpours, with the potential for flash flooding and health risks of certain infectious diseases from water contamination or disease-carrying vectors such as mosquitoes, ticks, and rodents, and heat-related illnesses.

Wyoming may benefit from changing climate. Shorter, milder winters could mean longer growing seasons and increasing crop yields, though higher temperatures may mean changing crops produced to those that are better adapted to a warmer climate and that are more drought resistant. The milder climate could attract more tourists. Taking advantage of sun and wind to produce electricity could provide economic benefits. The effect of climate change on agriculture will be mixed, and some crops such as potatoes and wine grapes could be negatively affected by rising temperatures, decreasing yields. By comparison, the orchard crops will mature more quickly at height temperatures, with increased quality and market-share value. Some areas may need to change crops for those with higher drought resistance and adaptability to a warmer climate.

Wyoming's glaciers are melting at a rapid pace because of milder temperatures brought on by global warming. Warmer temperatures also mean less snowpack in the mountains and earlier snowmelt, leading to more winter runoff and reduced summer flows in many Wyoming streams. Snowpack also stores much of Wyoming's clean water supply for drinking, agriculture, and wildlife. Any reduction in snow would increase pressures on this valuable and scarce resource.

On the basis of energy consumption data from Energy Information Administration's State Energy Consumption, Price, and Expenditure Estimates, released June 1, 2007, Wyoming's total CO_2 emissions from fossil fuel combustion for 2004 was 63.54 million metric tons, made up of contributions from commercial (0.86 million metric tons), industrial (10.12 million metric tons), residential (0.86 million metric tons), transportation (8.07 million metric tons), and electric power (43.62 million metric tons).

Wyoming's current incentive programs and tax breaks targeted at reducing carbon emissions are designed to encourage energy efficiency and the use of renewable energy sources such as wind and solar power. New laws enacted in 2007 include authorizing a clean-coal task force and providing funding for the clean-coal research, extending a tax benefit for an additional four years (until 2012) for renewable power generation facilities such as wind farms, and improved funding for the Wyoming Game and Fish Department—the state's agency for managing both game and nongame species of wildlife. In addition, the legislature approved project money drawn on the interest in the Wyoming Wildlife and National Resources Trust Fund, established in 2005, to enhance aspen and sage on the Bates Creek watershed and aspen, sage, bitterbrush, and sumac near Lander, both for wildlife foraging.

Yemen

LOCATED IN THE southern region of the Arabian Peninsula, the Republic of Yemen has a land area of 203,849 sq. mi. (527,968 sq. km.), with a population of 22,389,000 (2006 est.) and a population density of 104 people per sq. mi. (40 people per sq. km.). Only 3 percent of the land in Yemen is arable, with 13 percent of that area being under permanent cultivation. In addition, 34 percent of the country is used as meadows or pasture, and 8 percent of the country is forested.

Yemen has a very low rate of per capita carbon dioxide emissions, being 0.8 metric tons per person in 1991, rising gradually to 1.03 metric tons in 2004. The entire electricity production in the country comes from fossil fuels, with liquid fuels being responsible for 96 percent of Yemen's carbon dioxide emissions. In terms of the sector producing the carbon dioxide in the country, 48 percent comes from transportation, with 20 percent from electricity and heat production, 20 percent from residential use, and 7 percent from manufacturing and construction.

The effect of global warming and climate change has already been dramatic in Yemen, with the alienation of some marginal arable land. The rise in temperature has made it harder to grow crops in arid parts of the country, and there has been extensive bleaching of coral reefs along the Red Sea coastline and the Socotra Archipelago.

The Yemen government of Ali Abdullah Saleh took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992, and accepted the Kyoto Protocol to the UN Framework Convention on Climate Change on September 15, 2004, with it entering into force on February 16, 2005.

Younger Dryas

MARKING THE BOUNDARY between the Holocene and Pleistocene epochs, the Younger Dryas, a period of glacial conditions between 12,900 and 11,500 years ago, is named for *Dryas octopetala*, a flower that is adapted to the cold. *Dryas*' pollen is found in abundance in strata of this age. *Dryas*' pollen is also found in older strata, necessitating the term Younger Dryas to distinguish this time from older periods in which *Dryas*' pollen is abundant. Locked in an ice age, earth had finally warmed and the glaciers had begun to retreat 15,000 years ago. Counteracting this warming trend, the Younger Dryas reduced temperatures 50 degrees F in only a decade. Glaciers once more advanced in North America and Europe. Rainfall diminished, and frigid winds carried dust from central Asia throughout Europe.

Climatologists have identified three causes of the Younger Dryas, though it is uncertain whether all three operated at the same time. The fact that the Southern Hemisphere cooled before the Northern Hemisphere suggests that some mechanism cooled the south, whereas no mechanism was then operating in the north. The rapid change in climate that was the Younger Dryas may have caused the extinction of large mammals in North America and the collapse of the first Native American culture. In western Asia, the Younger Dryas may have prompted humans to invent agriculture. The end of the Younger Dryas ushered in the modern climate.

The Younger Dryas was part of the Cenozoic Ice Age, which locked the world in glaciers 100,000 years ago. The climate was particularly cold as recently as 18,000 years ago. From these frigid conditions, the climate gradually warmed until 15,000 years ago, the glaciers began to retreat. The Younger Dryas interrupted this warming trend, restoring glacial conditions to earth.

Climatologists have advanced three causes of the Younger Dryas. The leading explanation focuses on ocean currents. The Gulf Stream brings warm water from the tropics to the North Atlantic Ocean, warming the Atlantic coasts of North America and Europe. The Gulf Stream remained undisturbed as the North American glacier began to retreat north 15,000 years ago. In the initial centuries of retreat, the ice sheet emptied its water down the Mississippi River and into the Gulf of Mexico. By 12,900 years ago, however, the North American glacier had retreated to the Great Lakes. Melted water no longer flowed south down the Mississippi River but now went east along the St. Lawrence River to the Atlantic Ocean. This cold water shut down the Gulf Stream, robbing North America and Europe of its warmth and returning the climate to glacial conditions.

Climatologists have identified a second cause in the impact of an asteroid near the Great Lakes 12,900 years ago. Upon impact, the asteroid ejected enormous amounts of debris, dust, and ash into the atmosphere, blocking out sunlight and cooling the Earth. A third cause might have been the sudden, and unexplained, cessation of El Niño. Every two to seven years, warm water from the western Pacific Ocean and Indian Ocean flows east, warming the west coasts of South and North America. Without El Niño, these continents cooled, returning them to glacial conditions. Possibly more than one cause initiated the Younger Dryas.

The Younger Dryas ended as abruptly as it had begun, when temperatures rose 50 degrees F (28 degrees C) in just 10 years. Glaciers retreated to Antarctica, Greenland, and the North Pole, and rainfall again became abundant. The Cenozoic Ice Age, having cooled the Earth for 100,000 years, finally ended with the close of the Younger Dryas. Forests returned to Scandinavia, Germany, and North America. The return of warmth and rainfall, along with the invention of agriculture, allowed humans to settle in communities. With some exceptions, humans were no longer nomads. The end of the Younger Dryas initiated the modern climate. Although temperatures fluctuated in modernity, the retreat of glaciers has so far been permanent. Perhaps glaciers will return one day, though there is no evidence that they will come soon.

Zambia

THE REPUBLIC OF Zambia lies in the interior of southern Africa and shares its borders with the Democratic Republic of Congo, Angola, Zimbabwe, and five other countries. From 1924, the country was known as Northern Rhodesia and was administered as a British protectorate by the United Kingdom. It achieved independence in 1964 and was renamed the Republic of Zambia for the Zambezi River.

Zambia is a landlocked country with a tropical climate. Most of the country consists of flat plateau with altitudes of 3,281–4,921 ft. (1,000–1,500 m.), which contributes to a milder climate. Average maximum temperatures during the hot, rainy season (November to March) range from 79–95 degrees F (26–35 degrees C); the cooler, dry season (April to August) brings high temperatures of 77–82 degrees F (25–28 degrees C). Annual rainfall ranges from 750 mm. in the south to more than 1,300 mm. in the north.

Rising temperatures and erratic rainfall are the primary symptoms of climate change. The most significant risks of climate change include water scarcity, reduced agricultural productivity, spread of vector-borne diseases such as malaria, risk of forest fires, reduced fish and wildlife stocks, and increased flooding and droughts. Farmers, rural households, and communities that depend on natural resources for their livelihoods are the most vulnerable to the effects of climate change. The government has embarked on a National Adaptation Programme for Action, with support from the United Nations Development Programme.

With declining per capita food production, food security is already a grave concern. Food-insecure people requiring humanitarian assistance number roughly one million. Food security may be further threatened by the effects of climate change, especially declining rainfall, and is exacerbated by the existing challenges of chronic poverty, HIV/AIDS, and an ineffective food distribution system. Northern Zambia is prone to flooding, whereas the south is increasingly dry.

Maize is an extremely important crop—the cornmeal-based *nshima* is served with nearly every meal—but maize is highly vulnerable to drought. Shorter rainy seasons, later start of rains, and declining rainfall are associated with reduced productivity of maize and other crops. Some farmers have switched to earlier-maturing, drought-resistant crops such as sweet potatoes as an adaptation strategy, but many are reluctant to pass up government maize subsidies and the steady demand for cornmeal.

Deforestation is a continuing problem, and the clearing of forests for agriculture, construction, and industrialization is likely to increase the risks of climate change. Forests protect watersheds, provide erosion control, and absorb carbon that would otherwise contribute to global warming. Deforestation rates are estimated between 200,000 and 300,000 hectares per year. Extensive forest exploitation is related to the production of charcoal, which contributes to carbon monoxide emissions. Eighty-three percent of urban households use charcoal for cooking fuel.

Miombo woodlands provide an important source of timber and nontimber forest products. Although Miombo woodlands require regular burning, rising temperatures and declining rainfall may lead to increases in wildfires. Wildfires and deforestation threaten traditional bark-hive beekeeping and the reproductive capacity of Mophane caterpillar products, an important source of nutrition and income for rural households.

Zimbabwe

A LANDLOCKED COUNTRY located in southern Africa, Zimbabwe (formerly Rhodesia) has a land area of 150,871 sq. mi. (390,757 sq. km.), with a population of 13,349,000 (2006 est.) and a population density of 85 people per sq. mi. (33 people per sq. km.). Its economy has been heavily reliant on agriculture, with 7 percent of the country being arable, 13 percent being used as meadows or pasture, and 62 percent being forested.

In Zimbabwe, some 53.3 percent of electricity generation comes from fossil fuels, with 46.7 percent from hydropower. This extensive use of hydropower, much of it from the Kariba Dam, as well as the declining economy in the country, has led to Zimbabwe having a low rate of per capita carbon dioxide emissions—1.6 metric tons per person in 1990, falling to 0.81 metric tons in 2004. In 1999, electricity production contributed 55 percent of Zimbabwe's carbon dioxide emissions, with manufacturing and construction making up 23 percent and transportation a further 20 percent. In terms of the source of carbon dioxide emissions, 86 percent were from solid fuels, with 10 percent from liquid fuels, and most of the remainder from gaseous fuels. Problems with electricity supplies in the country have led to many people reverting to the use of private generators. The economy has also been badly damaged by a decline in the demand for tobacco—the most important single export in the country.

The effects of global warming on the country have been a steady alienation of marginal arable land, which, together with a general decline in the economy, has seen widespread impoverishment. The rise in temperature has also affected the productivity of fish farms. The Zimbabwean government of Robert Mugabe took part in the United Nations Framework Convention on Climate Change, signed in Rio de Janeiro in May 1992, but the government has so far not expressed an opinion on the Kyoto Protocol to the UN Framework Convention on Climate Change. However C. Madova, co-vice president of the African Region at the World Bank addressed the Fifth World Bank Conference on Environmentally and Socially Sustainable Development in Washington, D.C., in December 1997, supporting measures to reduce world emissions.

Glossary

A

Acid Deposition

Acidic aerosols in the atmosphere are removed from the atmosphere by wet deposition (rain, snow, fog) or dry deposition (particles sticking to vegetation). Acidic aerosols are present in the atmosphere primarily due to discharges of gaseous sulfur oxides (sulfur dioxide) and nitrogen oxides.

Aerosol

A collection of airborne solid or liquid particles, with a typical size between 0.01 and 10 micrometers (μm) and residing in the atmosphere for at least several hours. Aerosols may be of either natural or anthropogenic origin. Aerosols may influence climate in two ways: directly through scattering and absorbing radiation, and indirectly through acting as condensation nuclei for cloud formation or modifying the optical properties and lifetime of clouds.

Afforestation

The planting of new forests on land which historically had been covered by forest.

Albedo

The fraction of solar radiation reflected by a surface or object, often expressed as a percentage. Most snow-covered surfaces have a high albedo; the albedo of soils ranges from high to low; vegetation covered surfaces and oceans have a low albedo. The Earth's albedo varies mainly through varying cloudiness, snow, ice, leaf area, and land cover changes.

Alleroed

A village in Denmark whose name is used for a warm period at the end of the last glacial.

Alliance of Small Island States (AOSIS)

The group of Pacific and Caribbean nations who call for relatively fast action by developed nations to reduce greenhouse gas emissions. The AOSIS countries fear the effects of rising sea levels and increased storm activity predicted to accompany global warming. Its plan is to hold Annex I Parties to a 20 percent reduction in carbon dioxide emissions by 2005.

Allometric Equation

An equation that uses known growth measurements to estimate related unknown growth measurements.

Alternative Energy

Energy derived from nontraditional sources (e.g., compressed natural gas, solar, hydroelectric, wind, and others).

Annex I Parties

Industrialized countries that, as parties to the Framework Convention on Climate Change, have pledged to reduce their greenhouse gas emissions by the year 2000 to 1990 levels. Annex I Parties consist of countries belonging to the Organisation for Economic Co-operation and Development (OECD) and countries designated as Economies-in-Transition.

Anthropogenic

Made by people or resulting from human activities. Usually used in the context of emissions that are produced as a result of human activities.

Atmosphere

The gaseous envelope surrounding the Earth. The dry atmosphere consists almost entirely of nitrogen (78.1 percent volume mixing ratio) and oxygen (20.9 percent volume mixing ratio), together with a number of trace gases, such as argon (0.93 percent volume mixing ratio), helium, radiatively active greenhouse gases such as carbon dioxide (0.035 percent volume mixing ratio), and ozone. In addition the atmosphere contains water vapor, whose amount is highly variable but typically 1 percent volume mixing ratio. The atmosphere also contains clouds and aerosols. The atmosphere can be divided into a number of layers according to its mixing or chemical characteristics, generally determined by its thermal properties (temperature). The layer nearest the Earth is the troposphere, which reaches up to an altitude of about about 5 mi. (8 km) in the polar regions and up to nearly 11 mi. (17 km) above the equator. The stratosphere, which reaches to an altitude of about 31 mi. (50 km.) lies atop the troposphere. The mesosphere which extends up to 50–56 mi. (80–90 km.) is atop the stratosphere, and finally, the thermosphere, or ionosphere, gradually diminishes and forms a fuzzy border with outer space.

Atmospheric Lifetime

The lifetime of a greenhouse gas refers to the approximate amount of time it would take for the anthropogenic increment to an atmospheric pollutant concentration to return to its natural level (assuming emissions cease) as a result of either being converted to another chemical compound or being taken out of the atmosphere via a sink. This time depends on the pollutant's sources and sinks as well as its reactivity. The lifetime of a pollutant is often considered in conjunction with the mixing of pollutants in the atmosphere; a long lifetime will allow the pollutant to mix throughout the atmosphere. Average lifetimes can vary from about a week (sulfate aerosols) to more than a century (chlorofluorocarbons [CFCs], carbon dioxide).

B

Baseline Emissions

The emissions that would occur without policy intervention (in a business-as-usual scenario). Baseline estimates are needed to determine the effectiveness of emissions reduction programs.

Berlin Mandate

A ruling negotiated at the first Conference of the Parties (COP 1), which took place in March, 1995, concluding that the present commitments under the Framework Convention on Climate Change are not adequate. Under the Framework Convention, developed countries pledged to take measures aimed at returning their greenhouse gas emissions to 1990 levels by the year 2000.

Biogeochemical Cycle

The chemical interactions that take place among of key chemical constituents essential to life, such as carbon, nitrogen, oxygen, and phosphorus.

Biomass

Organic nonfossil materials that are biological in origin, including organic material (both living and dead) from above and below ground, for example, trees, plants, crops, roots, and animals and animal waste.

Biomass Energy

Energy produced by combusting renewable biomass materials such as wood. The carbon dioxide emitted from burning biomass will not increase total atmospheric carbon dioxide if this consumption is done on a sustainable basis (i.e., if in a given period of time, regrowth of biomass takes up as much carbon dioxide as is released from biomass combustion). Biomass energy is often suggested as a replacement for fossil fuel combustion, which has large greenhouse gas emissions.

Biome
A naturally occurring community of flora and fauna (or the region occupied by such a community) adapted to the particular conditions in which they occur (e.g., tundra).

Biosphere
The region of land, oceans, and atmosphere inhabited by living organisms.

Black Carbon
Operationally defined species based on measurement of light absorption and chemical reactivity and/or thermal stability; consists of soot, charcoal, and/or possible light-absorbing refractory organic matter.

Borehole
Any exploratory hole drilled into the Earth or ice to gather geophysical data. Climate researchers often take ice core samples, a type of borehole, to predict atmospheric composition in earlier years.

Bubble
A system that lets several countries meet a reduction target together while having different individual targets.

C

Capital Stocks
The accumulation of machines and structures that are available to an economy at any point in time to prune goods or render services. These activities usually require a quantity of energy that is determined largely by the rate at which that machine or structure is used.

Carbon Cycle
The global scale exchange of carbon among its reservoirs, namely the atmosphere, oceans, vegetation, soils, and geologic deposits and minerals. This involves components in food chains, in the atmosphere as carbon dioxide, in the hydrosphere, and in the geosphere.

Carbon Dioxide (CO_2)
The greenhouse gas whose concentration is being most affected directly by human activities. CO_2 also serves as the reference to compare all other greenhouse gases. The major source of CO_2 emissions is fossil fuel combustion. CO_2 emissions are also a product of forest clearing, biomass burning, and non-energy production processes such as cement production. Atmospheric concentrations of CO_2 have been increasing at a rate of about 0.5 percent per year and are now about 30 percent above preindustrial levels.

Carbon Equivalent (CE)
A metric measure used to compare the emissions of the different greenhouse gases based upon their global warming potential (GWP). Greenhouse gas emissions in the United States are most commonly expressed as "million metric tons of carbon equivalents" (MMTCE). Global warming potentials are used to convert greenhouse gases to carbon dioxide equivalents.

Carbon Sequestration
The uptake and storage of carbon. Trees and plants, for example, absorb carbon dioxide, release the oxygen and store the carbon. Fossil fuels were at one time biomass and continue to store the carbon until burned.

Carbon Sinks
Carbon reservoirs and conditions that take in and store more carbon (carbon sequestration) than they release. Carbon sinks can serve to partially offset greenhouse gas emissions. Forests and oceans are common carbon sinks.

Chlorofluorocarbons and Related Compounds
This family of anthropogenic compounds includes chlorofluorocarbons (CFCs), bromofluorocarbons (halons), methyl chloroform, carbon tetrachloride, methyl bromide, and hydrochlorofluorocarbons (HCFCs). These compounds have been shown to deplete stratospheric ozone, and therefore are typically referred to as ozone-depleting substances. The most ozone-depleting of these compounds are being phased out under the Montreal Protocol.

Clean Development Mechanisms (CDM)
Article 12 of the Kyoto Protocol provides for the CDM whereby developed countries are able to invest in emissions-reducing projects in developing countries to obtain credit to assist in meeting their assigned

amounts. The details of the CDM have yet to be negotiated at the international level.

Climate
The average weather for a particular region and time period. Climate is not the same as weather, but rather, it is the average pattern of weather for a particular region. Climatic elements include precipitation, temperature, humidity, sunshine, wind velocity, phenomena such as fog, frost, and hail storms, and other measures of the weather.

Climate Change
The term *climate change* refers to all forms of climatic inconsistency. Climate change has been used synonymously with the term *global warming*.

Climate Change Action Plan
Unveiled in October 1993 by President Clinton, the CCAP is the U.S. plan for meeting its pledge to reduce greenhouse gas emissions under the terms of the Framework Convention on Climate Change (FCCC). The goal of the plan was to reduce U.S. emissions of greenhouse gases to 1990 levels by 2000.

Climate Feedback
An atmospheric, oceanic, terrestrial, or other process that is activated by the direct climate change induced by changes in radiative forcing. Climate feedbacks may increase (positive feedback) or diminish (negative feedback) the magnitude of the climate change.

Climate Lag
The delay that occurs in climate change as a result of some factor that changes only very slowly.

Climate Model
A quantitative way of representing the interactions of the atmosphere, oceans, land surface, and ice.

Climate Modeling
The simulation of the climate using computer-based models.

Climate Sensitivity
The equilibrium response of the climate to a change in radiative forcing; for example, a doubling of the carbon dioxide concentration.

Climate System (or Earth System)
The five physical components (atmosphere, hydrosphere, cryosphere, lithosphere, and biosphere) that are responsible for the climate and its variations.

Cloud Condensation Nuclei
Airborne particles that serve as an initial site for the condensation of liquid water and which can lead to the formation of cloud droplets.

CO_2 Fertilization
The enhancement of plant growth as a result of elevated atmospheric CO_2 concentrations.

Coalbed Methane
Coalbed methane is methane contained in coal seams, and is often referred to as virgin coalbed methane, or coal seam gas. For more information, visit the Coalbed Methane Outreach program site.

Coal Mine Methane
Coal mine methane is the subset of CBM that is released from the coal seams during the process of coal mining. For more information, visit the Coalbed Methane Outreach program site.

Cogeneration
The process by which two different and useful forms of energy are produced at the same time. For example, while boiling water to generate electricity, the leftover steam can be sold for industrial processes or space heating.

Compost
Decayed organic matter that can be used as a fertilizer or soil additive.

Conference of the Parties (COP)
The supreme body of the United Nations Framework Convention on Climate Change (UNFCCC). It comprises more than 180 nations that have ratified the Convention. Its first session was held in Berlin, Germany, in 1995 and it is expected to continue meeting on a yearly basis. The COP's role is to promote and review the implementation of the Convention.

Cryosphere
One of the interrelated components of the Earth's system, the cryosphere is frozen water in the form

of snow, permanently frozen ground (permafrost), floating ice, and glaciers. Fluctuations in the volume of the cryosphere cause changes in ocean sea level, which directly impact the biosphere.

D

Deforestation

Those practices or processes that result in the change of forested lands to nonforest uses. This is often cited as one of the major causes of the enhanced greenhouse effect for two reasons: (1) the burning or decomposition of the wood releases carbon dioxide; and (2) trees that once removed carbon dioxide from the atmosphere in the process of photosynthesis are no longer present and contributing to carbon storage.

Desertification

The progressive destruction or degradation of existing vegetative cover to form desert. This can occur due to overgrazing, deforestation, drought, and the burning of extensive areas.

Diurnal Temperature Range

The difference between maximum and minimum temperature over a period of 24 hours.

E

Economic Potential

The portion of the technical potential for GHG emissions reductions or energy-efficiency improvements that could be achieved cost-effectively in the absence of market barriers. The achievement of the economic potential requires additional policies and measures to break down market barriers.

Eddy Mixing

Mixing due to small scale turbulence processes (eddies). Such processes cannot be explicitly resolved by even the finest-resolution atmosphere-ocean general ciculation models currently in uses and so their effects must be related to the larger-scale conditions.

El Niño

A climatic phenomenon occurring irregularly, but generally every three to five years. El Niños often first become evident during the Christmas season (El Niño means Christ-child) in the surface oceans of the eastern tropical Pacific Ocean. The phenomenon involves seasonal changes in the direction of the tropical winds over the Pacific and abnormally warm surface ocean temperatures. The changes in the tropics are most intense in the Pacific region; these changes can disrupt weather patterns throughout the tropics and can extend to higher latitudes.

Emission Permit

A nontransferable or tradeable allocation of entitlements by a government to an individual firm to emit a specific amount of a substance.

Emission Quota

The portion or share of total allowable emissions assigned to a country or group of countries within a framework of maximum total emissions and mandatory allocations of resources or assessments.

Emissions

The release of a substance (usually a gas when referring to climate change) into the atmosphere.

Emission Standard

A level of emission that under law may not be exceeded.

Energy Intensity

Ration of energy consumption and economic or physical output. At the national level, energy intensity is the ratio of total domestic primary energy consumption or final energy consumption to gross domestic product or physical output.

Enhanced Greenhouse Effect

The natural greenhouse effect has been enhanced by anthropogenic emissions of greenhouse gases. Increased concentrations of carbon dioxide, methane, and nitrous oxide, CFCs, HFCs, PFCs, SF_6, NF_3, and other photochemically important gases caused by human activities such as fossil fuel consumption and adding waste to landfills trap more infrared radiation, thereby exerting a warming influence.

Equilibrium Response

The steady state response of the climate system (or a climate model) to an imposed radiative forcing.

Evapotranspiration
The sum of evaporation and plant transpiration. Potential evapotranspiration is the amount of water that could be evaporated or transpired at a given temperature and humidity, if there was water available.

F

Fluorocarbons
Carbon-fluorine compounds that often contain other elements such as hydrogen, chlorine, or bromine. Common fluorocarbons include chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), hydrofluorocarbons (HFCs), and perfluorocarbons (PFCs).

Forcing Mechanism
A process that alters the energy balance of the climate system, i.e., changes the relative balance between incoming solar radiation and outgoing infrared radiation from Earth. Such mechanisms include changes in solar irradiance, volcanic eruptions, and enhancement of the natural greenhouse effect by emissions of greenhouse gases.

G

Geosphere
The soils, sediments, and rock layers of the Earth's crust, both continental and beneath the ocean floors.

Glacier
A multiyear surplus accumulation of snowfall in excess of snowmelt on land and resulting in a mass of ice at least 0.1 km2 in area that shows some evidence of movement in response to gravity. A glacier may terminate on land or in water. Glaciers are found on every continent except Australia.

Global Warming
Global warming is an average increase in the temperature of the atmosphere near the Earth's surface and in the troposphere, which can contribute to changes in global climate patterns. Global warming can occur from many causes, both natural and human induced.

Global Warming Potential (GWP)
Defined as the cumulative radiative forcing effects of a gas over a specified time horizon resulting from the emission of a unit mass of gas relative to a reference gas. The GWP-weighted emissions of direct greenhouse gases in the U.S. inventory are presented in terms of equivalent emissions of carbon dioxide, using units of teragrams of carbon dioxide equivalents.

Greenhouse Effect
Trapping and buildup of heat in the atmosphere (troposphere) near the Earth's surface. Some of the heat flowing back toward space from the Earth's surface is absorbed by water vapor, carbon dioxide, ozone, and several other gases in the atmosphere and then reradiated back toward the Earth's surface. If the atmospheric concentrations of these greenhouse gases rise, the average temperature of the lower atmosphere will gradually increase.

Greenhouse Gas (GHG)
Any gas that absorbs infrared radiation in the atmosphere. Greenhouse gases include, but are not limited to, water vapor, carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), ozone (O_3), hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6).

H

Halocarbons
Compounds containing either chlorine, bromine, or fluorine and carbon. Such compounds can act as powerful greenhouse gases in the atmosphere. The chlorine and bromine containing halocarbons are also involved in the depletion of the ozone layer.

Hydrocarbons
Substances containing only hydrogen and carbon. Fossil fuels are made up of hydrocarbons.

Hydrochlorofluorocarbons (HCFCs)
Compounds containing hydrogen, fluorine, chlorine, and carbon atoms. Although ozone-depleting substances, they are less potent at destroying stratospheric ozone than chlorofluorocarbons (CFCs). They have been introduced as temporary replacements for CFCs and are also greenhouse gases.

Hydrologic Cycle
The process of evaporation, vertical and horizontal transport of vapor, condensation, precipitation, and the flow of water from continents to oceans. It is a

major factor in determining climate through its influence on surface vegetation, the clouds, snow and ice, and soil moisture. The hydrologic cycle is responsible for 25 to 30 percent of the midlatitudes' heat transport from the equatorial to polar regions.

Hydrosphere
The component of the climate system comprising liquid surface and subterranean water, such as oceans, seas, rivers, freshwater lakes, underground water.

I

Ice Core
A cylindrical section of ice removed from a glacier or an ice sheet in order to study climate patterns of the past. By performing chemical analyses on the air trapped in the ice, scientists can estimate the percentage of carbon dioxide and other trace gases in the atmosphere at a given time.

Infrared Radiation
Radiation emitted by the Earth's surface, the atmosphere and the clouds. It is also known as terrestrial or longwave radiation. Infrared radiation has a distinctive range of wavelengths longer than the wavelength of the red color in the visible part of the spectrum.

Intergovernmental Panel on Climate Change (IPCC)
The IPCC was established jointly by the United Nations Environment Program and the World Meteorological Organization in 1988. The purpose of the IPCC is to assess information in the scientific and technical literature related to all significant components of the issue of climate change. With its capacity for reporting on climate change, its consequences, and the viability of adaptation and mitigation measures, the IPCC is also looked to as the official advisory body to the world's governments on the state of the science of the climate change issue.

L

Landfill
Land waste disposal site in which waste is generally spread in thin layers, compacted, and covered with a fresh layer of soil each day.

Longwave Radiation
The radiation emitted in the spectral wavelength greater than 4 micrometers corresponding to the radiation emitted from the Earth and atmosphere.

M

Methane (CH_4)
A hydrocarbon that is a greenhouse gas with a global warming potential most recently estimated at 23 times that of carbon dioxide (CO_2). Methane is produced through anaerobic (without oxygen) decomposition of waste in landfills, animal digestion, decomposition of animal wastes, production and distribution of natural gas and petroleum, coal production, and incomplete fossil fuel combustion.

Metric Ton
Common international measurement for the quantity of greenhouse gas emissions. A metric ton is equal to 2,205 lbs. or 1.1 short tons.

Mount Pinatubo
An active volcano located in the Philippine Islands that erupted in 1991. The eruption of Mount Pinatubo ejected enough particulate and sulfate aerosol matter into the upper atmosphere to block some of the incoming solar radiation from reaching Earth's atmosphere.

N

Natural Gas
Underground deposits of gases consisting of 50 to 90 percent methane (CH_4) and small amounts of heavier gaseous hydrocarbon compounds such as propane (C_3H_8) and butane (C_4H_{10}).

Nitrogen Oxides (NOx)
Gases consisting of one molecule of nitrogen and varying numbers of oxygen molecules. Nitrogen oxides are produced in the emissions of vehicle exhausts and from power stations. In the atmosphere, nitrogen oxides can contribute to formation of smog, can impair visibility, and have health consequences.

Nitrous Oxide (N_2O)
A powerful greenhouse gas with a global warming potential of 296 times that of carbon dioxide (CO_2). Major sources of nitrous oxide include soil cultivation

practices, especially the use of commercial and organic fertilizers, fossil fuel combustion, nitric acid production, and biomass burning.

O

Oxidize

To chemically transform a substance by combining it with oxygen.

Ozone (O_3)

Ozone, the triatomic form of oxygen (O_3), is a gaseous atmospheric constituent. In the troposphere, it is created both naturally and by photochemical reactions involving gases resulting from human activities (photochemical smog). In high concentrations, tropospheric ozone can be harmful to a wide range of living organisms. Tropospheric ozone acts as a greenhouse gas. In the stratosphere, ozone is created by the interaction between solar ultraviolet radiation and molecular oxygen (O_2). Stratospheric ozone plays a decisive role in the stratospheric radiative balance. Depletion of stratospheric ozone, due to chemical reactions that may be enhanced by climate change, results in an increased ground-level flux of ultraviolet (UV-) B radiation.

Ozone-Depleting Substance (ODS)

A family of man-made compounds that includes chlorofluorocarbons (CFCs), bromofluorocarbons (halons), methyl chloroform, carbon tetrachloride, methyl bromide, and hydrochlorofluorocarbons (HCFCs). These compounds have been shown to deplete stratospheric ozone, and therefore are typically referred to as ODSs.

Ozone Layer

The layer of ozone that begins approximately 9 mi. (15 km.) above Earth and thins to an almost negligible amount at about 31 mi. (50 km.), shields the Earth from harmful ultraviolet radiation from the Sun.

Ozone Precursors

Chemical compounds, such as carbon monoxide, methane, nonmethane hydrocarbons, and nitrogen oxides, which in the presence of solar radiation react with other chemical compounds to form ozone, mainly in the troposphere.

P

Particulate Matter (PM)

Very small pieces of solid or liquid matter such as particles of soot, dust, fumes, mists, or aerosols.

Parts per Billion (ppb)

Number of parts of a chemical found in one billion parts of a particular gas, liquid, or solid mixture.

Parts per Million (ppm)

Number of parts of a chemical found in one million parts of a particular gas, liquid, or solid.

Perfluorocarbons (PFCs)

A group of human-made chemicals composed of carbon and fluorine only. These chemicals were introduced as alternatives, along with hydrofluorocarbons, to the ozone-depleting substances.

Photosynthesis

The process by which plants take CO_2 from the air (or bicarbonate in water) to build carbohydrates, releasing O_2 in the process. There are several pathways of photosynthesis with different responses to atmospheric CO_2 concentrations.

Precession

The comparatively slow torquing of the orbital planes of all satellites with respect to the Earth's axis, due to the bulge of the Earth at the equator which distorts the Earth's gravitational field.

R

Radiation

Energy transfer in the form of electromagnetic waves or particles that release energy when absorbed by an object.

Radiative Forcing

Radiative forcing is the change in the net vertical irradiance (expressed in Watts per square meter: Wm-2) at the tropopause due to an internal change or a change in the external forcing of the climate system, such as, for example, a change in the concentration of carbon dioxide or the output of the Sun.

Recycling

Collecting and reprocessing a resource so it can be used again. An example is collecting aluminum cans, melting them down, and using the aluminum to make new cans or other aluminum products.

Reforestation
Planting of forests on lands that have previously contained forests but that have been converted to some other use.

Residence Time
The average time spent in a reservoir by an individual atom or molecule. With respect to greenhouse gases, residence time usually refers to how long a particular molecule remains in the atmosphere.

Respiration
The biological process whereby living organisms convert organic matter to CO_2, releasing energy and consuming O_2.

S

Short Ton
Common measurement for a ton in the United States. A short ton is equal to 2,000 lbs. or 0.907 metric tons.

Sink
Any process, activity, or mechanism which removes a greenhouse gas, an aerosol, or a precursor of a greenhouse gas or aerosol from the atmosphere.

Soil Carbon
A major component of the terrestrial biosphere pool in the carbon cycle. The amount of carbon in the soil is a function of the historical vegetative cover and productivity, which in turn is dependent in part upon climatic variables.

Solar Radiation
Radiation emitted by the Sun. It is also referred to as shortwave radiation. Solar radiation has a distinctive range of wavelengths (spectrum) determined by the temperature of the Sun.

Stratosphere
Region of the atmosphere between the troposphere and mesosphere, having a lower boundary of approximately 5 mi. (8 km.) at the poles to 9 mi. (15 km.) at the equator and an upper boundary of approximately 31 mi. (50 km.). Depending upon latitude and season, the temperature in the lower stratosphere can increase, be isothermal, or even decrease with altitude, but the temperature in the upper stratosphere generally increases with height due to absorption of solar radiation by ozone.

Streamflow
The volume of water that moves over a designated point over a fixed period of time. It is often expressed as cubic feet per second (ft3/sec).

Sulfate Aerosols
Particulate matter that consists of compounds of sulfur formed by the interaction of sulfur dioxide and sulfur trioxide with other compounds in the atmosphere. Sulfate aerosols are injected into the atmosphere from the combustion of fossil fuels and the eruption of volcanoes.

Sulfur Hexafluoride (SF_6)
A colorless gas soluble in alcohol and ether, slightly soluble in water. A very powerful greenhouse gas used primarily in electrical transmission and distribution systems and as a dielectric in electronics.

T

Thermohaline Circulation
Large-scale density-driven circulation in the ocean, caused by differences in temperature and salinity. In the North Atlantic the thermohaline circulation consists of warm surface water flowing northward and cold deep water flowing southward, resulting in a net poleward transport of heat.

Trace Gas
Any one of the less common gases found in the Earth's atmosphere. Nitrogen, oxygen, and argon make up more than 99 percent of the Earth's atmosphere. Other gases, such as carbon dioxide, water vapor, methane, oxides of nitrogen, ozone, and ammonia, are considered trace gases.

Troposphere
The lowest part of the atmosphere from the surface to about 6 mi./10 km. in altitude in mid-latitudes (ranging from 5.5 mi. [9 km.] in high latitudes to 10 mi. [16 km.] in the tropics on average) where clouds and "weather" phenomena occur.

U

Ultraviolet Radiation (UV)

The energy range just beyond the violet end of the visible spectrum. Although ultraviolet radiation constitutes only about 5 percent of the total energy emitted from the sun, it is the major energy source for the stratosphere and mesosphere, playing a dominant role in both energy balance and chemical composition.

United Nations Framework Convention on Climate Change (UNFCCC)

The Convention on Climate Change sets an overall framework for intergovernmental efforts to tackle the challenge posed by climate change. It recognizes that the climate system is a shared resource whose stability can be affected by industrial and other emissions of carbon dioxide and other greenhouse gases.

W

Wastewater

Water that has been used and contains dissolved or suspended waste materials.

Water Vapor

The most abundant greenhouse gas, it is the water present in the atmosphere in gaseous form. Water vapor is a part of the natural greenhouse effect.

Weather

Atmospheric condition at any given time or place. It is measured in terms of such things as wind, temperature, humidity, atmospheric pressure, cloudiness, and precipitation.

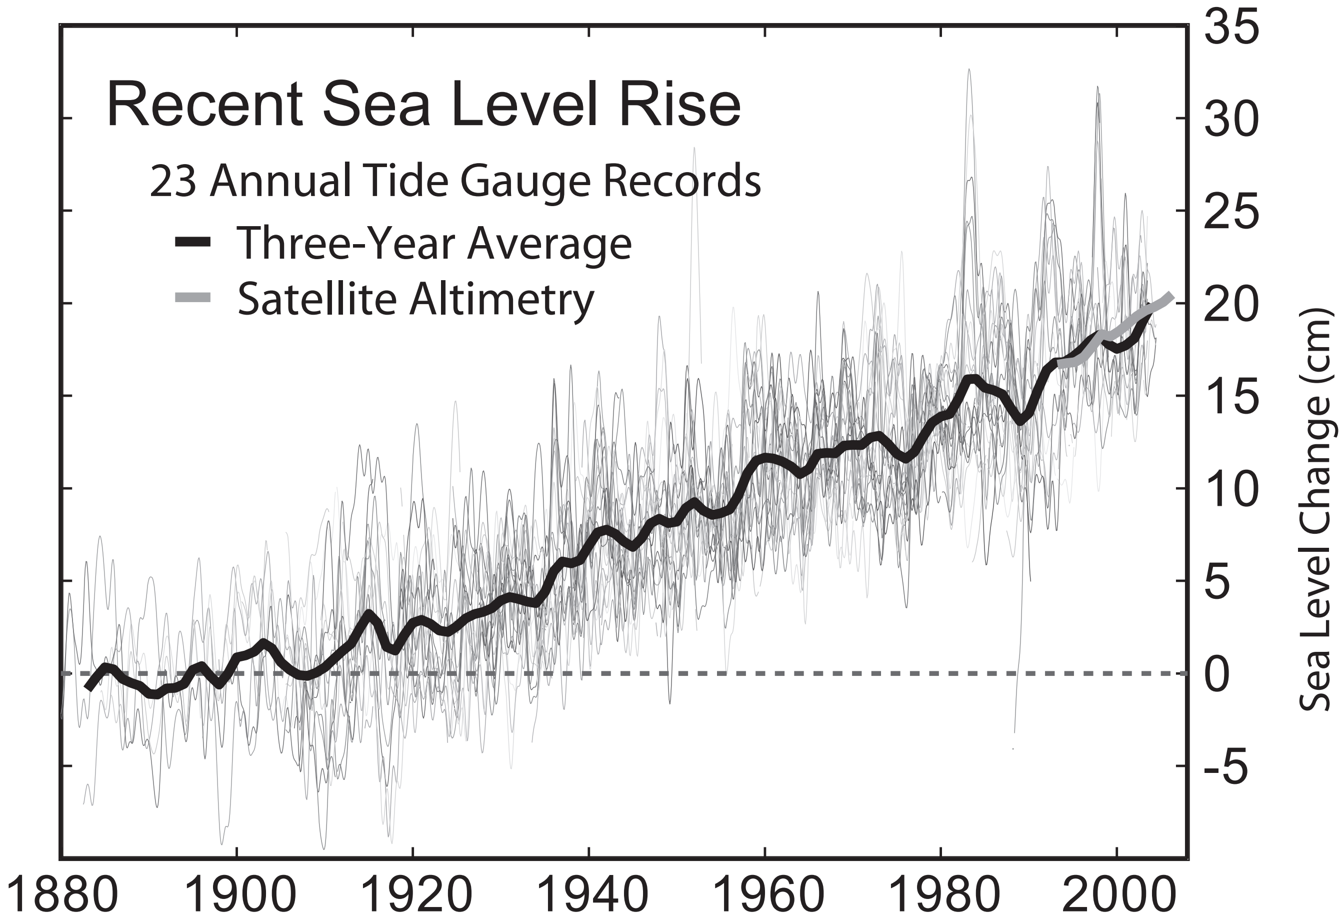
This image shows the instrumental record of global average temperatures as compiled by the Climatic Research Unit of the University of East Anglia and the Hadley Centre of the UK Meteorological Office. Data set HadCRUT3 was used, which follows the methodology outlined by Brohan et al. (2006). Following the common practice of the IPCC, the zero on this figure is the mean temperature from 1961 to1990.

The uncertainty in the analysis techniques leading to these measurements is discussed in Foland et al. (2001) and Brohan et al. (2006). They estimate that global averages since ~1950 are within ~0.05 degrees C of their reported value with 95 percent confidence. In the recent period, these uncertainties are driven primarily by considering the potential impact of regions where no temperature record is available. For averages prior to ~1890, the uncertainty reaches ~0.15 degrees C driven primarily by limited sampling and the effects of changes in sea surface measurement techniques. Uncertainties between 1880 and 1890 are intermediate between these values.

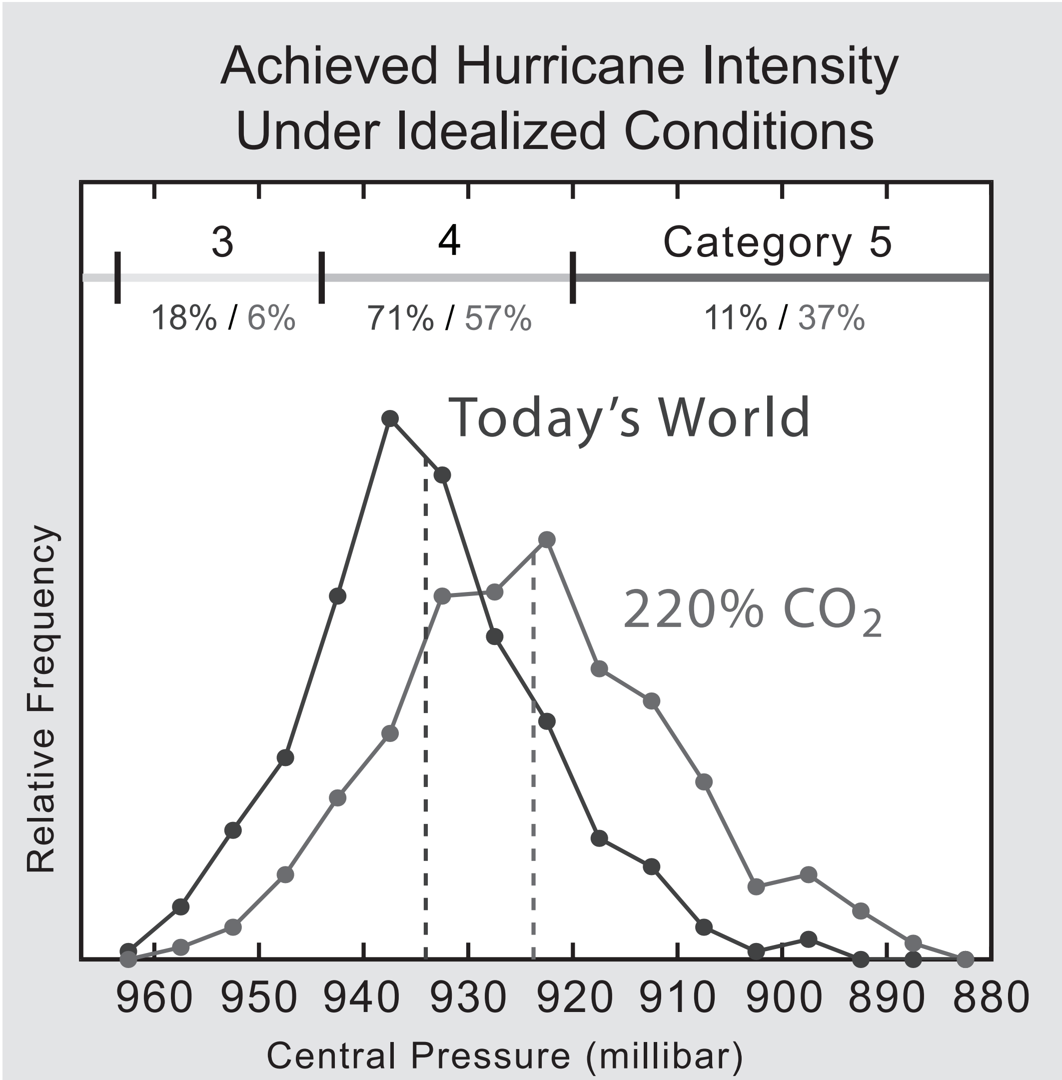
Incorporating these uncertainties, Foland et al. (2001) estimated the global temperature change from 1901 to 2000 as 0.57 ± 0.17 degrees C, which contributed to the 0.6 ± 0.2 degrees C estimate reported by the Intergovernmental Panel on Climate Change (IPCC 2001a, [1]). Both estimates are 95 percent confidence intervals.



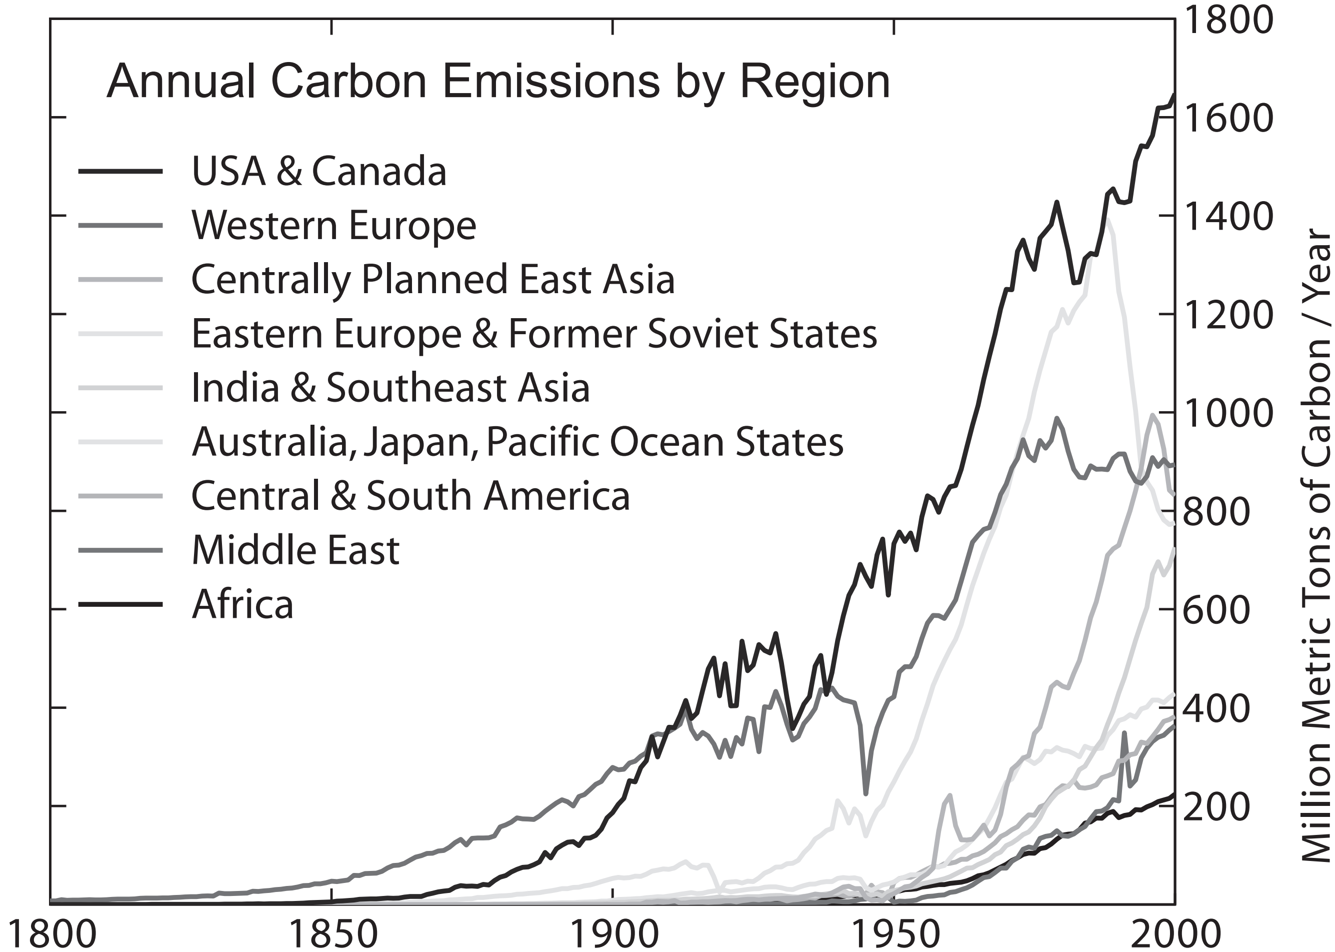
This figure shows the change in annually averaged sea level at 23 geologically stable tide gauge sites with long-term records as selected by Douglas (1997). The thick dark line is a three-year moving average of the instrumental records. This data indicates a sea level rise of ~18.5 cm. from 1900–2000. Because of the limited geographic coverage of these records, it is not obvious whether the apparent decadal fluctuations represent true variations in global sea level or merely variations across regions that are not resolved.

For comparison, the recent annually averaged satellite altimetry data from TOPEX/Poseidon are shown in the thick gray line. These data indicate a somewhat higher rate of increase than tide gauge data, however the source of this discrepancy is not obvious. It may represent systematic error in the satellite record and/or incomplete geographic sampling in the tide gauge record. The month-to-month scatter on the satellite measurements is roughly the thickness of the plotted gray curve.

Much of recent sea level rise has been attributed to global warming.

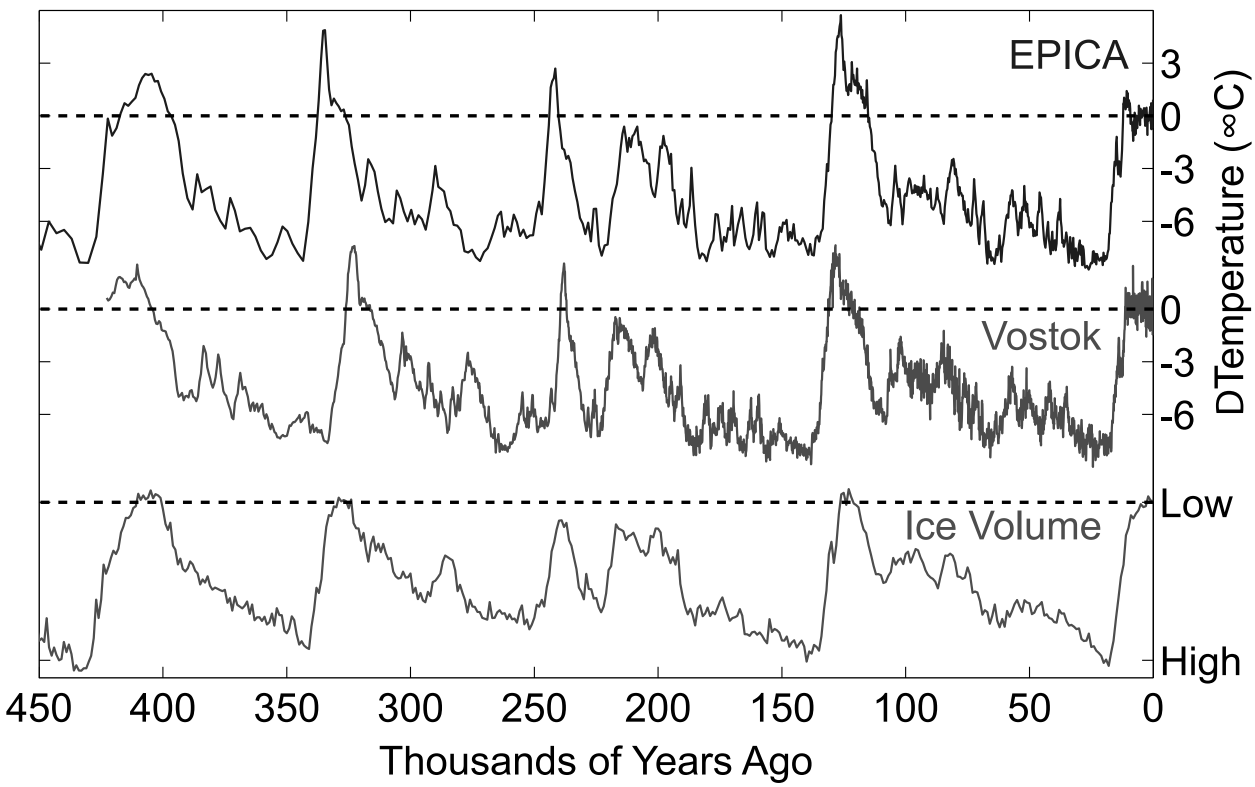


This figure, which reproduces one of the key conclusions of Knutson and Tuleya (2004), shows a prediction for how hurricanes and other tropical cyclones may intensify as a result of global warming. Specifically, Knutson and Tuleya performed an experiment using climate models to estimate the strength achieved by cyclones allowed to intensify over either a modern summer ocean or over an ocean warmed by carbon dioxide concentrations 220 percent higher than present day. A number of different climate models were considered as well as conditions over all the major cyclone-forming ocean basins. Depending on site and model, the ocean warming involved ranged from 0.8 to 2.4 degrees C. Results, which were found to be robust across different models, showed that storms intensified by about one-half category (on the Saffir-Simpson Hurricane Scale) as a result of the warmer oceans. This is accomplished with a ~6 percent increase in wind speed or equivalently a ~20 percent increase in energy (for a storm of fixed size). Most significantly these result suggest that global warming may lead to a gradual increase in the probability of highly destructive category 5 hurricanes. This work does not provide any information about future frequency of tropical storms. Also, since it considers only the development of storms under nearly ideal conditions for promoting their formation, this work is primarily a prediction for how the maximum achievable storm intensity will change. Hence, this does not directly bear on the growth or development of storms under otherwise weak or marginal conditions for storm development (such as high upper-level wind shear). However, it is plausible that warmer oceans will somewhat extend the regions and seasons under which hurricanes may develop.



This figure shows the annual fossil fuel carbon dioxide emissions, in million metric tons of carbon, for a variety of non-overlapping regions covering the Earth. Data source: Carbon Dioxide Information Analysis Center. Regions are sorted from largest emitter (as of 2000) to the smallest:

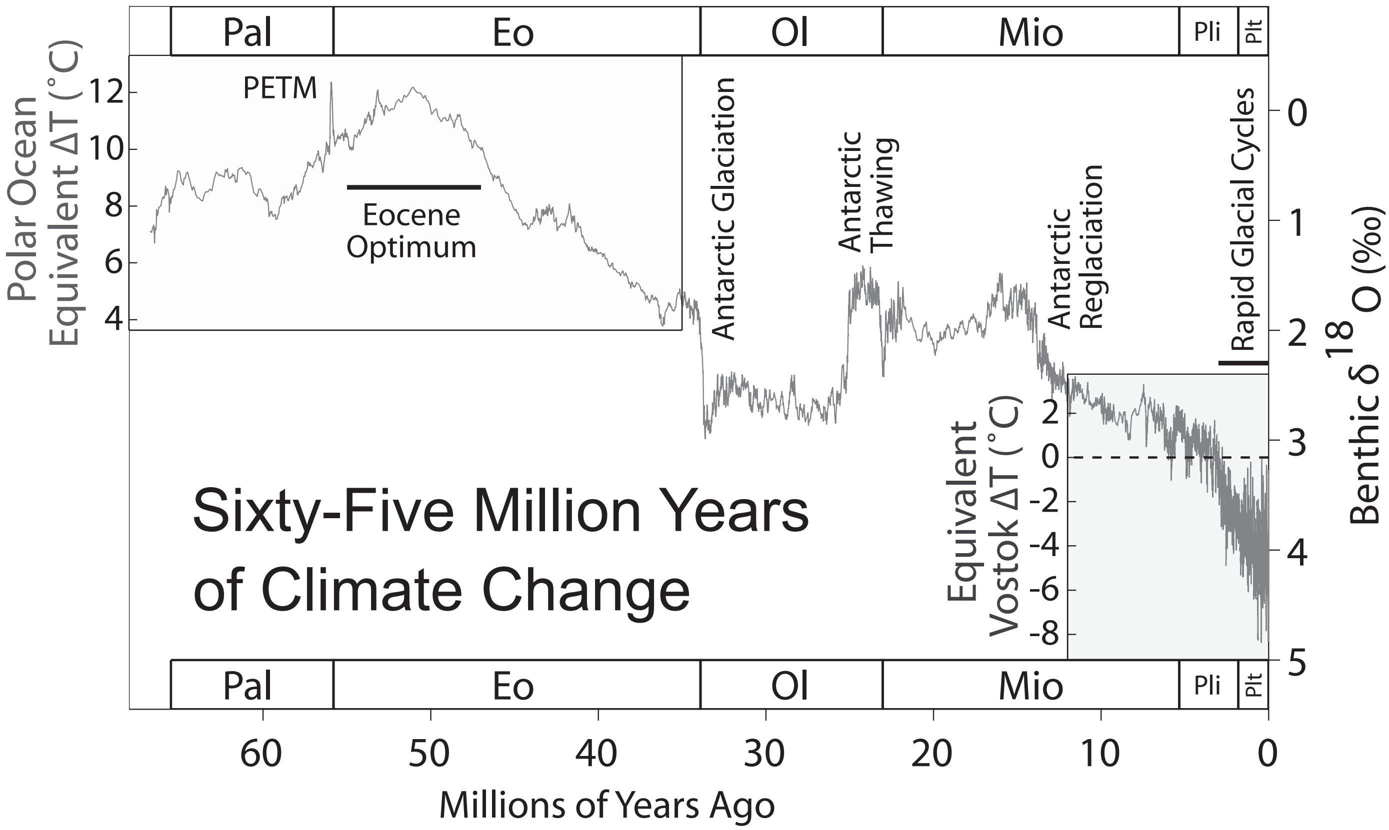
United States and Canada
Western Europe (plus Germany)
Communist East Asia (China, North Korea, Mongolia, etc.)
Eastern Europe, Russia, and Former Soviet States
India and Southeast Asia (plus South Korea)
Australia, Japan and other Pacific Island States
Central and South America (includes Mexico and the Caribbean)
Middle East
Africa



This figure shows the Antarctic temperature changes during the last several glacial/interglacial cycles of the present ice age and a comparison to changes in global ice volume. The present day is on the right.

The first two curves show local changes in temperature at two sites in Antarctica as derived from deuterium isotopic measurements (δD) on ice cores (EPICA Community Members 2004, Petit et al. 1999). The final plot shows a reconstruction of global ice volume based on δ18O measurements on benthic foraminifera from a composite of globally distributed sediment cores and is scaled to match the scale of fluctuations in Antarctic temperature (Lisiecki and Raymo 2005). Note that changes in global ice volume and changes in Antarctic temperature are highly correlated, so one is a good estimate of the other, but differences in the sediment record do not necessarily reflect differences in paleotemperature. Horizontal lines indicate modern temperatures and ice volume. Differences in the alignment of various features reflect dating uncertainty and do not indicate different timing at different sites.

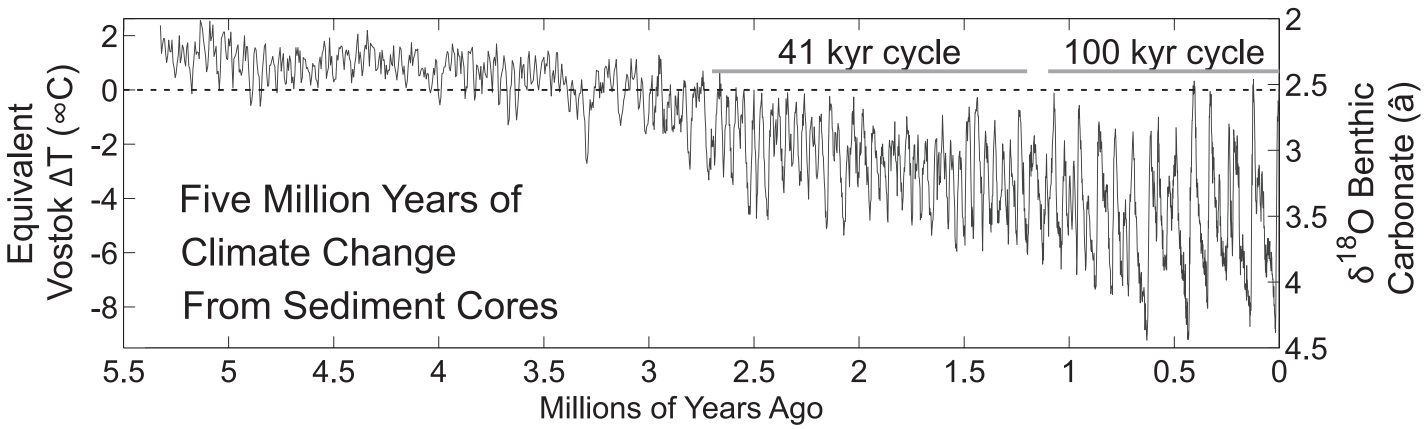
The Antarctic temperature records indicate that the present interglacial is relatively cool compared to previous interglacials, at least at these sites. It is believed that the interglacials themselves are triggered by changes in Earth's orbit known as Milankovitch cycles and that the variations in individual interglacials can be partially explained by differences within this process. For example, Overpeck et al. (2006) argues that the previous interglacial was warmer because of increased solar radiation at high latitudes. The Liesecki and Raymo (2005) sediment reconstruction does not indicate significant differences between modern ice volume and previous interglacials, though some other studies do report slightly lower ice volumes/higher sea levels during the 120 ka and 400 ka interglacials (Karner et al. 2001, Hearty and Kaufman 2000). It should be noted that temperature changes at the typical equatorial site are believed to have been significantly less than the changes observed at high latitude.



This figure shows climate change over the last 65 million years. The data is based on a compilation of oxygen isotope measurements (δ18O) on benthic foraminifera by Zachos et al. (2001), which reflect a combination of local temperature changes in their environment and changes in the isotopic composition of seawater associated with the growth and retreat of continental ice sheets.

Because it is related to both factors, it is not possible to uniquely tie these measurements to temperature without additional constraints. For the most recent data, an approximate relationship to temperature can be made by observing that the oxygen isotope measurements of Lisiecki and Raymo (2005) are tightly correlated to temperature changes at Vostok, Antarctica as established by Petit et al. (1999). Present day is indicated as 0. For the oldest part of the record, when temperatures were much warmer than today, it is possible to estimate temperature changes in the polar oceans (where these measurements were made) based on the observation that no significant ice sheets existed and hence all fluctuation in (δ18O) must result from local temperature changes (as reported by Zachos et al.).

The intermediate portion of the record is dominated by large fluctuations in the mass of the Antarctic ice sheet, which first nucleates approximately 34 million years ago, then partially dissipates around 25 million years ago, before re-expanding toward its present state 13 million years ago. These fluctuations make it impossible to constrain temperature changes without additional controls. Significant growth of ice sheets did not begin in Greenland and North America until approximately 3 million years ago, following the formation of the Isthmus of Panama by continental drift. This ushered in an era of rapidly cycling glacials and interglacials (upper right). Also appearing on this graph are the Eocene Climatic Optimum, an extended period of very warm temperatures, and the Paleocene-Eocene Thermal Maximum (labeled PETM). Due to the coarse sampling and averaging involved in this record, it is likely that the full magnitude of the PETM is underestimated by a factor of 2 to 4 times its apparent height.

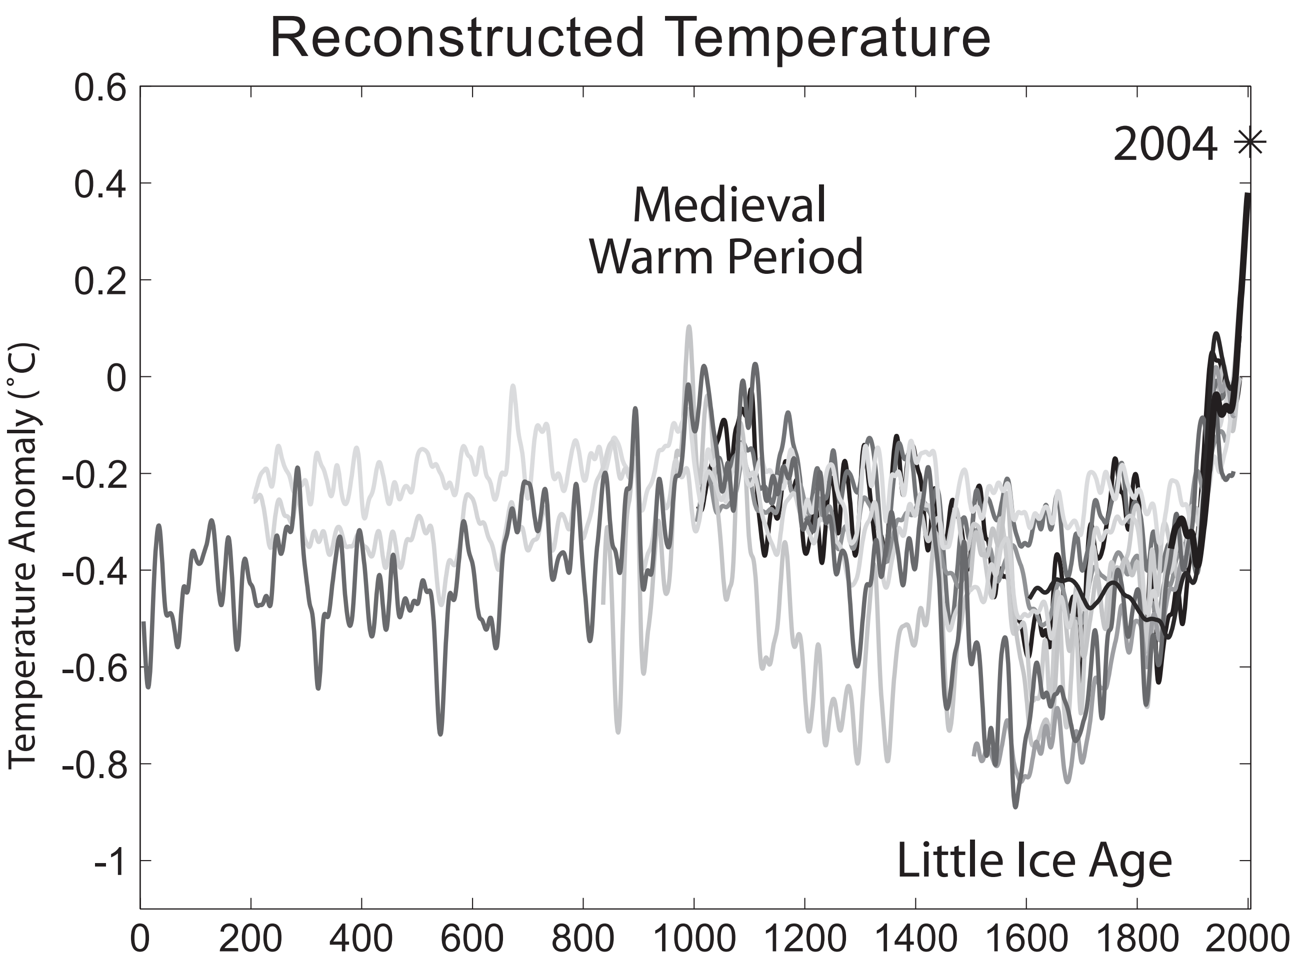


This figure shows the climate record of Lisiecki and Raymo (2005) constructed by combining measurements from 57 globally distributed deep-sea sediment cores. The measured quantity is oxygen isotope fractionation in benthic foraminifera, which serves as a proxy for the total global mass of glacial ice sheets.

Lisiecki and Raymo constructed this record by first applying a computer-aided process of adjusting individual "wiggles" in each sediment core to have the same alignment (i.e.. wiggle matching). Then the resulting stacked record is orbitally tuned by adjusting the positions of peaks and valleys to fall at times consistent with an orbitally driven ice model (see Milankovitch Cycles). Both sets of these adjustments are constrained to be within known uncertainties on sedimentation rates and consistent with independently dated tie points (if any). Constructions of this kind are common, however, they presume that ice sheets are orbitally driven, and hence data such as this can not be used in establishing the existence of such a relationship.

The observed isotope variations are very similar in shape to the temperature variations recorded at Vostok, Antarctica, during the 420 kyr for which that record exists. Hence the right-hand scale of the figure was established by fitting the reported temperature variations at Vostok (Petit et al. 1999) to the observed isotope variations. As a result, this temperature scale should be regarded as approximate and its magnitude is only representative of Vostok changes. In particular, temperature changes at polar sites, such as Vostok, frequently exceed the changes observed in the tropics or in the global average. A horizontal line at 0 degrees C indicates modern temperatures (circa 1950).

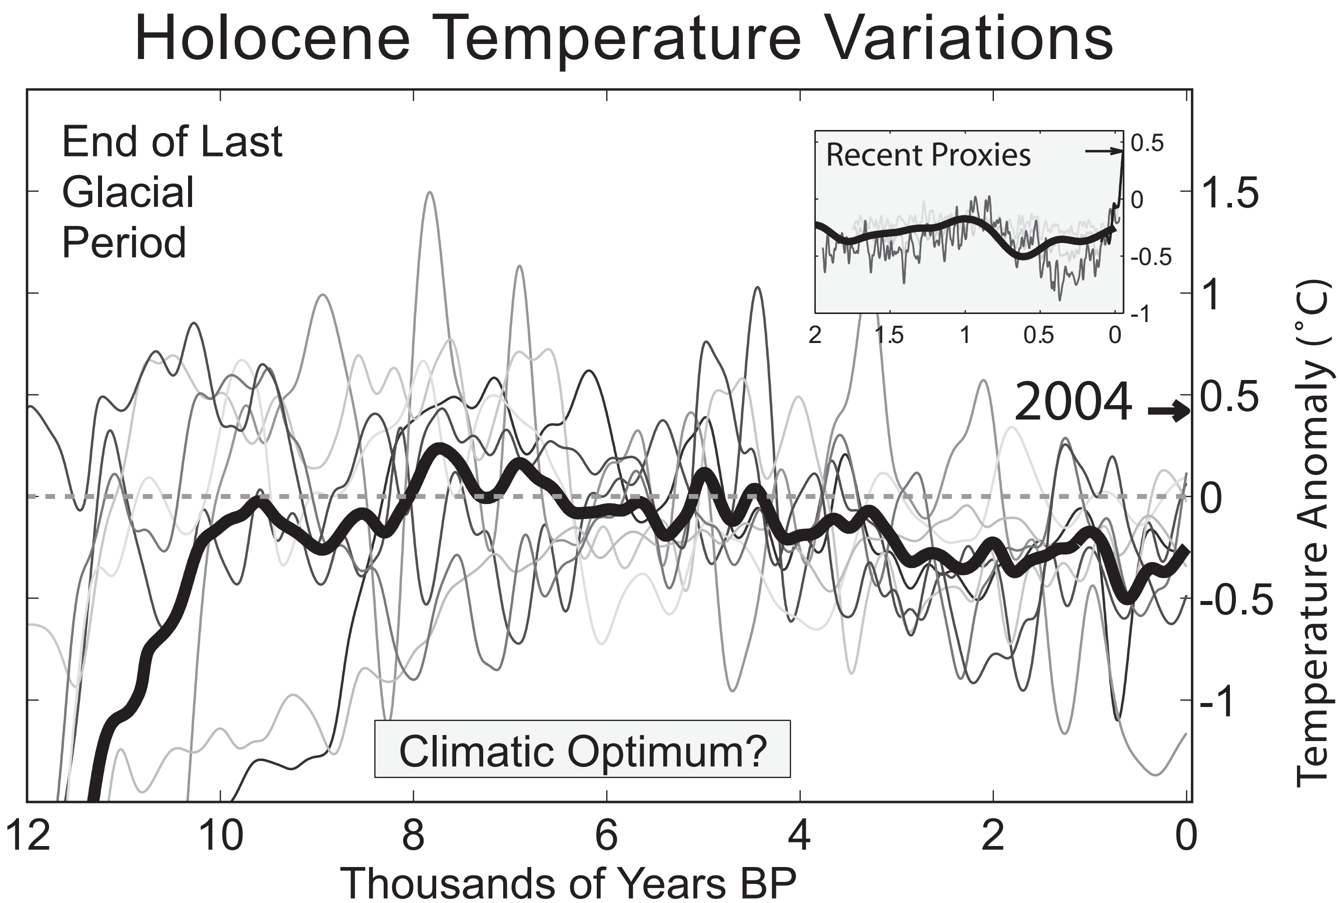
Labels are added to indicate regions where 100 kyr and 41 kyr cyclicity is observed. These periodicities match periodic changes in Earth's orbital eccentricity and obliquity, respectively, and have been previously established by other studies (not relying on orbital tuning).



This image is a comparison of 10 different published reconstructions of mean temperature changes during the last 2,000 years. More recent reconstructions are plotted toward the front and in redder colors, older reconstructions appear towards the back and in bluer colors. An instrumental history of temperature is also shown in black. The medieval warm period and Little Ice Age are labeled at roughly the times when they are historically believed to occur, though it is still disputed whether these were truly global or only regional events. The single, unsmoothed annual value for 2004 is also shown for comparison.

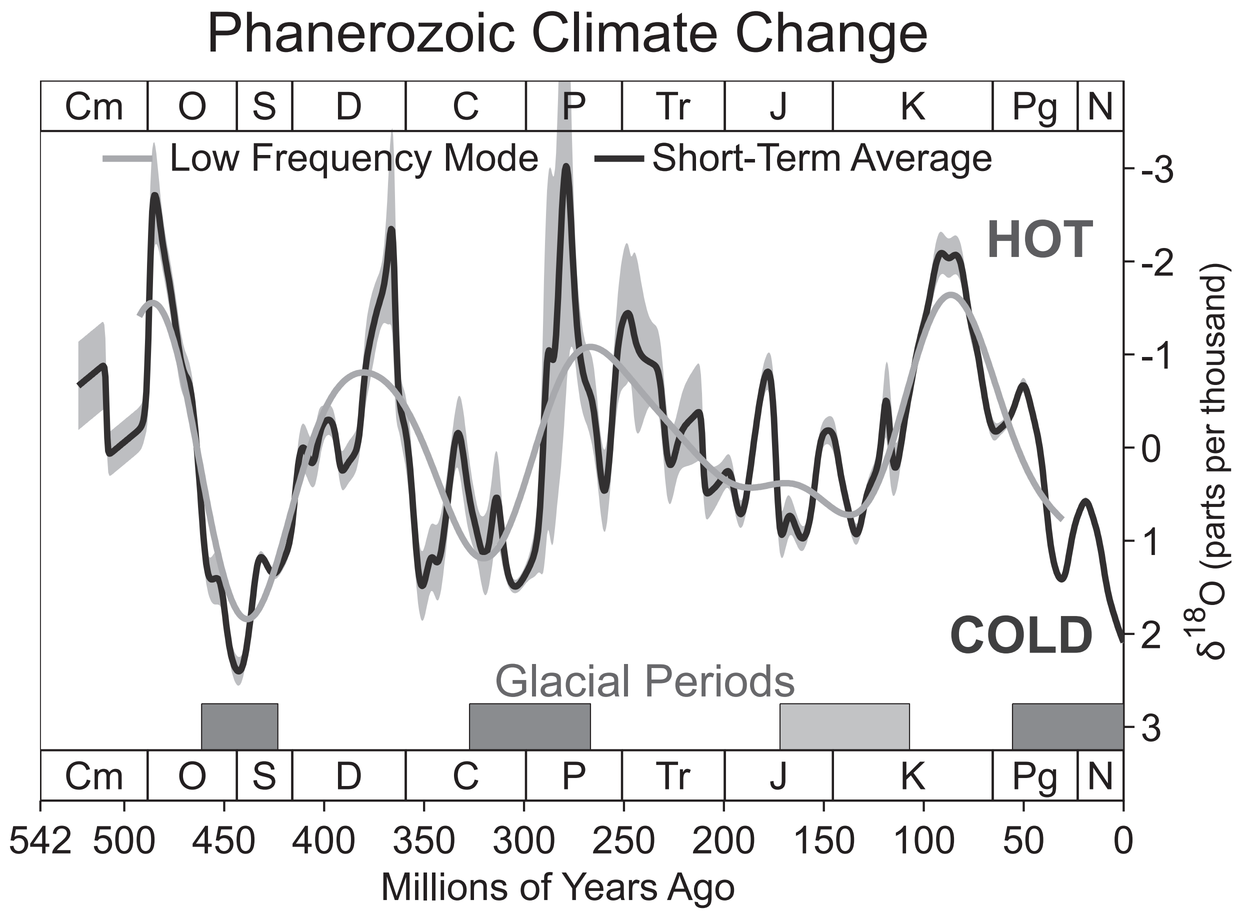
It is unknown which, if any, of these reconstructions is an accurate representation of climate history; however, these curves are a fair representation of the range of results appearing in the published scientific literature. Hence, it is likely that such reconstructions, accurate or not, will play a significant role in the ongoing discussions of global climate change and global warming.

For each reconstruction, the raw data has been decadally smoothed with a $\sigma = 5$ yr Gaussian weighted moving average. Also, each reconstruction was adjusted so that its mean matched the mean of the instrumental record during the period of overlap.



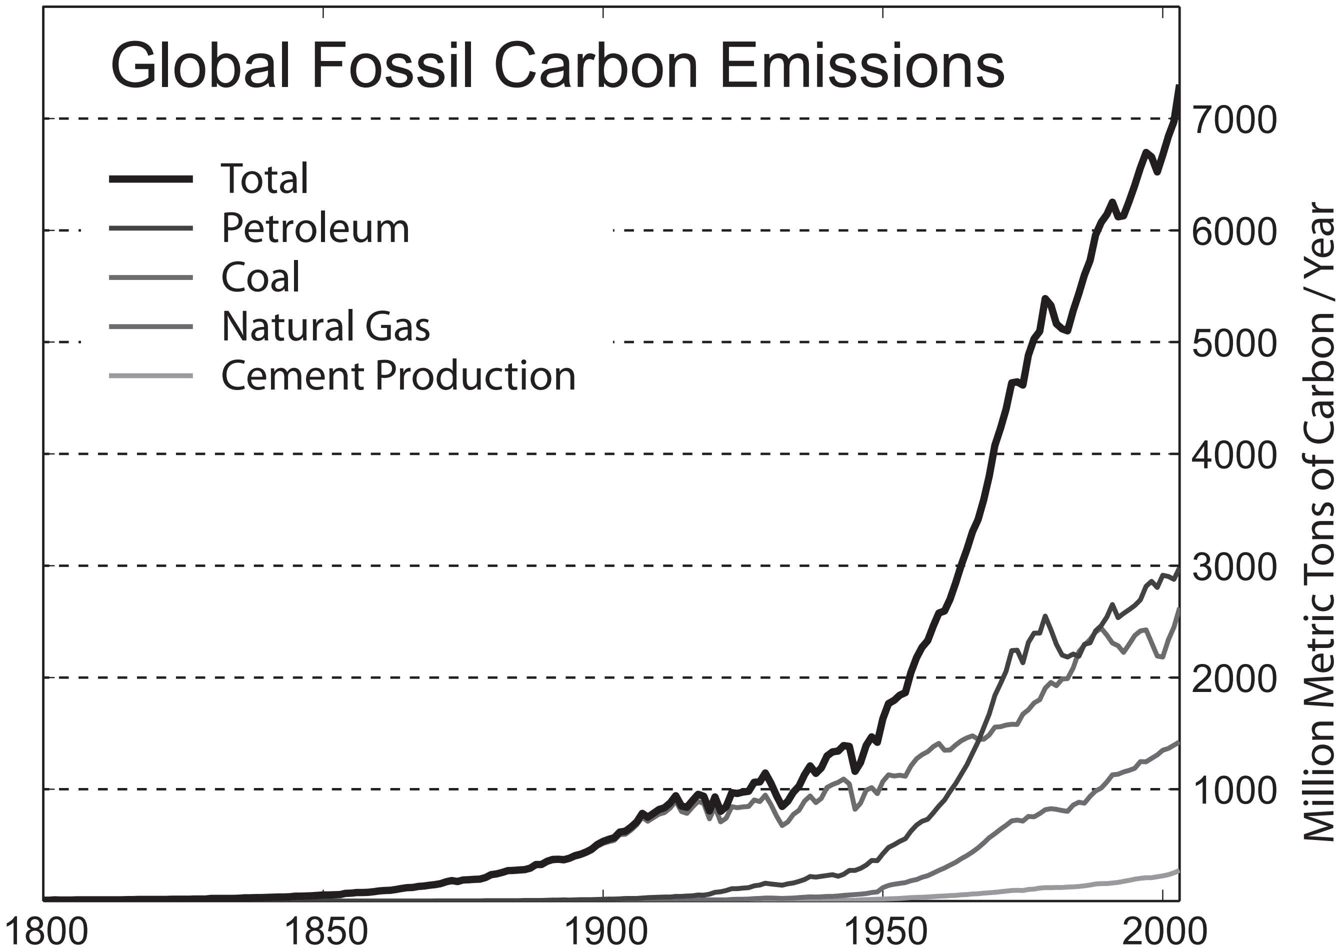
The main figure shows eight records of local temperature variability on multi-centennial scales throughout the course of the Holocene, and an average of these (thick dark line). The records are plotted with respect to the mid-20th-century average temperatures, and the global average temperature in 2004 is indicated. The inset plot compares the most recent two millennia of the average to other high resolution reconstructions of this period. At the far left of the main plot climate emerges from the last glacial period of the current ice age into the relative stability of the current interglacial. There is general scientific agreement that during the Holocene itself temperatures have been quite stable compared to the fluctuations during the preceding glacial period. The average curve above supports this belief. However, there is a slightly warmer period in the middle which might be identified with the proposed Holocene climatic optimum. The magnitude and nature of this warm event is disputed, and it may have been largely limited to summer months and/or high northern latitudes.

Because of the limitations of data sampling, each curve in the main plot was smoothed, and consequently, this figure can not resolve temperature fluctuations faster than approximately 300 years. Further, while 2004 appears warmer than any other time in the long-term average, an observation that might be a sign of global warming, it should also be noted that the 2004 measurement is from a single year. It is impossible to know whether similarly large short-term temperature fluctuations may have occurred at other times but are unresolved by the resolution available in this figure. The next 150 years will determine whether the long-term average centered on the present appears anomalous with respect to this plot. Since there is no scientific consensus on how to reconstruct global temperature variations during the Holocene, the average shown here should be understood as only a rough, quasi-global approximation to the temperature history of the Holocene. In particular, higher resolution data and better spatial coverage could significantly alter the apparent long-term behavior.



This figure shows the long-term evolution of oxygen isotope ratios during the Phanerozoic eon as measured in fossils, reported by Veizer et al. (1999), and updated online in 2004 [1]. Such ratios reflect both the local temperature at the site of deposition and global changes associated with the extent of continental glaciation. As such, relative changes in oxygen isotope ratios can be interpreted as rough changes in climate. Quantitative conversion between this data and direct temperature changes is a complicated process subject to many systematic uncertainties, however, it is estimated that each 1 part per thousand change in δ18O represents roughly a 1.5–2 degrees C change in tropical sea surface temperatures (Veizer et al. 2000). Also shown on this figure are blue bars showing periods when geological criteria (Frakes et al. 1992) indicate cold temperatures and glaciation as reported by Veizer et al. (2000). All data presented here have been adjusted to the 2004 ICS geologic timescale. The "short-term average" was constructed by applying a σ = 3 Myr Gaussian weighted moving average to the original 16,692 reported measurements. The gray bar is the associated 95 percent statistical uncertainty in the moving average. The "low frequency mode" is determined by applying a band-pass filter to the short-term averages in order to select fluctuations on timescales of 60 Myr or greater.

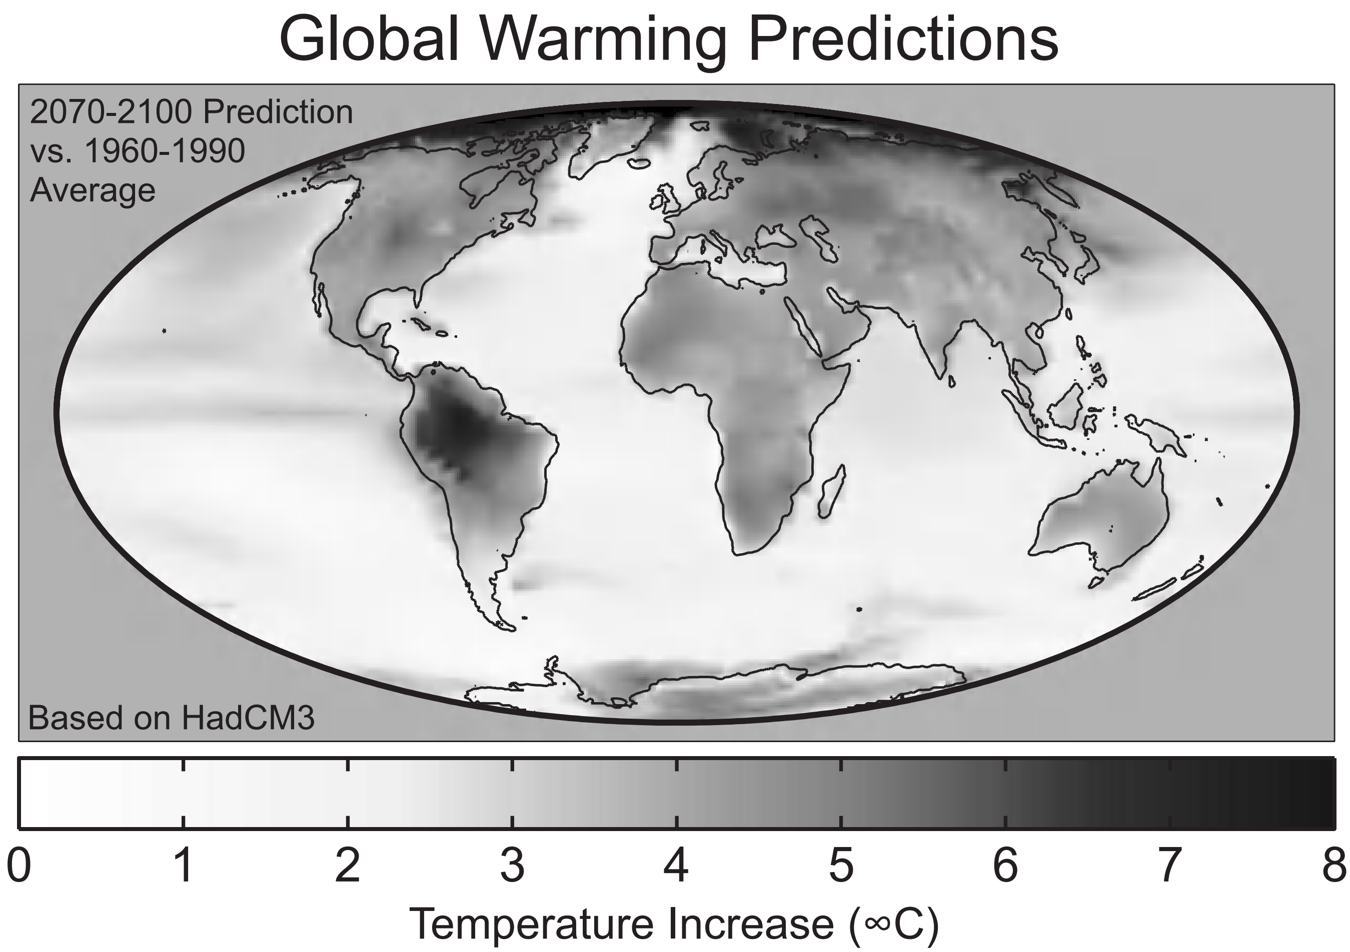
On geologic time scales, the largest shift in oxygen isotope ratios is due to the slow radiogenic evolution of the mantle. It is not possible to draw any conclusion about very long-term (>200 Myr) changes in temperatures from this data alone. However, it is usually believed that temperatures during the present cold period and during the Cretaceous thermal maximum are not greatly different from cold and hot periods during most of the rest the Phanerozoic. Some recent work has disputed this (Royer et al. 2004) suggesting instead that the highs and lows in the early part of the Phanerozoic were both significantly warmer than their recent counterparts. Common symbols for geologic periods are plotted at the top and bottom of the figure for reference.



Global annual fossil fuel carbon dioxide emissions, in million metric tons of carbon, as reported by the Carbon Dioxide Information Analysis Center.

Original data: [full text] Marland, G., T.A. Boden, and R. J. Andres (2003). "Global, Regional, and National CO2 Emissions" in *Trends: A Compendium of Data on Global Change*. Oak Ridge, Tenn., U.S.A.: Carbon Dioxide Information Analysis Center, Oak Ridge National Laboratory, U.S. Department of Energy.

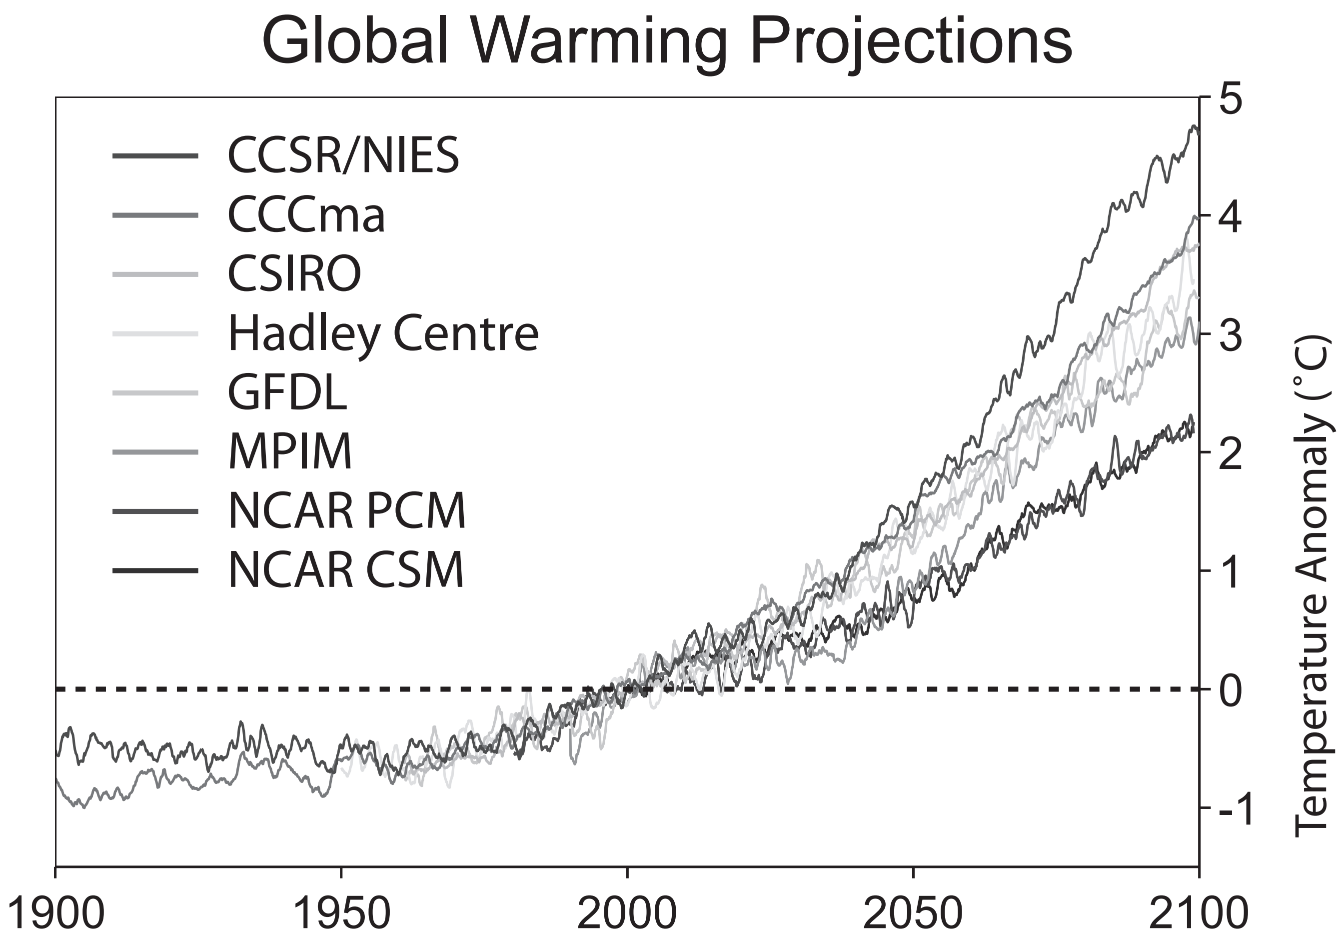
The data is originally presented in terms of solid (e.g., coal), liquid (e.g., petroleum), gas (i.e., natural gas) fuels, and separate terms for cement production and gas flaring (i.e., natural gas lost during oil and gas mining). In the plotted figure, the gas flaring (the smallest of all categories) was added to the total for natural gas. Note that the carbon dioxide releases from cement production result from the thermal decomposition of limestone into lime, and so technically are not a fossil fuel source.



This figure shows the predicted distribution of temperature change due to global warming from the Hadley Centre HadCM3 climate model. These changes are based on the IS92a ("business as usual") projections of carbon dioxide and other greenhouse gas emissions during the next century, and essentially assume normal levels of economic growth and no significant steps are taken to combat global greenhouse gas emissions.

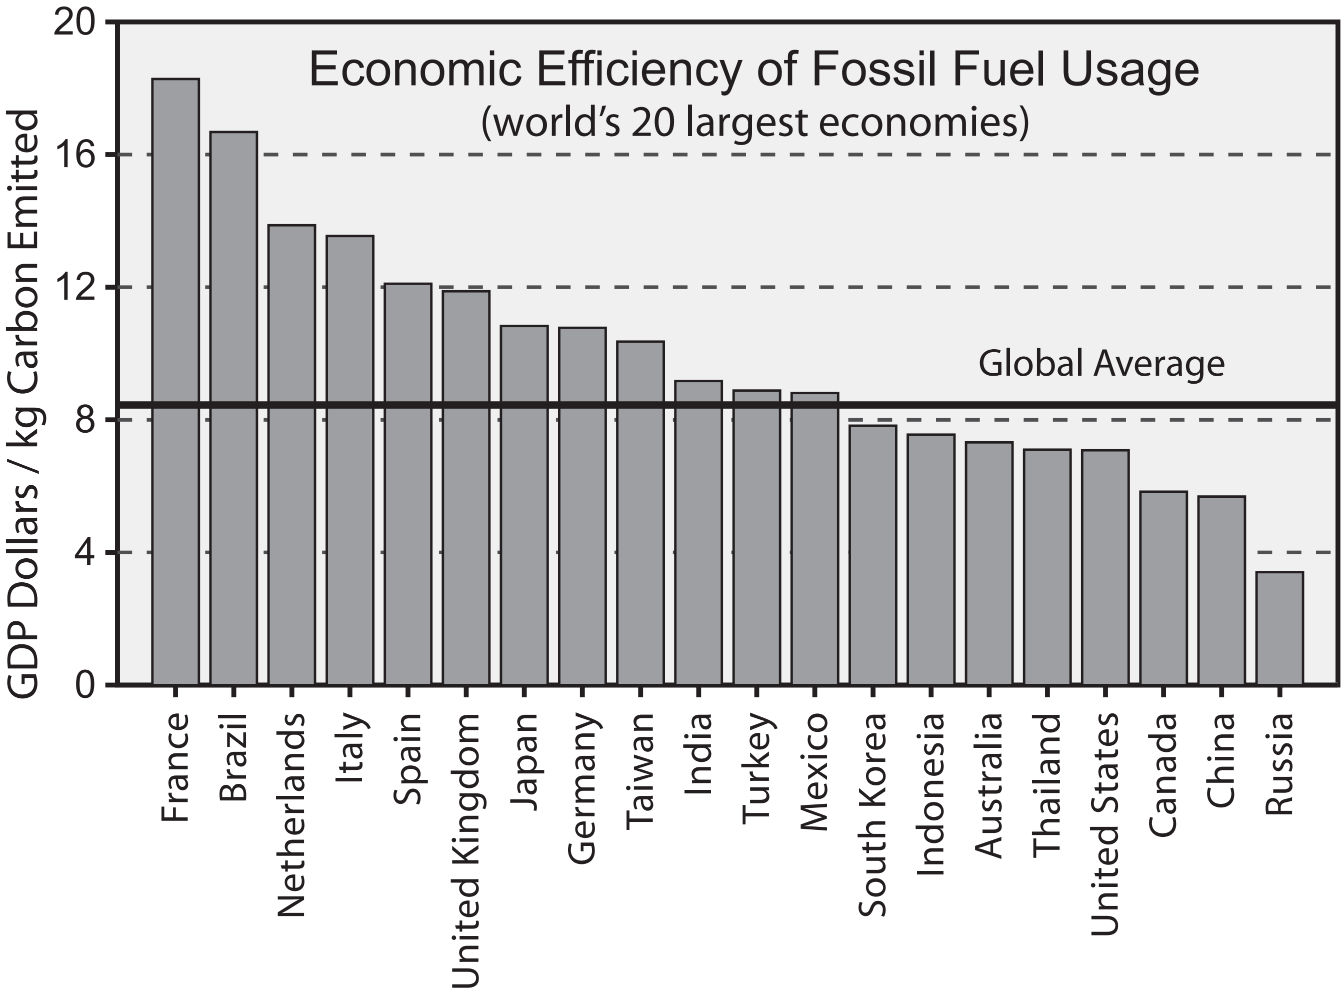
The plotted gray tints show predicted surface temperature changes expressed as the average prediction for 2070–2100 relative to the model's baseline temperatures in 1960–90. The average change is 3.0 degrees C, placing this model on the lower half of the Intergovernmental Panel on Climate Change's 1.4-5.8 degrees C predicted climate change from 1990 to 2100. As can be expected from their lower specific heat, continents are expected to warm more rapidly than oceans with an average of 4.2 degrees C and 2.5 degrees C in this model, respectively. The lowest predicted warming is 0.55 degrees C south of South America and the highest is 9.2 degrees C in the Arctic Ocean (points exceeding 8 degrees C are plotted as black).

This model is fairly homogeneous except for strong warming around the Arctic Ocean related to melting sea ice and strong warming in South America related to predicted changes in the El Niño cycle and Brazillian rainforest. This pattern is not a universal feature of models, as other models can produce large variations in other regions (e.g., Africa and India) and less extreme changes in places like South America.



This figure shows climate model predictions for global warming under the SRES A2 emissions scenario relative to global average temperatures in 2000. The A2 scenario is characterized by a politically and socially diverse world that exhibits sustained economic growth but does not address the inequities between rich and poor nations, and takes no special actions to combat global warming or environmental change issues. This world in 2100 is characterized by large population (15 billion), high total energy use, and moderate levels of fossil fuel dependency (mostly coal). At the time of the IPCC Third Assessment Report, the A2 scenario was the most well-studied of the SRES scenarios.

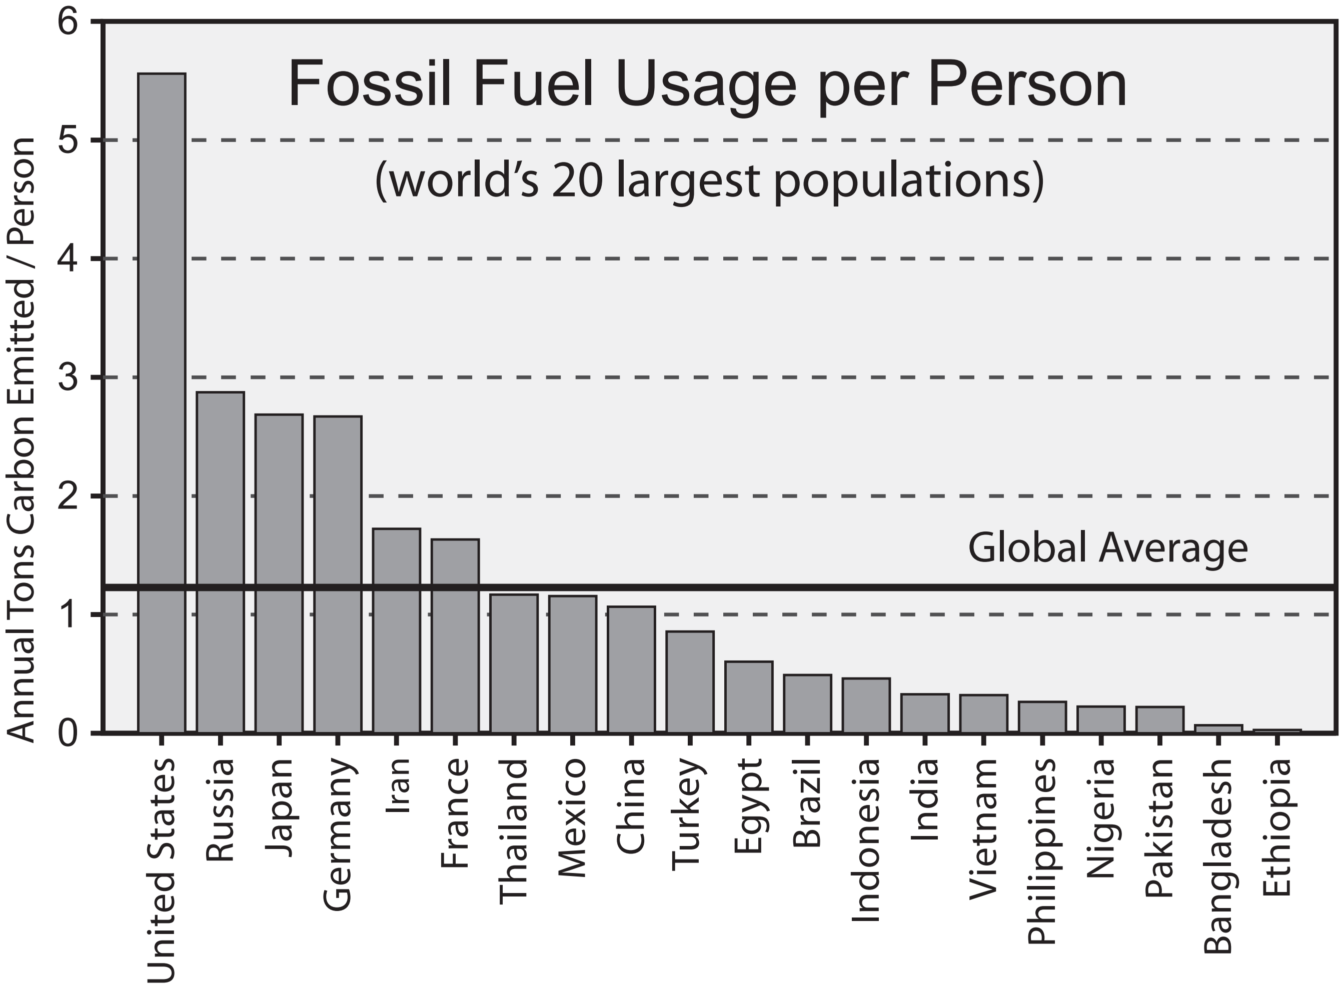
The IPCC predicts global temperature change of 1.4-5.8 degrees C due to global warming from 1990 to 2100 (IPCC 2001a). As evidenced above (a range of 2.5 degrees C in 2100), much of this uncertainty results from disagreement among climate models, though additional uncertainty comes from different emissions scenarios.



This figure shows an estimate of how efficiently the world's 20 largest economies convert fossil fuel usage into wealth as expressed by the ratio of their gross domestic product (calculated by the method of purchasing power parity in U.S. dollars) over the number of kilograms of fossil fuel carbon released into the atmosphere each year. The relatively narrow range of variation between most countries in this figure suggests that the pursuit of wealth in the present world is strongly tied to the availability of fossil fuel energy sources.

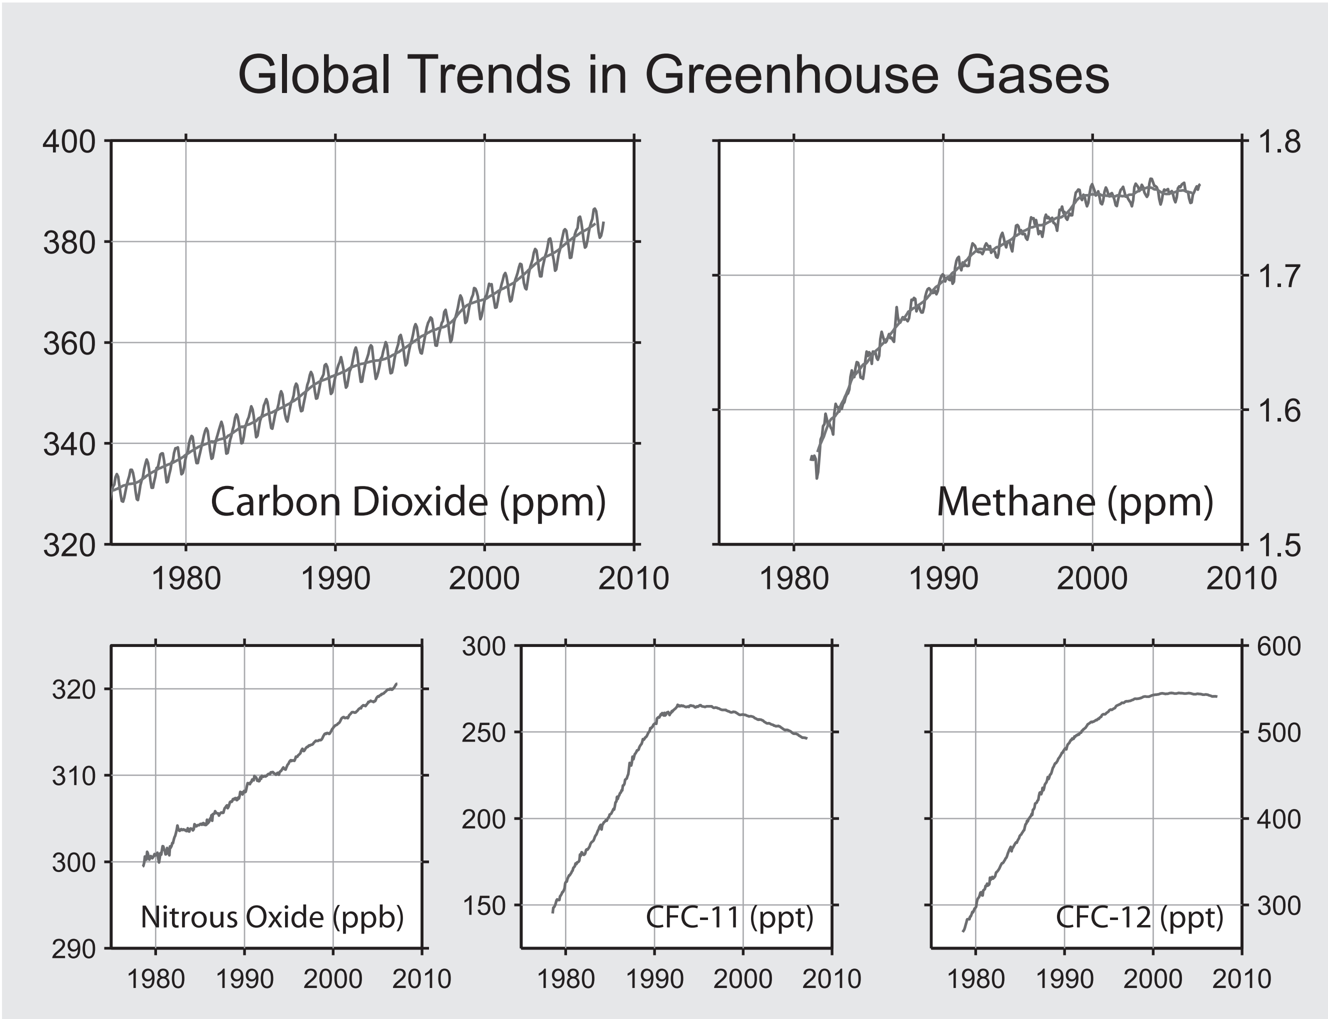
As countries may be reluctant to combat fossil fuel emissions in ways that cause economic decline, this figure serves to suggest the degree to which different large economies can decrease emissions through short-term improvements in efficiency and alternative fuel programs.

The two countries that produce the highest GDP per kilogram carbon, Brazil and France, are heavily reliant on alternative energy sources, hydroelectric and nuclear power, respectively.



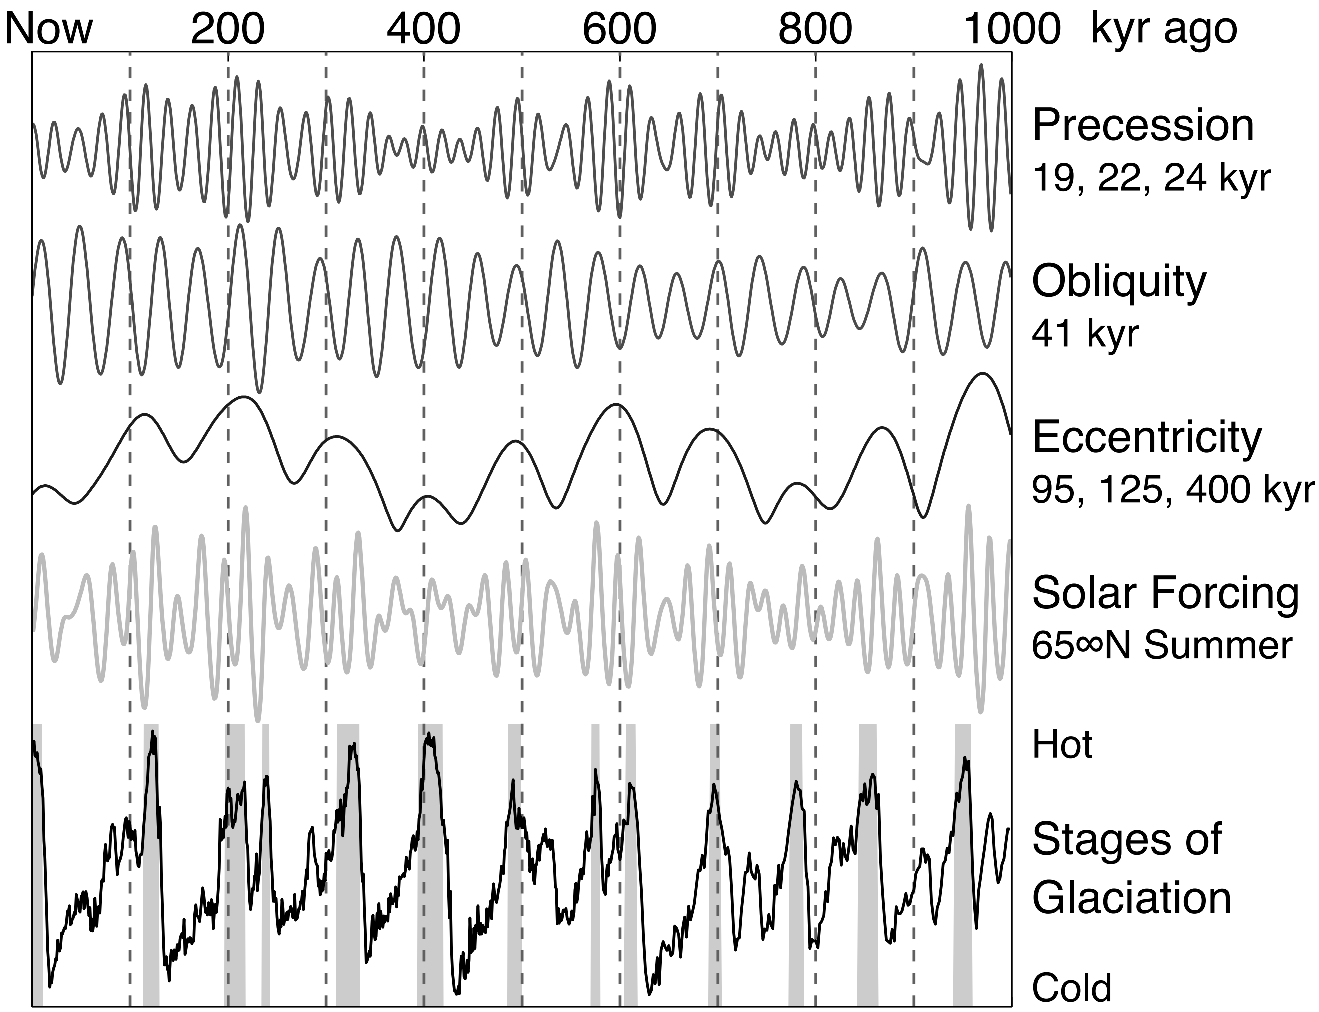
This figure shows the disparity in fossil fuel consumption per capita for the countries with the twenty largest populations. The large range of variation is indicative of the separation between the rich, industrialized nations and the poor/developing nations. The global average is also shown.

As most countries desire wealth and aim to develop that wealth through the development of industry, this figure suggests the degree to which poor nations may strive to increase their emissions in the course of trying to match the industrial capacity of the developed world. Managing such increases and dealing with the apparent social inequality of the present system will be one of the challenges involved in confronting global warming.



Global trends in major greenhouse gas concentrations. The rise of greenhouse gases, and their resulting impact on the greenhouse effect, are believed to be responsible for most of the increase in global average temperatures during the last 50 years. This change, known as global warming, has provoked calls to limit the emissions of these greenhouse gases (e.g., Kyoto Protocol). Notably, the chlorofluorocarbons CFC-11 and CFC-12 shown above have undergone substantial improvement since the Montreal Protocol severely limited their release due to the damage they were causing to the ozone layer.

At present, approximately 99 percent of the 100-year global warming potential for all new emissions can be ascribed to just the three gases: carbon dioxide, methane, and nitrous oxide.



Milankovitch Cycles

The Earth's orbit around the sun is slightly elliptical. Over time the gravitational pull of the moon and other planets causes the Earth's orbit to change following a predictable pattern of natural rhythms, known as Milankovitch cycles. Over a ~100,000 year cycle the Earth migrates from an orbit with near-zero eccentricity (a perfect circle) to one with approximately 6 percent eccentricity (a slight ellipse). In addition, the tilt of the Earth axis, known as its obliquity, varies from 21.5 to 24.5 degrees with a 41,000 year rhythm. And lastly, the orientation of the Earth's axis rotates with a ~20,000-year cycle relative to the orientation of the Earth's orbit. This cycle, known as "precession", affects the intensity of the seasons.

The figure shows the pattern of changes in each of the three modes of orbital variability: eccentricity, obliquity, and precession. These changes in the Earth's orbit lead to a complex series of changes in the amount of sunlight that a given location on Earth can expect to receive during a given season. An example is shown for summer sunlight near the Arctic circle. Sunlight at this location is believed to influence the growth and decay of ice sheets during ice ages. The last line shows measured changes in climate during the last million years with warm interglacials highlighted in gray bands. As can be seen, such interglacials appear to preferentially occur near maxima in eccentricity and slightly following times of maximum summer sunlight.
